℞	Trichlorid of iodin . . .	gr. lxxx
	Saccharin	gr. viii
	Boiled water	Oi.

This is used as a gargle ten times a day, diluted ten times with water. After garling a suitable quantity the following powder is blown into the nose:

℞	Powdered soziodolate of sodium .	1 part
	Sublimed sulphur	3 parts.

In addition from 15 to 40 drops of the ethereal tincture of perchlorid of iron is given four times a day.

Naphthalin in the Treatment of Tape- and Pinworms.—The following formulæ are recommended:

1. For tapeworm in adults:

℞	Naphthalini	gr. xv
	Ol. bergamii	gtt. i.

M. Sig. For one dose on an empty stomach. One ounce of castor oil is to be taken immediately afterward. —*Mirovitch.*

2. For tapeworm in children:

℞	Naphthalini	gr. ss–i
	Ol. ricini	ʒ ss
	Ol. bergamii	gtt. ii.

M. To be taken in one dose on an empty stomach.—*Mirovitch.*

3. For pinworms in adults:

℞	Naphthalini . . .	gr. lxxv–ʒ iss
	Ol. olivæ	ʒ ii–iiss.

M. Sig. For one rectal injection.—*Minerbi.*

4. For pinworms in children:

℞	Naphthalini	gr. xvi–xxiv
	Ol. olivæ	ʒ i–ii.

M. Sig. For one rectal injection.—*Minerbi.*

For Acute Cystitis.

℞	Potassii citrat.	ʒ iss
	Spts. etheris nitrosi . . .	ʒ ii
	Ext. buchu fl.	ʒ i
	Syr. simpl.	q.s.ad. ʒ iv.

M. Sig. Two teaspoonfuls every three hours.

ORIGINAL ARTICLES.

ABSCESS OF THE LUNG, WITH CLINICAL DATA.[1]

BY HENRY L. ELSNER, M.D.,

OF SYRACUSE, N. Y.;

PROFESSOR OF THE SCIENCE AND ART OF MEDICINE AND CLINICAL MEDICINE IN THE COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

THE following clinical histories deserve to be recorded because they exemplify the great difficulty often experienced in locating exactly one or more pus-foci in the lung; because they accentuate the importance of adhering to persisting physical signs as diagnostic aids most likely to be unfailing, in spite of repeated failure to prove that these are correctly interpreted; and, finally, because the prognosis in desperate cases of lung abscess is proved to be good, if such cases can be radically treated.

CASE I.—I had a satisfactory experience with abscess of the lung in the case of Charles L. S., the manager of a local brewery, aged thirty-four years, a temperate man, whom I first saw on February 16, 1895. He had a severe pneumonia with marked cardiac asthenia. During the period of convalescence, on the eleventh day, and four days after crisis he developed all the physical signs of pus-accumulation in the middle lobe of the right lung.

I refrain from giving in detail the history of this patient because it corresponds so closely with that of Case II., which I am about to report in full. However, I must add that the localization of the pus in the lung was exceedingly difficult. It was only found after three exploratory punctures. The lung was freely incised and drained while the patient was greatly exhausted. The incision was followed by considerable hemorrhage, but the patient made a perfect recovery, returning to his business about the end of May of the same year.

I have had occasion to examine this man repeatedly, and find that he now has a functionally active and normal lung.

CASE II.—On February 24, 1897, I was called to attend A. C. Y., aged twenty-six years, a young married man without occupation, of intemperate habits. He had been leading a riotous life, and had indulged in all imaginable excesses. He daily drank large quantities of whisky, absinthe, and brandy, and had also acquired the cocain habit. He was syphilitic, and had been repeatedly treated by myself and others for delirium tremens.

The family history shows the father to have died of angina pectoris; the mother and one sister are living and well. There is no tuberculous taint in the family.

The young man had been given to out-of-door sports, was well-nourished, and of excellent muscular development. He was of florid complexion, but his face was puffy from excessive drinking. Before the onset of his present illness he had been drinking much more than usual, owing to financial and other troubles. On February 23d he felt chilly, but had no well-defined chill. On the 24th, the day on which I saw him first, he had complained of great pain radiating through his right lung, more or less shortness of breath, and had begun to cough. It was evident that he was suffering from pleuropneumonia in its incipient stage, involving the middle and lower lobes of the right lung. His temperature was 101° F., pulse 90, respirations 37. Physical examination revealed a high-pitched percussion-note over the diseased area, exaggerated breathing, and a few friction-sounds. During the next two or three days all of the usual symptoms and physical signs of croupous pneumonia were manifest.

On February 26th the patient had delirium tremens in connection with pneumonia. The sputum was rusty; temperature, 104.8° F.; pulse, 120; respirations, 55. There was marked leucocytosis, 15,000 white blood-corpuscles in one c. mm. of blood. The patient was kept in bed with great difficulty, was continually picking at the bed-clothes, and imagined that he was to be taken away. The sputum, examined bacteriologically, showed pneumococci of Fraenkel, also abundant staphylococci. There was no marked change in the general or local conditions of the patient until March 1st, when there was a decided fall of temperature and improvement in heart strength, though the pulse continued above 100; the respirations were now 34.

The crisis was passed between the night of March 1st and the morning of the 2d. The patient was covered with profuse perspiration on the morning of the 2d. The symptoms of delirium tremens were considerably modified, but his mind was not clear. Toward the evening of March 2d the patient's mind became clearer, and he complained of intense pain on deep inspiration in the infrascapular and infra-axillary regions of the right side. These pains became so severe as to require the hypodermatic use of morphin. His temperature now was 104° F. He had a well-defined chill, the symptoms of delirium tremens were intensified, there was less expectoration, and the cough was dryer and shorter than it had been during the preceding days.

On the morning of March 3d the percussion-note over the painful regions was higher pitched than be-

[1] Read at the Ninety-third Annual Meeting of the Medical Society of the State of New York, held at Albany, January 31 and February 1 and 2, 1899.

fore. The quality became flat during the day, there were but few crepitant or subcrepitant râles, and the breathing was more decidedly amphoric than bronchial. The character of the breathing, with increasing flatness, the sudden rise of temperature, and the chill aroused the suspicion of pus-accumulation, in consequence of which a long hypodermic-needle attached to a piston-syringe was introduced as a confirmatory maneuver. I failed to find pus, much to my disappointment.

On March 4th the patient was more wildly delirious, and the percussion-note over the area which had given flatness the day before was rapidly becoming tympanitic. The breathing was not purely amphoric, but yet decidedly musical in character. The sputum was more purulent (with blood streaks) than the day before. On the morning of March 5th, his temperature continuing high, the pulse being very rapid and unsatisfactory, and the physical signs in the right lung persisting, I again introduced the exploratory needle, but failed to find pus.

The pain continued to be severe in the right lung. The general appearance of the patient was not at all reassuring; his temperature had suddenly risen to 105° F. After a severe chill on the morning of March 6th, it was evident that the pneumonic process had extended to the left lung. The percussion-note in the left interscapular region and at the left apex was abnormally high-pitched and dull, the breathing bronchial, the voice-sound markedly increased, and vocal fremitus exaggerated. There were also abundant crepitant râles. The physical signs in the right lung were not materially changed. The sputum was now more bloody, was characteristic of the second day of a croupous pneumonia, and during the next three or four days there were all of the characteristic physical signs and subjective symptoms of a croupous pneumonia involving the left apex and the lung in the left interscapular region. The leucocytosis had disappeared after the crisis on March 2d, but now there were 14,000 white blood-corpuscles in one c.mm. of blood. While the pneumonia involving the left lung continued, the symptoms of delirium tremens were controlled by the use of chloral hydrate and the hypodermatic injection of morphin. The microscopic examination of the sputum showed abundant red corpuscles, leucocytes, pneumococci, and staphylococci.

March 7th, 8th, and 9th the physical signs were not materially changed. The pneumonia of the left lung was following a typical course. The physical signs in the right lung, which led me to conclude that there was either an empyema or a lung abscess, persisted, and on each of these days, after taking every possible antiseptic precaution, the exploratory needle was used with negative result, much to my chagrin. I had almost concluded, after having made six punctures with the needle, that my efforts were not to be rewarded with success. The patient was unconscious most of the time, and was not at all annoyed by the repeated prodding to which he was subjected. On the morning of March 10th it was evident that resolution had commenced in the left lung. The pulse, however, was very feeble, averaging 120 per minute during the morning, the temperature ranging between 103 and 104° F. There had been excessive perspiration during the night. During the morning the patient had a violent chill, which was followed by profuse perspiration. These subjective symptoms prompted me to make one more attempt to localize the pus in the right lung, but again the result was negative, and as I was to leave the city for a holiday on the evening of that day, I reluctantly turned the case over to Dr. Curtin.

Toward the evening of March 10th the condition of the patient became so serious that I was asked to see him once more before leaving the city, and in company with Dr. Curtin examined him thoroughly without finding any change in the physical signs. These seemed to me so conclusive that I could not leave the city content without making a final attempt to localize the pus, and in the presence of Dr. Curtin introduced the needle once more, and in withdrawing the piston filled the syringe with a dirty, foul-smelling pus. The few instruments which I needed were hurriedly sterilized, and under cocain and methyl chlorid I opened the right pleura, making a liberal incision in the seventh intercostal space, the center of which was on a line drawn from the angle of the scapula downward. The was no pus in the pleural cavity. On introducing my index-finger into the pleural cavity I found but few adhesions of the lung to the pleura, but felt a fluctuating mass just beneath the pleura in the dependent part of the lung, which I readily opened, and gave exit to about half a pint of pus of the same character as that which had been withdrawn by the needle. As we were not supplied with gauze, I introduced a large-sized drainage-tube into the lung cavity, which was anchored to the chest-wall, thus establishing free drainage. There was slight hemorrhage on cutting into the subpleural lung tissue, which gave little trouble after the pus had been emptied.

Dr. Curtin cared for the patient during the next ten or twelve days. He remained more or less delirious, the drainage was free, there was abundant pus discharge, his temperature remained nearly normal, his pulse improved in character, there was no recurrence of chills, and the left lung gradually returned to its normal condition. The sputum was repeatedly examined for tubercle bacilli, with negative results. In about two months drainage was no longer needed, and about the end of May the wound had completely closed, the percussion-note over the original seat of the abscess was slightly higher pitched than normal, air entered to the base of the lung, the patient had no cough, had gained weight, had discontinued the use of stimulants of all kinds, and was to all appearances perfectly well. In spite of the fact that he has returned to his former intemperate habits, he has had no further lung symptoms, though he has had repeated attacks of delirium tremens.

Case III.—On September 1, 1898, I was called to treat Lupeta F., a girl, aged seven years, born of American parents in Mexico, with negative family

history, and without hereditary taint. Until her fifth year she had enjoyed excellent health, was an unusually bright and active child, but of decided nervous temperament. From the fifth year to the time of her illness she had suffered from repeated attacks of vomiting, supposed to have been due to gastro-intestinal indigestion, associated with moderate pain in the epigastrium. She was taken sick one week before I saw her, during my absence from the city, and had been attended by Dr. Van Duyn, who turned the case over to me at the time above mentioned.

The symptoms during the week preceding my first visit were rather vague, and did not justify a diagnosis. It was supposed during the first days of her illness that she was suffering from one of her usual attacks, but with more pain than before. When I first saw her it was evident that she was very ill. The pains which were present during the first days of her illness were of a severe shooting and darting nature, radiating through the lower thoracic and upper abdominal regions. Occasionally she retched and vomited, but had no cough. Her temperature had ranged between 102° and 103.5° F., her pulse was uniformly rapid, above 130, and her respiration averaged between 20 and 25. Dr. Van Duyn reported negative signs on physical examination. The symptoms on September 1st strongly resembled those of typhoid fever. There was continuous fever, more or less delirium, considerable intestinal distention, with rapid pulse and slight enlargement of the spleen.

Careful physical examination elicited an abnormal high-pitched note over the left apex. There was normal vesicular breathing. The changed percussion-note was the only physical sign to arouse suspicion. As the child had lived most of her life in Mexico we were prompted to make a blood examination, which, however, proved negative as far as hemocytozoa and Widal reaction were concerned.

September 2d the temperature reached 105° F., pulse 120 to 140, and respirations between 20 and 30; no other important symptoms. On September 3d, temperature 103° to 104° F.; later, 105° F.; pulse 130 to 140; respirations between 28 and 36. My record shows that on this day I detected a slight dulness at the base of the right lung. Otherwise there were no subjective or objective symptoms. There was no cough. September 4th, temperature remained between 101° and 104 F., respirations between 36 and 40. The changed percussion-note at the base of the right lung was positive. Flatness was now persistent from the angle of the scapula to the base of the lung, and there was weakened voice-sound and breathing.

There were sudaminæ over the entire body. The dulness at the left apex persisted without further change. On September 5th the flatness had extended higher up, there was absence of voice and breathing sounds, vocal fremitus was diminished, and the temperature remained as high as the day before. The nurse reported one large roseola on the back. Widal reaction negative; no other symptoms of typhoid.

The child's mind remained clear. A long exploring needle attached to a glass syringe was introduced with the firm belief that there was an accumulation of pus in the pleural cavity. No pus was found. On September 6th, 7th, and 8th the physical signs and general condition of the patient remained the same. The temperature remained as high as before, there was but little cough, and no expectoration; there was a marked leucocytosis, the pulse was growing more feeble, and the heart-muscle showed evidences of degeneration. On September 9th the condition of the child became alarming; the physical signs persisted. In the absence of symptoms of pneumonia, and because of the gradual increase of flatness at the base of the right lung from day to day, I decided to put the child under chloroform and again search for pus. Assisted by Dr. Jacobson, who agreed with me in my suspicion, the child was carefully examined. She took the chloroform kindly. We explored in various directions, making five or six punctures, but failed to locate the pus. This experience satisfied us that we were not dealing with an empyema, but in all probability either multiple pus-foci with infiltration of lung tissue, or acute extensive infiltrating tubercle alone. Examination of the blood, which was obtained with the exploring-needle, gave negative results.

From September 10th until September 18th two attempts were made to find pus in the lung. The symptoms grew more alarming from day to day while the physical signs persisted; the temperature averaged 104° F., pulse 140. On September 18th I recognized a small area of amphoric breathing in the infra-axillary region of the right lung; otherwise physical signs were unchanged. There was but little cough, no expectoration. On September 19th an exploratory puncture was made. The blood withdrawn was examined bacteriologically, and found to contain only a few leucocytes, no tubercle bacilli, a few staphylococci. On September 20th the temperature had reached 105.2° F., the pulse was so rapid and feeble that it could scarcely be counted, averaging between 160 and 200, and the respirations were from 40 to 60.

Drs. Jacobson and Van Duyn were called in consultation. Both examined the child carefully, and were impressed by the physical signs, which we concluded were due to one of three conditions: either complete consolidation of the lung with occlusion of a bronchus, of tuberculous or inflammatory origin, abscess of the lung, or encapsulated empyema. It was evident that the child could not long continue in her present condition. We explained to the parents the uncertainty of affording relief by surgical interference, but were agreed that an exploratory operation offered the only hope of saving the child. Accordingly, the patient was once more chloroformed, and under strict antiseptic precautions I made an incision between the seventh and eighth ribs, the center of which formed a right angle with a line drawn from the angle of the scapula, and opened the right pleural cavity, in which no pus was found. The incision was en-

larged, the ribs readily drawn apart, and the index-finger introduced. There were no adhesions of the lung to the pleura, but the lung-tissue felt hard and abnormally dry. The exploring needle was introduced into the lung to the depth of about three inches through the opening between the ribs, and we were rewarded with success, withdrawing pus. The lung was incised. There was moderate hemorrhage. The incision was enlarged with the finger, which was introduced to the depth of about three inches, when a moderate flow of pus followed. Twenty inches of iodoform gauze was packed in the lung for drainage. The wound was dressed antiseptically.

The general condition of the child was not influenced by the operation. She was desperately ill during the following two weeks. There was free drainage of pus from the lung; some days there seemed to be more than others. It seemed as if innumerable small pockets of pus found exit from time to time along the line of least resistance. The child required stimulation and careful watching during many anxious days. The physical signs commenced to improve about October 5th, the flatness gave way to dulness, gradually there was a return to normal resonance, and by Christmas the little one was able to be about the house. After three or four weeks of gauze-drainage a rubber tube was substituted. This was finally withdrawn, having been shortened from time to time as we progressed in the treatment of the case. At no time after the operation was there expectoration of blood; neither was there much cough. After Christmas there were absolutely no symptoms referable to the lung. The child gained in flesh and weight, had normal appetite, and, as her parents expressed themselves, was in every way better than at any time since her fifth birthday.

The subsequent history of this case is of intense interest. Unfortunately, after convalescence and while the child was enjoying freedom from all symptoms, about January 5, 1899, there was a recurrence of vomiting, which soon proved to be of meningeal origin. During the next few days the symptoms of basilar meningitis, with paralysis, developed, and the child died on January 16, 1899, of tubercular meningitis.

In the first two cases reported it is very evident that the lung abscesses followed pneumococcic and final staphylococcic infection. The abscesses were subpleural, such as Bushnell has recently described. Such cases are not at all rare, but I am well satisfied that in the majority of these the complication is not recognized, and the patient finally dies from exhaustion, pyemia, or sepsis, or Nature comes to the rescue, and the abscess ultimately communicates with the bronchus or with the pleural cavity. In 150 cases of pneumonia, which I recently reported, I diagnosed abscess of the lung three times, and in 750 cases reported by Sello there were eleven cases of lung abscess, which would show the complication to occur in about 1.5 per cent. of pneumonia cases.

In Case III. it is more difficult to explain satisfactorily the infection which led to the suppurative process in the right lung. The unfortunate ending of this case would strengthen the conclusion that the dulness which I detected at the left apex on my first visit was in some way related to the abscess in the opposi e ung. Possibly, there was here a central focus of latent tuberculosis to which pyogenic cocci had been added which may have been aspirated or migrated from this point through some of the many avenues of escape to the opposite lung, and multiple abscesses resulted. The subsequent history of this case proves still further that the child had been suffering since its fifth year from solitary tubercle of the brain, which was responsible beyond doubt for the repeated attacks of vomiting, and from which the general basilar meningitis ultimately spread. Th · roseola which the nurse found on the child's back during the early days of the disease was probably of cerebral origin, a true *tache cerebral.*

Cases of solitary brain tubercle are frequent, as is proven by the recent work of Bruns, who found solitary tubercle present in five of thirty-one cases of brain tumor studied by him. This pathologic condition has been confirmed by others. It has been my experience that in these cases there is not infrequently a long prodromal period during which the symptoms are vague, but if carefully studied one is made suspicious, at least, of brain disorder. If there was infiltrating tubercle associated with the abscess, the admission of light, air, and drainage were sufficient to dissipate all external evidences of its presence, for all the physical signs of disease had disappeared. Unfortunately, a post-mortem was not allowed.

It may be concluded that there are no distinctive physical signs of lung abscess, but, nevertheless, as in the cases reported, the presence of markedly changed tissue, as shown by objective symptoms referable to the lung, must lead to a strong suspicion of pus accumulation when the presence of all other lung and pleural diseases have been excluded by bacteriological and clinical methods. Indeed, what Leube says of the diagnosis of abscess of the liver is equally true of abscess of the lung. He holds that we are not to diagnose the former until we have excluded all other liver diseases. Of course, in almost all cases the abscess is secondary, and we have the preceding history to aid us. The physical signs must necessarily depend largely upon the variety of abscess, whether of bronchogenic, hematogenic, or pleurogenic origin. Recent medical literature strengthens the conclusion that the majority of patients with lung abscesses recover if they are radically treated. I can imagine no cases more des-

perate than those which I have reported, and the results certainly warrant a careful search where lung abscess is suspected.

The persistent use of the exploratory needle, with or without pleurotomy, is indicated, for in no other way can the diagnosis be corroborated. I have made many exploratory punctures—no harm has come from any of them—and I have had the satisfaction of saving many lives by the aid which this method of diagnosis has given. These explorations have led me to open freely into the pleural cavity in cases of recurring tuberculous pleurisy with the same success which has delighted the surgeon in cases of peritoneal tuberculosis. The history of Case III. would at least warrant the suspicion that superficial lung tuberculosis may ultimately prove to be favorably influenced by incision, drainage, and the admission of air and light.

THE DIAGNOSIS AND MANAGEMENT OF OCCIPITO-POSTERIOR POSITIONS IN LABOR CASES.[1]

BY CHARLES H. GLIDDEN, M.D.,
OF LITTLE FALLS, N. Y.

THE diagnosis and management of occipito-posterior positions have given me more anxiety and caused me more hard work than any other single class of cases which I have had to manage. The importance of a close study of this particular abnormal presentation has been impressed upon me after an experience of sixteen years of more or less active obstetric work, during which time I have had upward of thirty cases of persistent vertex-posterior presentation, nearly all of which required instrumental aid in delivery. The infant mortality, the damage done to the maternal soft parts, the prolonged suffering and shock to both mother and child, and the outlay of strength and skill on the part of the obstetrician in the management of these cases justify our earnest consideration of this subject.

At the end of pregnancy the cephalic end of the child presents in nearly 97 per cent. of all cases. In 75 per cent. of all head presentations the occiput points to the left side of the mother, and in 73 per cent. anteriorly. There remains, then, 25 per cent. of cases in which the occiput points to the right side of the mother, the great majority of them posteriorly. A large proportion of these right posterior presentations become right anterior by a process of rotation during the second stage of labor and are, therefore, uncomplicated. It is only those cases that remain persistently right posterior that will present unusual difficulties in management.

The diagnosis of right posterior position of the vertex is, I believe, rarely made in private practice, most physicians being content when they have learned the mere fact that the head presents. That this is very far from being a complete diagnosis in any case I abundantly proved in the earlier years of my own experience. Granted that it is important to know that the head presents at the beginning of labor, it is more important to know the relative position of the vertex to the pelvis. That it is possible to make a correct diagnosis of the presentation at the first examination in a majority of cases there can be no doubt even at the very earliest stage of labor, or, better still, before labor has actually begun. This may be done chiefly through the abdominal walls. The gynecologist becomes expert in the diagnosis of tumors by abdominal palpation, bimanual manipulation, etc. Why should not the obstetrician become equally expert in determining the position of the fetus in utero by the same methods? It is undoubtedly true that the lives of many infants might be spared if more intelligent methods of determining and correcting malpresentation were observed early in labor. It is probably also true that the number of idiots and epileptics might be greatly lessened if more scientific methods of delivery were adopted instead of the almost universal use of the obstetric forceps regardless of position or presentation and regardless of the amount of injury to the fetal head. Abdominal palpation and auscultation are practised in all lying-in asylums as a matter of routine just as much as the careful attention to the details of asepsis and the weekly examination of the urine. In a recent report of the Preston Retreat in Philadelphia Dr. Richard Norris says, "Diagnosis by abdominal palpation is highly valued and constantly practised." Of course in private practice opportunities for examination are not so great and conveniences not so many as in institutions, but if one appreciates the importance and necessity of an early diagnosis of presentation and position it is no more difficult to make these examinations than it is to examine the urine, a duty but few physicians neglect in these days.

The exact method of diagnosis by external means is described as follows by Reynolds of Harvard: "Abdominal inspection is mainly valuable as affording a hint of the existence of transverse presentations and of multiple pregnancy. . . . Palpation is the most important part of the abdominal examination. It should be performed only in the intervals between the pains provided labor has already begun, all pressure of the hands being intermitted with the appearance of each contraction. The physician standing by the patient's side facing toward the feet presses the finger-tips of each hand

[1] Read before the New York State Medical Association.

with a gradual and gentle motion downward behind the symphysis pubis in search of the fetal head, which, in cephalic presentation, is almost always to be felt in this situation as a marked transverse check to the examining hand. In this examination care should be taken to note on which side the head is most plainly perceived, since with a well-flexed head the frontal extremity is much the more easily reached; with the partially extended head but little difference is to be noticed, and in face presentations the occiput is much the more distinct. . . . The fundus should then be palpated as a further means of excluding a breech presentation. . . . In determining the position of the fetal head the hands should be placed along the sides of the uterus and should make gentle but deep pressure toward each other, that is, with the uterus and child directly between their palms in the effort to estimate the relative resistance offered by the right and left side of the uterus, the flat, firm back of the child usually presenting a resistance to pressure that is markedly greater than that of the yielding abdomen and the movable limbs."

Jewett says on the same subject: "The child's back is identified by the length and breadth of the resisting plane which is offered to the examining touch, and by absence of a sulcus between it and the fetal head. The side of the child presents a narrower plane than the back and a distinct sulcus separates it from the head. The small parts are usually felt as nodules which glide about under the touch. . . . By palpation, then, we ought to be able to determine not only the presentation but the position because the occiput must point toward that quarter of the pelvis in which the fetal back is found. Excluding those very infrequent positions, O. L. P. and O. D. A., it will be safe to say that all cases in which the back of the child points to the left side of the mother will be occipito-left-anterior, and all those in which it is found to the right side of the mother, occipito-right-posterior."

It is certainly strange that we have not more generally practised abdominal palpation as an aid in determining the presentation and position of the fetus at the beginning of labor. I have never seen it carefully undertaken by any physician and none of the older text-books contains any adequate descriptions of the method to be employed. Auscultation gives valuable evidence as to the condition of the fetus and may help one somewhat in recognizing its position. In vertex presentation the heart-sounds are heard most distinctly below the umbilicus, on the right or left side of the mother, according to the position of the back of the child. Bimanual manipulation is used chiefly in determining the degree of flexion or extension of the head and is of great importance in management, it being a valuable means of assisting flexion as well as rotation during the second stage.

Most of my cases have been in primiparæ and in these especially the careful exploration of the abdomen externally will be of much more value in determining the position than the vaginal touch. In fact very little can be learned by digital examination alone in a primipara because the soft parts are generally rigid and unyielding, and the resistance of the patient to prolonged examination at such times is very considerable. Still it may be possible after long experience and carefully educated touch to determine the position of the fetal head by noting the relative location of the large anterior and small posterior fontanels and the general direction of the sutures leading from them. But it is exceedingly difficult to satisfactorily locate either sutures or fontanels through the walls of the cervix or through the unruptured membranes, and it is well to repeat that the diagnosis of right posterior position must be made early and before the membranes are ruptured if it is expected to correct the malposition by any manipulation aside from operative interference.

The last point with reference to diagnosis of posterior position to be mentioned is one peculiarly characteristic, *viz.*, prolonged first stage. In a given case in which a woman has been in labor from four to six hours or longer with but little advancement of the head, with slight dilatation of the cervix, with irregular and imperfect contractions of the uterus, with an apparent inability on the part of the patient to make the ordinary expulsive efforts, then one may suspect a vertex-posterior position. In such a case if every means has not already been adopted to determine with accuracy the exact position of the fetal head now is the time to do so. Abdominal inspection, palpation, bimanual manipulation, and auscultation of the fetal heart should now be practised in addition to the digital search for the fontanels and sutures, the examiner being careful not to rupture the membranes.

Having determined that the condition is one of R. O. P. presentation, how shall one proceed to deliver a living child with the least amount of injury to the mother? Its successful management will depend largely upon an early diagnosis. It will be exceedingly fortunate if we have made this diagnosis some weeks prior to term, as then much may be expected from postural treatment. When the patient is placed in the knee-chest position the anterior wall and fundus of the uterus are its lowest parts, and by influence of gravity the position of the child must be somewhat changed. If its head drops away from the

pelvic brim it will then be free to rotate on its axis. This position should be assumed by the patient several times daily, as long a time as possible before labor, at least, three or four weeks. She should remain in this position several minutes each time, and then recline on her side a short time before rising, in the hope that as the child's head again settles down against the brim it may attain an anterior position. The position must be such that the abdomen does not come in contact either with the bed or with the thighs of the patient. If no examination of the patient has been made prior to the commencement of labor it is still worth while to try postural treatment. The position must now be maintained as long as possible and between pains it may be possible to aid rotation, but this is doubtful as any manipulation of the uterus externally increases the frequency and force of the contractions and so defeats the object desired. With a tractable patient, who will assume this position and remain there until rotation has taken place, one may succeed in engaging the head in the anterior position and keeping it there, the patient keeping the prone position as much as possible with this end in view.

As before stated, a good proportion of these right posterior presentations become right anterior by a natural process of rotation during the second stage of labor, but the process by which this rotation is accomplished is, unfortunately, so delicately balanced that it is always likely to fail. It is only in those cases in which the vertex remains persistently right posterior that unusual difficulties in management will be presented.

The mechanism of labor in R. O. P. positions is quite complicated, and it will be sufficient here to say that it is necessary that the fetal head should enter the pelvic brim well flexed in order that the subsequent progress may be satisfactory and that upon the amount of extension will depend the difficulties to be encountered. That is to say, the more the head is extended, the more difficult will be its passage, and the less likelihood of rotation. From the nature of things, there being a mechanical misfit between the head and the pelvis, extension is likely to take place more or less markedly during the slow passage of the head through the superior strait, and a decided molding of the head also. Therefore the principal duty of the accoucheur at this time is to make quite frequent examinations in order to mark the degree of extension and antagonize it as much as possible. It is not wise to wait until both mother and child are exhausted. Unless there is pretty prompt progress, interference will quite surely be necessary. Before deciding exactly what course to pursue, the dimensions of the pelvis should be carefully estimated, or better still, accurately measured, and also the fetal head, so far as possible. If the patient be a primipara the rigidity of the soft parts must also be considered. If there be quite a roomy pelvis and easy adaptation of the head, careful bimanual manipulation before rupture of the membranes may succeed in pushing the forehead of the child upward and foreward, freeing it from the brim, in the hope that on its re-entrance it may be better situated. After rupture of the membranes it will be well to anesthetize the patient, dilate the os sufficiently, and then introduce the hand and push the forehead upward until it touches the chest, and maintain this complete flexion by pressure upon the head through the abdominal wall until the occiput has been well forced down by the uterine contractions. These directions I have followed out carefully in quite a large number of cases, but with not very flattering success.

Three methods of delivery are now possible, *viz.*, manual rotation and immediate application of the forceps; forceps without rotation; and podalic version. In skilful hands the first method is probably under all circumstances the most satisfactory, and certainly the most scientific, but it is difficult to perform and rather than make protracted efforts at manual rotation it would be much wiser to perform version at once. It has been my fortune or misfortune to have about thirty of these persistent posterior positions to manage, and it is my belief that in the majority of cases, taking into consideration the safety of both mother and child, the forceps, carefully and skilfully handled, without protracted attempts at rotation, offers the best means of terminating these cases. The amount of traction is a matter of consideration. Only after considerable experience can the safety line in this respect be determined. Traction should only be practised during uterine contractions, and in the interval the forceps should be unlocked and the head pushed back slightly. Continued pressure of the locked forceps, or holding on to them to prevent the head from receding, should never be practised. If good progress follows quite promptly there need be no fear as to an ultimate safe delivery. If great disparity exists between the diameter of the pelvis and the fetal head, or if there be uterine inertia, or if the mother or child seems unable to endure the prolonged strain, or if the condition of the soft parts of the mother makes it probable that great damage will be done, as extensive laceration, etc., then the forceps should be removed at once and with the patient completely anesthetized podalic version should be performed. It is probably true that there is less danger of laceration in delivery with forceps in anterior positions

than in the extraction of the after-coming head in version.

In every case attempts should be made at rotation, whether the membranes have ruptured or not. If the liquor amnii has pretty well drained off, then there will be less probability of success and the forceps may now be applied without rotation. If the pelvis is fairly roomy and the fetal head not unduly large or ossified, the accoucheur will be able to bring the occiput down with the head well flexed, and keeping in mind the normal mechanism, assist in the rotation of the occiput down and to the right, and finally bring it out under the pubes through the outlet in almost a normal right anterior position. In three instances I have been able to accomplish this, thereby preventing the extensive laceration of the perineum that must surely occur when the occiput is dragged out in posterior positions.

The safety of the child will, of course, depend largely upon the length of time consumed in the delivery, the amount of pressure produced by the forceps, and the degree of adaptation between the head and the pelvis. In normal labor pressure upon the head is intermittent and the molding process a slow one. During instrumental delivery one should imitate Nature as far as possible. Unless the head rotates into an anterior position as it passes through the pelvic outlet,the pressure of the frontal and parietal bones against the pubes of the mother will be tremendous, and will likely produce fatal injury to the child's brain. If care and patience be exercised and time given for the slow molding of the head, a living child will usually be delivered. I do not believe that the risks to the child in posterior positions are much greater in skilful delivery with the forceps than in version. Five infants in my thirty cases have been still-born. Three of these were delivered with forceps and two by version. All of the others were delivered with forceps, after attempt at manual rotation. In three, as above stated, rotation took place during the second stage. In only one instance was the result bad for the mother, and this only resulted in prolonged convalescence on account of neuritis from pressure, and laceration of the cervix and peritoneum.

NASAL CATARRH IN CHILDREN; ITS CAUSE AND TREATMENT.[1]

By CLARENCE C. RICE, M.D.,
OF NEW YORK;
PROFESSOR OF RHINOLOGY AND LARYNGOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Is it of importance to consider catarrhal diseases of the nose and throat in children as a condition widely different from that in adults? Are the pathologic conditions and the etiologic processes which produce nasal catarrh in the young different from those which we recognize as being present in older people? Nasal catarrh in children would seem to be a very prevalent disease if we include under this broad heading those many cases of mouth-breathing patients who present themselves at clinics and in private practice with the nostrils obstructed by mucus or mucopurulent secretion. It is because many practitioners seem to be in the habit of considering all these cases as types of simple nasal catarrh, and apparently do not recognize the real pathologic condition, that I believe it is wise to consider these affections somewhat more in detail. I see, as I believe we all do, many of these cases which are diagnosed as simple nasal catarrh, and which are treated with nothing more than a nasal spray, which certainly deserve other and better attention.

It seems wise in the beginning to consult the writings of those practitioners who have given special study to the general ailments of children and obtain their views in regard to nasal catarrh. Their opinions should have weight, not only because based on large experience, but because their point of view, seeing as they do children at home suffering from acute diseases, may be quite different from that of the rhinologist who sees his patients only as they come to the office. It is only within the last few years that text-books on diseases of children have treated the matter of nasal catarrh in children in more than a casual manner Either the subject has been superficially treated or else the matter would seem to be a repetition of what one might expect to find relating to the nasal catarrh of adults in works on rhinology. In two older text-books we notice that nasal catarrh is described under the chapter devoted to measles. We find the subject usually treated under the two general heads of acute and chronic; and such writers seeing, as they do, children passing through the various diseases of childhood, the eruptive fevers, most of which are accompanied by *acute* coryzas, naturally lay great stress on the importance of these in developing *chronic* nasal catarrh. We find a strong tendency, and perhaps not too strong, in such writings to lay great stress upon the importance of heredity as a predisposing cause to nasal catarrh, and the statement is common that enlargement of the faucial and nasopharyngeal tonsils is in itself strongly indicative of a scrofulous or tubercular diathesis. At first thought this would not seem to us to be true; it certainly is not borne out by our experience, but we must remember the general practitioner sees con-

[1] Read before the Section on Laryngology and Rhinology of the New York Academy of Medicine, November 23, 1898.

stantly the rachitic, scrofulous, poorly nourished little patients who pretty generally have post-nasal adenoids, whereas the stronger and more robust children, who are not ill enough to require the services of the family physician, go to the office of the nose and throat specialist. It can be definitely stated that we see a large number of children who have enlarged faucial tonsils and the post-nasal space blocked with adenoids who are the picture of health. It is true that in many instances if these children are not relieved by operation the evil effects arising from closed nostrils will show themselves in the many disastrous ways which are common to mouth-breathing children. In many text-books, too, we find the term "catarrhal diathesis" employed, but we cannot believe that this should be considered a very tangible factor, because we find catarrhal diseases present to such a large extent in children of the best physical types.

From our standpoint many of the writers on diseases of children lay altogether too much stress upon the importance of a child's tendency to scrofula, tuberculosis, or syphilis as predisposing causes to chronic nasal catarrhs, and fail to search for and discover *local nasal lesions* which are the important etiologic factors in making any transient nasal disturbance a chronic process. One can hardly dispute the writer who says that chronic rhinitis is invariably due to some fault of the general health, because it is difficult to prove that any child is as well as it might be. But in nearly all the cases of chronic nasal catarrh which we see in children we are in the habit of finding some local lesion which has made an acute catarrhal process a chronic one. The evils of overheated houses, badly ventilated rooms, and unsanitary conditions generally are emphasized in books on pediatrics, and cannot be too strongly dwelt upon. It is very possible that these causes are sufficient to lower the vitality so that the special germs which attack the nasal tissues are potent to produce catarrhal inflammations. Physicians specially interested in children's diseases believe that the exciting cause of catarrhal inflammations of the upper air-passages is, first, the involvement of the mucous surfaces during the eruptive fevers, and after that all general causes which tend to lower the vitality, while the rhinologist usually finds in some local nasal condition, if not the exciting cause of the coryza, at least a reason why it has become chronic and persistent. Both Dr. Jacobi[1] and Dr. Holt[2] speak of the various local nasal lesions in defining the causes of chronic nasal catarrh, such as polypi, adenoids, enlarged tonsils, deviated septa, etc.

We should state in the beginning that we shall have very little to say in regard to the acute coryzas in infants or in young children which precede or accompany the eruptive fevers and diphtheria. The family physician alone has the opportunity of treating this class of cases, while the office practitioner sees them only when they excite, as they very frequently do, a chronic rhinitis or some post-nasal affection. It would be of great value if the family physician would notice how often these acute coryzas do eventuate into chronic affections, and how frequently they excite the growth of lymphoid tissue in the middle and upper pharynx. These acute coryzas require treatment, but perhaps not materially different from that indicated in any acute coryza.

It may be convenient to divide catarrhal conditions of the nose in children under the heads of acute and chronic, and still farther into simple catarrhal or purulent, and again into hypertrophic and atrophic. For example, a nasal catarrh may be in type chronic atrophic with a purulent discharge, or it may be chronic hypertrophic with a simple catarrhal discharge, these names indicating the pathologic condition which is found and the character of the nasal discharge, rather, perhaps, than a well-marked disease which can always be differentiated from every other variety, because catarrhal discharges frequently become purulent for a time, and a hypertrophic process may degenerate into one of atrophy. Two other terms, which we think are convenient, not for stating the pathologic condition but for defining the cause, are idiopathic and symptomatic, the idiopathic catarrh usually being acute, such as an influenza, or such a severe coryza as accompanies the exanthemata; whereas in the symptomatic nasal catarrh the disturbance and the discharge are symptoms of some local lesion, such as tissue hypertrophy, deviations of and spurs on the septum, nasal polypi, foreign bodies, syphilitic ulcerations, and nasopharyngeal catarrh, either accompanied or unaccompanied by adenoid enlargement. We see all the time acute coryzas in children which are only symptomatic of a chronic pathological condition in the nose or pharynx. Some one has said that the frequently recurring attacks of an acute coryza or a persistent coryza in a child, would indicate a syphilitic or tubercular history. We believe that such an etiology is rare compared with the large number of cases in which acute exacerbations are due to post-nasal adenoids. We should like to state our position clearly as believing that in ninety per cent. of all cases of chronic nasal discharge occurring in children, who, as their par-

[1] Jacobi, "Therapeutics of Infancy and Childhood," p. 465, 1898.
[2] Holt, "Diseases of Infancy and Childhood," p. 432, 1897.

ents express it, constantly take cold on the slightest exposure, the nostrils being filled with a secretion of mucus and pus, the principal cause is the presence of some degree of enlargement of the nasopharyngeal tonsil which may or may not be accompanied by enlargement of the faucial tonsils. We even see nostrils blocked with discharge in the early stages of an atrophic rhinitis, in which the important constant lesion is post-nasal adenoids. We know that observers disagree as to what should be considered enlargement of the pharyngeal tonsil, but we feel that it requires only a small amount of adenoid hypertrophy to block up the nostrils, prevent drainage both forward and backward, and eventually produce a chronic nasal catarrh in young patients in whom the post-nasal space is so small and the patient too young to use what little space there is for clearing the nasal passages either by blowing the nose or forcibly drawing the secretions down into the middle pharynx. That a very small amount of adenoid tissue may be the entire cause of the mischief is frequently proved by the fact that when this little is removed and the nasal chambers are cleared, what has been called a chronic nasal catarrh disappears.

We can in a very words state all that we know in regard to purulent rhinitis in children. This disease is mentioned by a few writers, but hardly by anybody at more length than by Dr. Bosworth[1] of this city. He considers it a frequent disease in children, and one that resolves itself finally into an atrophic rhinitis. If there is any special germ which produces this disease it certainly is not known at present. The significant symptom of this, Dr. Bosworth says, is a bright yellow discharge of pus from both nostrils. I cannot believe that such a condition is common. How often do we see a bright yellow discharge of pus from both nostrils in children unless there should happen to be bilateral inflammation of the antrum or ethmoid or both? We must not confound a *unilateral* discharge of pus, which may be produced by a foreign body, syphilitic ulceration, necrosis, or empyema of some one of the sinuses, with this purulent rhinitis. We are quite willing to admit that there is frequently a semipurulent discharge in children in atrophic rhinitis, and perhaps during acute exacerbations the secretion is almost entirely pus, but this is but temporary, and the discharge soon becomes only partially purulent. I believe this type of disease should be called atrophic rhinitis from the beginning, and that this character can be recognized by the general condition of the nasal passages. I cannot believe that there exists a preceding purulent catarrh.

Bilateral empyema of the sinuses may be present for a short time after a severe and acute coryza, but its duration will be short unless the vault is filled with adenoid tissue. Some special infection may give to an acute coryza a purulent discharge for a time, but this is not chronic purulent rhinitis. There are also acute exacerbations in atrophic rhinitis when the discharge is temporarily purulent. All acute coryzas, in which variety we are most apt to see a secretion of pus, are also of the type most amenable to treatment, and the purulent discharge usually ceases when all obstructions to nasal respiration are removed and the passages cleansed. A chronic purulent rhinitis preceding and finally terminating in atrophic disease does not, I believe, occur frequently.

Let us here speak of the frequency of the various pathologic conditions which are found in children suffering from nasal catarrh, and of their relative importance. Dr. Chappell[1] of this city some time since gave a report of the various pathologic condition in 2000 cases of nasal disease in children, and they were tabulated as follows:

Adenoid enlargement, 60; enlarged faucial tonsils, 270; deviated nasal septa, 330; spurs on the septum, 150; cases of hypertrophy of the inferior turbinated, 260; cases of hypertrophy of the middle turbinated, 161; total, 1231.

We do not doubt that Dr. Chappell saw some degree of deviation of the septum in this large percentage of his cases, nor that there *appeared* to be hypertrophy of the turbinated structures in more than 420 cases (more than one-fifth of the total), but our observation does not agree at all with his in the infrequency of the existence of enlarged pharyngeal tonsil. We have not taken the pains to tabulate 2000 cases of nasal catarrh in children, but in 300 of which we have some memoranda some degree of enlargement of the third tonsil was found in ninety per cent. Dr. Chappell finds adenoid enlargement in only one-quarter of the cases of enlarged faucial tonsils. We have found enlargement of the third tonsil more commonly than that of the faucial tonsils in children. There may be some error in this argument because of the different views of observers as to what may be properly called enlargement of tonsillar tissue, but we have not been in the habit of considering enlargement of the faucial tonsils of any moment unless they were hypertrophied enough to produce some impediment to nasal respiration. Nor have we thought that it was worth while to recognize deviated septa unless they were sufficient to somewhat block the nostril or to produce irritation. There are many cases of slightly deviated septa occurring from the fifth to the tenth year which seem

[1] Bosworth, "Diseases of the Nose and Throat," vol. 1, p. 155.

[1] American Laryngological Society, February, 1889.

to me of little importance. In many of these there is congestion and temporary thickening of the nasal tissues, due not to the deviation of the septum, but to the presence of a chronic mucopurulent discharge caused by post-nasal blocking. Deviation of the septum in children is not a condition often competent to produce a chronic nasal catarrh. And the same may be said in regard to chronic hypertrophic changes in the nasal passages. Chronic hypertrophic rhinitis is a comparatively rare affection in children, and we mean by that that in very few instances of children under twelve years of age is there well-organized connective-tissue hypertrophy of the turbinated structures. It is true that when we examine the anterior portion of the nasal passages we see boggy swellings at the anterior ends of the turbinates in nostrils blocked with secretion, and if an observer is in the habit of diagnosing these as cases of "hypertrophic rhinitis" one need not go far to find them, but these apparent hypertrophies are, I believe, temporary if not neglected, and are caused by interference with the nasal circulation and impeded nasal respiration, and disappear so soon as the real cause of nasal obstruction is removed. We cannot reasonably expect to find firm, healthy, turbinated structures in a nostril impervious to the passage of air, and constantly covered with nasal discharge. The great harm in considering these cases of "hypertrophic rhinitis" is that they invite the application of the galvanocautery or mineral acid, or the use of the snare or scissors.

In regard to spurs on the sputum, we have rarely found them large enough in children under fourteen years of age to require operation. They, too, are made more prominent by the general nasal congestion incident very often to enlargement of post-nasal adenoids. I should have said that the cases of deviated septum in children under ten years of age which require attention are cases of marked traumatism. It is a question just how early enlargement of the third tonsil and mouth-breathing commence to elevate the arch of the hard palate, and so cause the nasal septum to become bent upon itself. We do not see this frequently before the tenth or twelfth year.

I have not thought it wise to take up your time in a consideration of the disease which we know in adults as nasopharyngeal catarrh, because in children this has not developed except as a symptom of enlargement of the pharyngeal tonsil, which is far more frequently the cause of nasal catarrhs in children than are deformities of the nasal septum. The reverse is true in adults. Since enlargement of lymphoid tissue, both in the upper and middle pharynx, is so common in children, it seems reasonable to believe that nasopharyngeal catarrh, with its accompanying enlargement of the pharyngeal tonsil, is a condition in children primary to anterior nasal lesions.

Disease of the accessory sinuses in children under ten years of age, if not actually rare, is not often recognized. I believe, however, that acute inflammation of the maxillary sinuses occurs more frequently than we have supposed, and that it nearly always resolves quickly without leaving a chronic condition, unless there is present persistent occlusion from some other lesion. In children it is more commonly bilateral, contrary to the rule in adults. It would be of interest to use the transillumination-test in cases of purulent discharge in children. We should naturally do this if the discharge was from one nostril. Grünwald[1] made autopsies in thirty cases of children where death was caused by diphtheria, scarlet fever, or measles, and found pus in the nasal chambers or sinuses or both in all, and chiefly in the antrum. This would not, we believe, be any strong proof that *chronic* suppuration of the sinuses was common in children, but we should think it likely that there was in such secretions germs competent to excite an atrophic rhinitis or an ozena. Grünwald further says that there is no data as to how these cases result. It would be of great interest to know whether such acute purulent inflammations of the nose and accessory sinuses are the beginning of a chronic atrophic rhinitis.

(To be continued.)

CLINICAL MEMORANDA.

REPORT OF A CASE OF SALPINGO-OOPHORECTOMY IN ACUTE PUEPERAL SEPSIS.[2]

BY HIRAM N. VINEBERG, M.D.,
OF NEW YORK.

MRS. S., aged twenty-three years, married eleven months, was delivered of a female child by Dr. ——, on October 22, 1898. The labor was normal except that the head "stuck" at the perineum. The doctor passed a couple of fingers into the rectum, hooking the chin and thus delivered the head. There was a moderate tear of the perineum which was sutured. The patient seemed to be getting on satisfactorily until the third day, when she had a temperature (oral) of 103° F. and a pulse of 106. On the fourth day her temperature was 102° F., on the fifth day, 101°, on the 6th, 99.8° F., pulse 96. On the eighth day she had a severe chill, her temperature went up to 104° F., her pulse to 120.

I saw her at 9 P.M. on that day (October 30th). Her temperature then was 102.4° F., and her pulse 108, full and strong. The tongue was coated with a white fur.

[1] Grünwald, *Die Lehre von den Naseneiterungen*, Munich, p. 3, 1896.

[2] Read before the Section on Obstetrics of the New York Academy of Medicine, December 22, 1898.

The abdomen was not distended nor sensitive to pressure. The tear in the perineum seemed healthy and was granulating. The cervix was fairly patulous, but there was no discharge, and consequently no fetid lochia. The doctor in attendance had given an intra-uterine douche at 3 P.M., but nothing had been washed away. The uterus was large, rather soft, reaching nearly to the umbilicus, and lying toward the right side of the abdomen. It was not especially sensitive to pressure.

At midnight, under full narcosis, I curetted the uterus very thoroughly, removing several small fragments from the posterior uterine wall. I could pass my finger readily into the uterus and was enabled to explore the whole of its interior up to the fundus by depressing the fundus with the other hand over the abdomen. I could feel several ridge-like elevations on the posterior wall which I ultimately succeeded in removing with the sharp curette. The uterus was then thoroughly irrigated with lysol, one per cent. While the patient was under the narcosis I made a careful bimanual examination and could not detect any exudate nor thickening of the adnexa.

October 31st (noon, twelve hours after the curettage), temperature 103⅘° F., pulse 104; 7 P.M., temperature 105⅘° F., pulse 128. Intra-uterine irrigations used every two hours by means of two large gum-elastic catheters which were left in the uterus, so that the nurse could carry out the treatment with very little disturbance to the patient. From this on the pulse and temperature rapidly fell, so that on November 1st, at 8 A.M., twelve hours later, the temperature was 102⅘° F., the pulse 110, the patient was perspiring freely, and the coating on the tongue was growing less.

November 2d, temperature ranged from 101.4° to 103.4° F.; pulse from 102 to 114.

November 3d, temperature 100.3° to 102° F.; pulse 102 to 110. Irrigations brought away considerable mucopurulent discharge from the uterus. The range of temperature and pulse remained about the same for the next three days.

November 7th (15th day of puerperium), temperature 98.3° to 99.2° F.; pulse 96 to 102. During this period the patient was given freely of stimulants, kumyss and beef-juice. Ergot was regularly administered and the bowels were moved two or three times daily. We were congratulating ourselves upon having gained the mastery over the sepsis and that our patient was out of danger, but on the following morning (November 8th, sixteenth day of the puerperium), without any appreciable reason the temperature and pulse began to go up again and the patient complained of severe pain in the right iliac region.

Now, for the first time, one could feel an elongated mass, about the thickness of the thumb, beneath the very thin abdominal wall. It seemed fixed and was exquisitely tender. The temperature had risen to 104° F. and the pulse to 140 at 4 P.M.

The time had now arrived in my opinion when a more radical course would have to be pursued as it was evident that the infection had passed beyond the uterine cavity and was traveling rapidly along the right appendage. Steps were taken to perform a laparotomy and one hour later, at 5 P.M., I opened the abdomen. The exterior of the uterus appeared normal. To the right of the uterus lay an ugly looking mass made up of the ovary and tube matted together. The ovary was double the normal size, of a dark-reddish color, edematous, and covered with almost black, angry-looking exudates. The tube presented the same dark appearance, was about the thickness of one's thumb, with the fimbriæ very much thickened and looking like a mass of unhealthy granulations. The infundibulo-pelvic ligament was very much infiltrated and reddish in color. I tied off the ovarian artery as close to the pelvic wall as possible, then rapidly excised the ovary and tube with scissors, following the excision right into the horn of the uterus.

The resulting wound was quickly closed with a looped continuous catgut suture. An opening was made through Douglas' cul-de-sac into the vagina, through which a strip of iodoform gauze was carried. Prior to this, some loose adhesions between the lower part of the uterus and rectum and posterior pelvic wall were broken up with the fingers. The vaginal gauze was loosely packed in the space occupied by these adhesions. Another strip of iodoform gauze was laid over the line of suture in the broad ligament, and the end made to pass out at about the lower two-thirds of the abdominal incision. The abdominal wound above and below this point was closed in the usual way, that is, each layer separately, catgut for the two inner layers and silkworm gut for the skin.

The patient withstood the operation fairly well, though her respiration was very rapid through the whole anesthesia. Her temperature fell to 101° F. thirty hours after the operation, but the pulse remained high, 140. It was, however, of a good quality and caused me no alarm. The patient voluntarily passed gas eighteen hours after the operation and at no time was there any evidence of peritoneal irritation. She had a natural movement of the bowels at the end of twenty-two hours.

On the 3d day after the operation the abdominal and vaginal gauze was removed and the wounds gently irrigated with saline solution.

On November 12th, four days after operation, temperature 99.4° F.; pulse 110. From this time on the patient made a gradual and steady recovery. There was considerable purulent discharge from the vaginal and abdominal openings, but the sutured portions of the abdominal incision healed by primary union.

At the present time (December 19th) both wounds are almost closed, the uterus is fairly well involuted, there is no tenderness nor exudate to be detected anywhere, and the patient has been out of bed during the past four days. She is still considerably emaciated, but her appetite and digestion are good. She is free from pain and it will not be long before she will have regained her usual weight.

This case offers many points of interest and is in line with my previous work in puerperal sepsis. It emphasizes the position I have taken, that puerperal sepsis is a surgical disease and should be treated on surgical principles. The first thing to do in a given case is to ascertain the

probable point of infection, and having come to a conclusion on this matter, the next thing to do is to attack it as one would an infected wound elsewhere. If in spite of our efforts the infection is spreading and gaining ground, then one must institute more radical measures according to the indications in each individual case. The present case forcibly illustrates the treacherous nature of puerperal sepsis. On the sixth and seventh days of the puerperium the danger-point was supposed to have been passed, the temperature and pulse being virtually normal. On the eighth day the temperature jnmped up to 104° F., and the pulse to 120. The same thing occurred on the sixteenth day, the pulse and temperature having again been normal during a period of about forty-eight hours, when, all of a sudden, the condition of the patient became alarming.

What would have happened if at this stage the abdomen had not been opened and the highly affected tube and ovary had not been removed? Various answers from an academic standpoint might be given. It might be stated that the infection for some unknown reason, would not have traveled any further, but would have been arrested at the pelvic attachment of the infundibulopelvic ligament; that adhesions would have formed about the diseased tube and ovary and that the woman would have recovered simply with a damaged tube and ovary. But a more trustworthy answer is to be found in an almost identical case under observation at the Basel clinic,[1] in which the alternative above referred to was followed. On the twenty-second day of the puerperium, after several periods of apparent quiescence, the infection evidently extended from the uterus to the right broad ligament. Instead of opening the abdomen the uterus was subjected to permanent irrigations and the patient to cold packs and cold douches, etc., with the result that death occurred six days later, *i. e.*, on the twenty-eighth day of the puerperium. The autopsy revealed purulent peritonitis, and suppurative thrombosis of the pelvic veins, secondary to suppuration of the thrombi at the placental site. On the fourteenth day of the puerperium the patient was subjected to a curettage and the uterine discharge was examined bacteriologically. No streptococci were found. On the twenty-second day the uterine discharge was again examined and this time streptococci were detected.

The case reported above bears out some points I tried to bring out in my paper on "Hysterectomy for Acute Puerperal Septic Metritis."[2]

1. That a bacteriological examination of the uterine discharge is not always trustworthy even in expert hands, and that when we place more reliance upon it than upon our clinical observation our patients' welfare is likely to suffer.

2. That a so-called sapremia may imperceptibly pass into a virulent, and rapidly fatal sepsis, and that a diagnosis of sapremia may often lull us into a false sense of security and permit the opportune moment to slip by when we might save our patient by surgical interference.

[1] Albert de Pourtales, *Archiv f. Gynäkologie*, Bd. lvii, Heft. 1.
[2] *New York Medical Journal*, April 2, 1898.

3. The mistaken conception that acute puerperal septicemia kills before the tenth day, as was asserted by one of my critics when I presented a report of my second case of abdominal hysterectomy for acute puerperal sepsis at a meeting of this section on February 24, 1898. It was stated in the discussion that the patients either die before the sixth or ninth day, or they get well without any radical procedure. In the six fatal cases reported by Pourtales [1] one patient died on the twenty-eighth day (the one above quoted), one on the ninth day, one on the seventh day, one on the twenty-fourth day, and one after the lapse of three months.

REPORT OF THREE CASES OF POST-TYPHOID SURGICAL LESIONS.

BY F. E. BUNTS, M.D.,
OF CLEVELAND, OHIO.

CASE I.—J. W. C., aged thirty-six years, a member of Battery A, First Ohio Volunteer Artillery. In 1891 he had a severe attack of typhoid fever lasting ten weeks. After his recovery his health remained excellent up to the time of his enlistment at the breaking out of the late war. He was encamped at Camp Thomas, at Chickamauga Park, until August 5, 1898. During this time he was not on the sick-list although he was in poor health from about August 1st. From Camp Thomas he went with his regiment to Camp Bushnell at Columbus, Ohio, arriving there on August 6th, and the next day, August 7th, reported at the hospital suffering from severe headache and fever. The following day his temperature rose to 103° F. and he remained on the sick-list until he reached home on August 9th, when he was obliged to go to bed and was under treatment about three weeks suffering from what was diagnosed by his physician as typhomalarial fever. His convalescence was rapid and in three weeks from the time he went to bed he was up and dressed and a few days later began to attend to his business as a building contractor. No symptoms developed until October 25th, when he noticed a dull pain in his left forearm. This continued slowly to increase in severity, and as swelling began to make its appearance he reported to me on November 9th for treatment for what he considered rheumatism. Believing that the case was one of periostitis following typhoid I put the part at rest and applied hot fomentations. The swelling increased gradually until November 16th, the pain remaining severe. On this date, under cocain, I made an incision into the forearm down to the radius, expecting to evacuate pus. I did not succeed in getting any, and feeling positive that it must be present, either subperiosteally or within the bone, I sent him to the hospital, and the next morning upon operating found the pus located about three-quarters of an inch from my point of entrance and evidently of subperiosteal origin. The bone was found denuded of periosteum and bathed in pus. It was considerably roughened, yet no evidence of osteomyelitis was present. The abscess was evacuated, the roughened bone chiseled and curetted, and the abscess-cavity cleaned of necrotic shreds of tissue,

[1] *Loc. cit.*

packed with gauze, and closed with a few sutures. The subsequent history showed nothing of interest, repair taking place promptly without further suppuration. A microscopic and bacteriologic examination of the pus made in the Pathological Laboratory of the Western Reserve Medical College, by Dr. W. T. Howard, showed it to contain an almost pure culture of the typhoid bacillus.

Case II.—W. C., aged thirty-eight years, private in B Troop, First Ohio Volunteer Cavalry, was taken sick with typhoid and admitted to the Regimental Hospital, at Lakeland, Fla., August 12, 1898. He had never previously had an attack of typhoid fever. The fever pursued a moderately severe course and on September 15th he was sent home to Ohio on sick furlough. On his arrival at home he was practically confined to his bed until October 12th. On the 13th of October he was suddenly attacked by a severe chill and great prostration. He was immediately sent to the hospital and was confined to his bed for several weeks with what was diagnosed by his attending physicians as a relapse of the typhoid. On September 29th, fourteen days after his discharge from the hospital at Lakeland he noticed a swelling in the left testicle. The pain was moderately severe, increasing as the swelling increased, and at the time of his admission to the hospital in Cleveland he suffered considerable pain, which, however, was relieved by rest, elevation, and hot applications. The relapse was severe and his condition most critical. However, convalescence eventually ensued, but the orchitis remained. No history of gonorrheal or syphilitic infection could be elicited and the orchitis was diagnosed to be a sequel of typhoid fever.

Strapping was resorted to in the hopes of reducing the swelling but was abandoned at the end of a week, no improvement having taken place. After this symptoms of softening and breaking down of the organ became manifest and it was decided to remove the testicle. This was done November 16, 1898, the only item of interest connected with the operation being that the pulse-rate during the entire operation ranged from 160 to 180, ether being the anesthetic given. The testicle was found entirely disorganized and a considerable amount of pus was also present. The specimen was sent to the Pathological Laboratory of the Western Reserve Medical College and examined by Dr. Howard, who reported that it contained a practically pure culture of the typhoid bacillus.

Case III.—T. F., aged twenty-eight years, a laborer. Patient first entered the Erie County Hospital March 22, 1897, suffering from typhoid fever. The history regarding the onset of the bone-lesion is not very accurate except that the leg had been painful and swollen for some time. The first operation for diseased bone was performed on the right tibia June 1, 1897. On July 7th a second operation was performed, and on July 28th when he entered the Charity Hospital he had two fistulous openings over the anterior aspect of the right tibia at about the junction of the lower and middle third. He was operated upon August 2d and a detached fragment one and one-half inches long of necrosed bone removed. The surrounding bone was thoroughly chiseled and curetted to remove diseased portions, but the marrow of the bone was not found to be in any way involved, the disease being apparently an ostitis following periostitis. No bacteriologic examination was made. The patient did not give a history of any injury which might have induced periostitis.

These three cases are illustrative of the fact that post-typhoid lesions occur not infrequently in adults, that the length of time intervening between the onset of the original disease and the full development of the subsequent surgical lesion is often very considerable, and that it is therefore incumbent upon the medical adviser to caution his patient about these possibilities and against unnecessary or undue exposure to injury. While in none of the three cases here reported was there a history of an injury, yet it is not improbable that a slight or neglected injury might have been the determining factor in the local activity of the typhoid bacillus and the development of suppuration.

The ages of these patients were respectively thirty-six years, thirty-eight years, and twenty-eight years, and the periods of development of pronounced symptoms, dating from the beginning of typhoid fever were 79 days, 48 days, and approximately 57 days. Of course these figures are inexact but they are sufficiently accurate to show at what a late date the typhoid bacillus is still present and sufficiently active to determine, upon very slight provocation, a suppurative lesion.

MEDICAL PROGRESS.

Differential Diagnosis between Syphilis in the Throat and Diphtheria.—Somers (*Phila. Med. Jour.*, January 28, 1899) says that in syphilis of the pharynx simulating diphtheria the temperature is not as high, the patches on the pharynx and tonsil are not as elevated, the adjacent tissues are not so violently inflamed and there is usually some concomitant symptom such as the dermal eruption. In a number of cases of diphtheria there is a somewhat symmetric arrangement of the membrane; but this is more marked in syphilis, and the "Dutch-garden" symmetry of syphilitic ulcers is rarely simulated. The crucial test is the presence of the diphtheria bacillus, but the history of the case, and the amount of acute constitutional symptoms together with the course of the disease, must be taken into account.

Poisoning by Camphor.—Berkholz (*Petersburger Med. Wochenschr.*, No. 51, 1898) describes the case of a young woman who took about 15 grams (one-half ounce) of camphor suspended in water, probably in order to produce an abortion. There was no immediate effect, but two hours later a violent headache developed, with vomiting, convulsions and later coma. The pulse was full and strong, and respiration rapid. Excitement increased until the patient became unconscious. The stomach was washed out several times and chloral and bromid were administered. After several days' illness she entirely recovered. The fatal dose of camphor is 2.5 to 7 grams (half a dram to a dram and a half) and the writer attributed the recovery of his patient to the fact that she had eaten a hearty dinner composed largely of hydrocarbons, a

short time after taking the poison. By this means there was formed in the intestine glyco-camphoric acid which is not poisonous. He recommends in an overdose of camphor, therefore, that the patient be given large doses of sugar as an antidote.

The Secret of Longevity.—A writer in the *Lancet*, January 21, 1899, says that no one has come nearer than George Humphrey to an accurate conception of the secret of longevity. The total number of aged persons whose life-history was examined by him was close on 1000, 74 of whom were centenarians. The conclusions arrived at by him were briefly these: (1) That the primary factor in a long life consists in an inherited durability; the vital machinery is wound up to go for a given period and but for accidents or in spite of them it will go till the time appointed. (2) That an important part of the primary inheritance is good digestive and nutritive power. (3) That temperance is necessary in the use of the nutritive functions both in eating and in drinking and in regard to all kinds of food and drink. (4) That an energetic temperament and active habits conduce to longevity.

Inoculation against the Plague.—A correspondent of the *Lancet* recently wrote regarding the plague in a town called Gaday as follows: "Inoculation seems to be proceeding merrily enough, and the inoculating officer who is one of the English special plague medical officers is much occupied, 500, 600 or even 700 people being often inoculated in one day. To see the crowds waiting and struggling to pass the barrier is a strange sight. Old men and women, young children, and mothers with babes in their arms form a daily crowd numbered by hundreds who wait for hours to get their chance of the day's inoculation and many go away disappointed after the doctor and staff have been fairly tired out. The example of Hubli has apparently given the people confidence and they are now eager to bring their 2 annas to go through the operation. It is unfortunate, however, to find that many of the inoculated get plague—even those who have been inoculated twice—and several of them have died. Many cases of suppuration have also followed inoculation notwithstanding that great care is exercised in all the details of the operation. That it affords protection has now been proved, and it has been observed that plague patients who have been previously inoculated are not so subject to delirium and mental obfuscation, nor do the buboes develop so readily or so frequently go on to softening. The fever generally is not so severe and the type of the disease is less virulent. In uninoculated cases the disease continues with unabated intensity."

Typhoid Fever in Infancy.—MORSE and THAYER (*Boston Med. and Surg. Jour.*, January 12, 1899) wished to learn whether typhoid fever in infancy is more common than is ordinarily supposed. The mildness of the symptoms, and their resemblance to those of the ordinary gastro-intestinal disturbances of infancy might account for its not being recognized. They applied Widal's test in the case of 50 babies under two years of age, with the following clinical diagnosis: simple diarrhea, 2 cases; fermental diarrhea, 45 cases; ileo-colitis, 3 cases. In only one case was a positive serum reaction obtained, and a test of the blood of the mother of this patient gave a positive serum reaction in fifteen minutes. She had a slow fever ten years before, but had not been ill since. The child had been fed from the fourth month on raw milk and water, and was taken sick when seven months old with greenish diarrhea and vomiting. The treatment began four days after the beginning of the attack, and in nine days the child was entirely well. Under these circumstances it seemed probable that this case was not one of typhoid fever. The authors therefore endorsed the commonly accepted view that typhoid fever is an unusual disease in infancy.

THERAPEUTIC NOTES.

Six Thousand Fractures Treated by Extension.—LOEW (*Bull. gen. de Ther.*, December 23, 1898) says that Bardenhauer was the first surgeon who was able to successfully surmount the difficulties of extension in the treatment of fractures. During the last ten years more than six thousand cases of fracture have been treated in the city hospital of Cologne on the principles he laid down. The theory of the method is to obtain as extensive a surface as possible for the attachment of the adhesive plaster. For example, in a fracture of the tibia, a broad strip of adhesive plaster is placed along the outer side of the leg from a hand's breadth below the knee to the ankle, and continued under the sole of the foot in a loop. It is then carried up the inner side of the leg, as high as on the other side. These side straps are held still more firmly in position by circular ones. A short piece of board is placed in the loop below the sole, and to a cord around this a weight of four to eight pounds is hung to give the required extension. The foot of the bed is elevated eight or twelve inches to keep the patient from slipping. In certain cases strips of plaster and weights are also applied to counteract rotation. At the end of ten days the bandages are changed throughout. The advantages of this method of treatment are that the site of fracture is exposed to view, and contusions can be watched and the dressing changed if necessary; that the fragments of the broken bone are exactly coapted, and false joints are avoided. The results of this method of treatment are marvelous. A short treatment and perfect results are the rule. A false joint is never seen. In ten days the union is often so far advanced that it is possible to remove all apparatus and to place the limb in a simple trough.

A Good Prescription in Case of Tapeworm.—CHAMBERLIN (*Bull. gen. de Therap.*, December 23, 1898) begins the treatment for tapeworm by a dose of castor oil or sulphate of magnesia, and as soon as this remedy has acted upon the bowels, he gives each hour, a teaspoonful of the following mixture:

℞ Spt. chloroformi . . . . . ℥ij
Ess. terebinth. rect. } aa . . ℥j
Ext. filicis ether }
Glycerini . . . . . ℥iv. M.

If the patient is a child a proportionately smaller dose is to be given. Thus for a child of two years the correct prescription would be

℞ Spt. chloroformi
Ess. terebinth. rect. } aa. . . 3 ss
Ext. filicis malis
Glycerini . . . . . 3 iv.

M. Sig. One teaspoonful every hour.

Applications of Eucain in the Esophagus and in the Rectum.—BAYER (*Centralbl. f. Inner. Med.*, January 7, 1899) anesthetizes the pharynx and upper portion of the esophagus with a 3-per-cent. solution of eucain before passing the esophageal tube. In two minutes the parts are absolutely insensible. In cases of carcinoma in which the act of swallowing even of fluids is well nigh impossible an application of eucain will enable the patient to swallow even solid food without difficulty. The eucain in such a case is applied by means of a syringe, and the patient easily learns to make the application. There is no danger from poisoning. Applied in the same strength on cotton eucain is the best agent for preparing the rectum for dilatation or the introduction of instruments, removing absolutely all pain. For obstinate tenesmus in connection with carcinoma the injection of 10 to 30 drops of the same solution has proved most satisfactory. There follows a feeling of comfort in the lowest section of the bowel which lasts sometimes for hours.

Applications of Guaiacol for Serous Pleurisy.—PROZOROVSKY (*La Presse Med.*, January 4, 1899) treated eleven patients suffering from serous pleurisy by painting the skin overlying the lesion twice daily with a mixture of guaiacol and tincture of iodin, 1 part to 4. The skin was then covered with an impermeable substance, and the patient was given either codein or Dover's powder. In every case the absorption of the exudate was more rapid than could have been expected from any other method of treatment. There was no constitutional disturbance and no cutaneous irritation unless it was found necessary to make more than six or seven applications. Five or six were usually sufficient to cause the complete disappearance of the fluid. There was a fall in temperature after each application, followed by a rise, so that the crest of the thermic curve came out two hours later. The author believes that guaiacol acts in two ways: by means of the cutaneous nerves it affects the thermic and vasomotor centers and so promotes absorption. By combining with morbid products circulating in the blood it keeps them from acting injuriously upon the pleura.

Efficacy of Guaiacol in Acute Epididymitis.—PERRY (*Medical Record*, January 7, 1899) reports twenty cases of acute epididymitis treated with guaiacol with success. He paints the pure guaiacol over the cord in the inguinal canal, and a mixture of one part of guaiacol and two parts of glycerin over the cord and epididymis in the scrotum. Pain is relieved in a few minutes, but returns in six or eight hours with less severity. On the first day, therefore, two or three applications may be necessary; afterward for four or five days one or two only. Most cases can be cured in four or six days, and some, if seen early, may be aborted. Most of the patients treated by him were gonorrheal. In some instances the pain which had existed in such a severe form for several days as to prevent sleep was so quickly removed that in an hour the patient was sleeping soundly. In a few cases the treatment was followed by that of oleate of mercury to facilitate the absorption of the exudate.

Care of an Infant's Teeth.—CARRIERE (*Rev. de Therap. Med.*, January 1, 1899) insists on the importance of looking after the teeth from the time a child is born. The mouth should be wiped out with cotton wet with Vichy-water after each nursing. The gums should be rubbed with the finger wet in the following solution in order to prevent pruritus and to relieve the pain of dentition:

℞ Cocain . . . . . gr. ij
Saccharin . . . . gr. j
Glycerin . . . . oz. j
Tinct. vanillæ . . . gtt. xxx.

If the child is much irritated by the eruption of the teeth 5 grains of bromid may be given in the morning, and at night an injection containing 4 grains of chloral and 5 drops each of tincture of valerian and tincture of musk.

The first teeth are very apt to decay about the third year. To prevent this the mouth should be cleaned in the morning with a little soap in order to counteract the acids of the food and of fermentation. At this age the teeth should be regularly brushed with a soft brush dipped in an antiseptic solution. People often think it is useless to have the milk teeth filled; but this is a mistake for the early loss of a first tooth produces in its place a scar tissue so that the second tooth has more difficulty in breaking through. This is the commonest cause of the deviation of the second teeth.

For Sycosis Barbæ.—Treatment by galvanocautery is advised for severe cases by BLOCBAUM. The needle is inserted from $\frac{1}{12}$ to $\frac{1}{9}$ of an inch into the pus-containing follicles, and the current then turned on. The needle is pulled out while red hot. About 60 follicles are thus treated at a sitting, ice-compresses then being applied for two hours, and the parts finally powdered with the following:

℞ Zinci oxidi
Ac. borici } aa . . . . parts i
Talci . . . . . parts ii.

M. Sig. External use.

In the morning the parts are washed with soap and water, dried with gauze, and repowdered. Treatment is given daily until all the affected follicles cicatrize. When the scabs come off, daily shaving is advised, also friction to detach loose hairs and empty the gland tubules.

The pain of this method only slightly exceeds that of epilation, and if necessary local anesthesia can be resorted to.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE WHEAT PROBLEM ONCE MORE.

WHEN Sir William Crookes, the president of the British Association for the Advancement of Science, saw fit in his presidential address, before that distinguished scientific body last summer, to refer to the possibility of there not being enough wheat to go around for the next generation, his declaration naturally attracted a great deal of attention. American commentators on the subject generally scoffed at the idea of a paucity of wheat so soon in the world's history. More than one of our medical contemporaries took pains to demonstrate to their readers that the idea was preposterous. Some of the most amusingly exaggerated claims were made and extensively copied as to the wheat-bearing capacity of our great West. Among others, for instance, that the State of Idaho alone could supply, if there was a demand for it at good prices, 400,000,000 bushels of wheat.

The statistician of the United States Department of Agriculture reviews the discussion in the current number of the *North American Review*, and gives what he considers conservative figures in the matter. All the acreage available for wheat in the United States, including land that may under the stimulus of better prices be reclaimed from aridity by irrigation, will not suffice in 1931 to supply the demands of even our own estimated population at that time, 130,000,000. The United States are at present the greatest exporters of wheat in the world, but in thirty-two years, *i. e.*, in the next generation there will be a deficiency of 50,000,000 of acres of the land necessary to supply our own population with wheat.

It may not be amiss then to bear in mind Sir William Crookes' prophecy that we shall have to learn in the very near future to consume more leguminous products in order to obtain our supply of nitrogenous material, and to unlearn certain present-day wasteful methods in the use and preparation of wheat-food products as well as certain unscientific methods in the cultivation of the cereal.

NEO-MALTHUSIANISM AND THE DOCTORS.

UNDER the above title Doctor Minime discusses in the *Journal de médicine de Paris* the continued diminution in the birth-rate of France. In 1897 there were 859,107 births, a decrease of 6479 from the preceding year, when the total was also disquieting to the statisticians. This total is the smallest ever recorded in that country since the beginning of the century, except in 1871, and during the epidemic of the grip. Fourier says the decrease is due to syphilis, Lancereaux to alcoholism, Roussel to neglect of young infants, but the writer of the article alluded to says, it is because the French are "past masters in the art of *coitus frustratus*, or *moucher la chandelle*."

The new Malthusian religion long adopted by the Faubourg Saint-Germain, is gradually numbering its converts among the bourgeoises, the Faubourg Saint-Antoine and even the rural districts. "It would ill become the physicians," says Doctor Minime, "to make an outcry against restrictive practices. A Malthusian has had the patience to conduct an inquest upon the Parisian medical body; do you know how many children he finds per family? *One and a quarter!*" In defense of this position he goes on to say:

I may cite myself as an example. I am in fact only a demi-Malthusian for I have three children. It goes without saying that I would have had twenty if I had not followed restrictive measures which the church condemns. For ten years I occupied an

apartment which cost four thousand francs a year. Now that the children are large and can no longer sleep in the drawers of a commode, I have to give to each of them a chamber and the rent of the apartment has grown to eight thousand francs.

But that is not all. Under the fallacious pretext that I have children the government doubled my taxes so that they are now 1600 francs a year. It is necessary to add to these figures 5600 francs for the care and the education of the children. Is that not a condition which would justify the most extreme Malthusianism? Of course one loves his country and is ready to die for her, but not to die—of hunger.

Oh, legislators, my friends; you especially, numerous physicians and surgeons, who sit in our parliaments(you are more than one hundred) study this question and do not increase our taxes in a direct ratio to the number of our children. The question is simple enough. He who has no children should pay more than he who has one. Let the unmarried man who has his sexual pleasure at the expense of the community, who takes our women and covers France with bastards at the expense of society bear the heavier burden. If he is to be tolerated, let him at least pay the double tax.

MALARIA AND TYPHOID.

In a recent issue a medical correspondent in Philadelphia attempted to blunt the edge of certain remarks of ours with regard to the awful condition of that city, anent, the typhoid epidemic there, by quoting the statistics for malaria and typhoid in New York and Brooklyn during the six years preceding 1890. Our medical correspondent, although manipulating statistics for the benefit of Philadelphia's showing disclaimed any idea of defending Philadelphia, and yet there seemed to be no other motive. In publishing his letter we absolutely refused to be diverted from the important point at issue, *viz.:* the mortality of typhoid *now* in Philadelphia. And without disclosing our correspondent's name, as he did not seem to wish it, we stated forcibly our opinion of medical defenders of Philadelphia in the matter of typhoid. Unfortunately for our correspondent his haste to have the defence of his town, or at least something that would divert attention from the present alarming condition there, published, led him to send his letter to a Philadelphia medical journal. Even that editor found his statistics too ancient and so they were brought down to something more than three years from date.

Our Philadelphia contemporary now thinks that the objection raised deserves a serious answer. That answer was given when we absolutely refused to entertain the idea of wiping out all malaria mortality in New York and Brooklyn in order to add it to the typhoid column, so that Philadelphia's typhoid statistics might not seem so *very* bad. This manipulation by our correspondent was an unwarranted trifling with statistics and deserved the severest condemnation. Statistics cease to have any meaning if altered in this wholesale fashion on a mere assumption.

Either the malaria reported by the New York and Brooklyn physicians was malaria or the profession of those cities must consider themselves accused by our correspondent of inability on a wholesale scale to diagnose malaria or else wilfully to have entered into a conspiracy (perhaps for the sole purpose of injuring Philadelphia) to criminally suppress facts.

That the malaria mortality for the two cities should be much greater than that of Philadelphia is not surprising. New York undoubtedly has endemic malaria in the low-lying lands along the Harlem and near both rivers, the East and North. New York always contains a large contingent of New Jersey's population and has perennially a numerous resident Southern colony. As the great entrepot of the country it always contains a large number of people from tropical countries besides a small army of sailors. Brooklyn has the questionable advantage of being situated on Long Island. Need we say more to obtain for it the privilege of a respectable mortality from malaria?

Now as to the statistics of the next six years from 1890 to 1896: The New York mortality from malaria drops from 24.62 to 7.87, but the mortality from typhoid does not ascend proportionately but drops from 24.27 to 19.72. In Brooklyn there has been a still greater fall in the mortality from typhoid despite a very large reduction in the malarial mortality. The mortality from malaria remains high but that is due to endemic malaria in a number of low lying districts. We doubt if any more mistakes of diagnosis as between malaria and typhoid are made in Brooklyn than even in Philadelphia.

All these considerations are elementary. They are obvious to any one who knows anything of the situation. It is to be expected that medical men and especially medical editors shall know something of such matters before writing about them and that

they shall not ignore them in order to malign, for obvious personal motives, a large body of professional brethren by the assumption that many of them frequently and persistently mistake typhoid fever for malaria.

But this is only "by the way." We are sincerely interested in seeing something done to reduce the awful mortality from typhoid fever in Philadelphia. More than 400 deaths in less than twelve weeks! Here is what should occupy the attention of physicians and medical journals in Philadelphia, not considerations and discussions calculated to divert the attention from these gruesome figures. Our first editorial on the subject was not meant to smirch Philadelphia's fair name, the Lord knows that is impossible in the matter of typhoid, but to arouse, if possible, lethargic burghers to a sense of civic duty. We have some evidence that it hurt. That was its intent. Meantime we await with impatience the opportunity to announce that something, *any thing* is being done to remedy the present dreadful state of affairs.

THE BACTERIOLGY OF DRINKING-WATER.

WE publish this week an abstract of Dr. Edward R. Dunham's paper on this subject read before the Harvard Medical Society of this city. The subject, it is needless to say, is an extremely important one, and, unfortunately, one with which, despite long years of most arduous and faithful work, bacteriologists have been able to accomplish very little that is of practical value. We have always seemed on the point of having some sure and definite bacteriologic data for judging as to the potability of a given water when new observations have shown their inconclusiveness. At present bacteriology practically assists very little our efforts to decide whether ordinary water is safe for drinking purposes or not. A good many bacteriologic examinations of Philadelphia water have been made in these last few years and yet we believe no definite conclusion as to the contamination of the water has been reached. That typhoid bacilli have been in the water-supply of that city most of the time during these years, a simple reference to the health statistics of the city will show. The fault, however, lies not with the observers but with the present inadequate bacteriologic methods.

Most of the data considered of value now in judging of drinking-water comes from chemistry. As was remarked in the discussion of Dr. Dunham's paper, a slight increase in the nitrites present in Croton water sends a spasm of anxiety through the authorities of the health department. This determination of the amount of organic matter present is the best criterion of the potability of water that sanitary science can at present give us. How liable to error it is, however, may be judged from a fact reported not long ago from England. A sample of reasonably good water was deliberately sown with typhoid bacilli and sent for examination to a well-known chemist of great experience in the examination of water for sanitary purposes. He pronounced it wholesome and safely potable at a time when a control sample of the same water was demonstrated to contain virulent typhoid bacilli.

In this dubious state of sanitary science with regard to drinking-water we welcome cordially Dr. Dunham's contribution to the subject. We consider that the conclusions he has reached by his investigations are the result of original work of a high order and that some of the methods he suggests will prove of great service in regaining once more for bacteriology the place it should hold as the mistress of sanitary science, especially in the department of drinking-water. The scheme of following the water in its cycle from the time it rises as vapor till it flows back to the sea and showing the sources and kinds of contamination it is liable to, with the modes of their determination, breathes a true scientific spirit. The methods of detecting the presence of colon bacilli and putrefactive bacteria deserve thorough practical trial for they seem to furnish the reliable delicate tests of the presence of sewage contamination which our present coarser chemical methods almost entirely miss. The work on the subject has been excellently done and the details have been elaborated with a patience that is worthy of the highest commendation.

EPITHELIAL REGENERATION, EPITHELIAL OVERGROWTH AND CANCER.

ONE day last year Professor Virchow asked some Americans who were working in his laboratory in the Pathological Institute at the Charité, Berlin, if they knew anything of Leo Loeb who was working somewhere in America on pathology and histology.

They confessed that they did not know. Virchow said that some of Loeb's recent work on epithelium was the best that had been done on that subject for many years, and that as a consequence he wanted to know more of the man. We are glad to note, therefore, that Loeb's work is beginning to attract here in America some of the attention that it evidently deserves. In the advance sheets of *Progressive Medicine*, the new quarterly review of medical progress, edited by Professor Hare, we find in the section on pathology an abstract of the article on "The Regeneration of Epithelium," which appeared in *Roux's Archiv f. Entwickelungsmechanik*, and which attracted Virchow's attention. This periodical is seldom abstracted in American medical journals and this is the first notice that we have seen of the work on this side the water. We think it worth while then to give some of the points of special interest.

Epithelium, in regeneration, develops certain histoclastic properties; that is, it removes tissues of a lower order that hinder its progress. From the margins of a tissue defect in the process of cicatrization, epithelial protoplasmic, or plasmodial, processes move in a sliding manner over the naked surface, enclosing and dissolving the crust and other obstacles. Regenerating epithelium readily removes even such substances as cartilage when it comes in its way. Below the protoplasmic layer, epithelial cells wander in from the margins of the defect and often grow down into the connective tissue, apparently checking the growth of the latter. The process is closely allied to that in carcinoma. At the same time active changes, such as mitoses, occur in the epithelial cells situated even at a distance from the margin of the wound. When the advancing epithelium meets obstacles, such as hair-follicles, cysts may form by fusion of cells around the object.

Loeb believes that the wandering of the cells as he has observed and described it is in response to sterectofusion, and that the active influence of particles of solid tissue on each other forms a determining factor in inducing mitoses in neighboring cells. If a minute portion of epithelium be transplanted to the center of the crust covering a skin defect, it begins to send out processes in all directions into the crust, the cells acting as separate organisms independent of blood-supply or nervous influences.

It is easy to see how important to the student of the etiology of carcinoma such observations are The essential vitality and reproductive activity of regenerating epithelium, with its germinal influence on surrounding cells, represent the awful biologic forces that run riot in the tissues in that segregation of epithelial cells we call cancer. The study of the conditions under which these forces are brought into play brings us nearer to the explanation of the origin of malignant neoplastic tissue. We have had for a number of years a new parasite described each year as the cause of cancer. We have had it of all forms, the simple ferment, the bacterium, the protozoon. Perhaps now we shall get a little nearer the explanation of the mystery, that has remained just as much a mystery despite all the parasitological work done upon it. These careful studies into the biology and pathology of the epithelial cells themselves will awaken new interest in a line of work that has been more or less neglected in recent years because parasitology seemed to present such an inviting field for successful work in etiology.

ECHOES AND NEWS.

The International Association of Railway Surgeons.—The next annual meeting of the Association will be held at Richmond, Va., May 31 and June 1 and 2, 1899. The secretary is Dr. Louis J. Mitchell of Chicago.

Typhoid Fever in Newark, N. J.—There were on March 18th, 105 cases of typhoid fever in Newark, N. J., the largest number ever recorded. The cases have nearly all been traced to the use of polluted Passaic River water.

A Woman Physician's Suicide.—Dr. Amelia C. Perry, sixty years of age, a woman physician very well known in and about her home at Hornellsville, New York, committed suicide by shooting herself near the heart on March 16th.

Smallpox in the South.—In North Carolina smallpox is rapidly assuming the proportions of an epidemic. Compulsory vaccination has been ordered in various places. At Greensborough failure to comply with the ordinance subjects the offender to a fine of $20.

To Bring Back Soldiers' Bodies.—The transport "Roumania" left Santiago on March 23d with 500 bodies of soldiers who have died in Cuba and Puerto Rico. She will arrive in New York about March 28th. In all there are 1900 bodies which the "Roumania" will bring to this country. The bodies upon arrival will be interred in Arlington Cemetery, Washington, unless otherwise requested by friends.

Dr. Skene's New Position.—Dr. A. J. C. Skene of Brooklyn has accepted the presidency of a proposed institution, to be called the Hospital for Breadwinners, which will be built for the accommodation of self-supporting women who are overtaken by ill health. Dr. Skene has been officially connected with the Long Island College Hospital for more than thirty years, and has just resigned the presidency of that institution.

Is There a Sense of Taste?—According to some experiments which have been made at the University of Iowa, sensations of taste seem really to be combinations of reports to the brain made by the nerves of sight, smell, and touch. For instance, few among a large number of persons upon whom tests were made could distinguish, when their eyes were covered and their noses closed, between weak solutions of tea, coffee, and quinin.

Physicians Forbidden to Testify.—On March 13th Governor Roosevelt signed an amendment to the civil code which had passed both houses at Albany. This amendment absolutely prohibits a physician from divulging any information he may have acquired in his professional capacity concerning any patient, either before or after the latter's death. For a long time the insurance law has permitted a physician to testify concerning the physical condition of a policy-holder.

Was It a Phantom Tumor.—The *Trained Nurse* for March, 1899, relates that a woman was recently taken to the Seney Hospital, Brooklyn, suffering from what appeared to be an abdominal tumor. The surgeons examined her and fixed upon a day for operating. Just before the time set the woman arose, dressed herself and walked out of the hospital. She had been "cured" by fright. If she had got into the clutches of a Christian Scientist, another "miracle" might have been reported.

Death Ends a Honeymoon.—On February 21st Dr. William Waldo Van Arsdale of New York City, while ill in bed with an acute attack of grip, married Miss Edith May White, a daughter of Dr. and Mrs. Whitman V. White. The doctor grew better and went with Mrs. Van Arsdale to Atlantic City wnere he suffered a relapse and died on March 17th. Dr. Van Arsdale was Chairman of the Surgical Section of the New York Academy of Medicine, Professor of Surgery in the New York Polyclinic, and Assistant Visiting Surgeon to the Mount Sinai Hospital.

New York City Board of Health and the Manufacture of Serum Antitoxins.—The Medical Board of the New York Foundling Hospital and the Medical Board of the Presbyterian Hospital of New York City have adopted resolutions deprecating the passage of the bill now before the Legislature restricting the New York City Board of Health in its manufacture of serum antitoxins, declaring that the passage of the bill would materially injure the interests of the community, and that any curtailment of the present facilities of the Health Department would react against the public good.

The Approaching Meeting of the American Medical Association.—Arrangements for the meeting of the Association at Columbus in June are rapidly approaching completion. The Grand Opera House which has a seating capacity for 1700 people has been secured for the general meetings and thirteen halls have been provided for those of the different sections. The hotel people are said to be lending generous assistance and give assurance that they can accommodate more than 2000 guests. The section dinners have all been arranged for and plans for general and private entertainments are well under way.

New Building for the Paris Academy of Medicine.—The Academy of Medicine of Paris has accepted the plans for its new home and work is about to be begun. Its old quarters were cramped and utterly unsuitable; the new building is to be palatial in size, architecture, and internal finish. It is hoped that part of it will be ready for occupancy before the International Medical Congress in August of next year. The architect is the well-known M. Rochet, and competent critics who have seen the plans pronounce them magnificent and unite in declaring that the new building will be one of the handsomest in Paris.

To Study Diseases in the Philippines.—The Johns Hopkins University is about to send Dr. Simon Flexner, Professor of Pathological Anatomy and Resident Pathologist of the Johns Hopkins Hospital, to Manila, in order that he may make a clinical and pathological study of diseases prevalent in the tropics. Two medical students, Messrs. Joseph M. Flint of Chicago and Frederick P. Gay of Boston, will go as assistants. The party will sail from Vancouver on March 27th and will return early in the fall. They will take with them the best modern instruments and appliances for the proposed investigation.

Spitting on the Floor of Public Conveyances.—The recent propaganda of ideas as to the prophylaxis of tuberculosis has led to a somewhat better enforcement on the part of street-car employees of the rules as to spitting on the floors of street-cars. The notice posted conspicuously in the electric cars of Scranton, Pa., commends itself by containing in condensed form the morally suasive motives that would prompt would-be violators to restrain themselves and repress their expectoration. It reads as follows: Spitting on the floor of street-cars and other public conveyances is strictly prohibited. By order of the Board of Health. Gentlemen will comply with this reasonable order which is in the interest of public health. Conductors are instructed to eject from the car any person refusing to comply with this order.

Christian Science Interferes.—The wife of Colonel Charles C. Rivers of Chelsea, Mass., on March 9th was stricken with paralysis. Dr. Hawes, who was called in, prescribed and gave a favorable prognosis. Mrs. Rivers was a Christian Scientist, and after the physician's visit, some of these "peculiar people" were called in to attend her. It is alleged that they discontinued the medical treatment, upon which the patient rapidly grew worse. Dr. Hawes was again called, but the case was then beyond medical control and the patient died on March 11th. The physi-

cian refused to sign a death-certificate, and a medical-examiner who had to be called upon, gave the cause of death as "neglect." The case has been submitted to the District Attorney, and a trial in the Massachusetts courts is likely to result to determine the legal standing of practitioners of Christian Science.

Health of Our Troops in the Philippines.—Lieutenant-Colonel Henry Lippincott, chief surgeon at Manila has forwarded to Surgeon-General Sternberg a report concerning health conditions in the Philippines. In this report it is stated that a convalescent hospital has been established at Corregidor Island, the capacity of which can be increased to accommodate 400 patients. The island is at the entrance to Manila Bay, where there is refreshing sea air and less excessive heat and an absence of the naturally unhealthy conditions surrounding Manila. The health of the commands continues fairly good. There is a marked decrease in the number of typhoid and malaria cases; complaints from dysentery remain about the same. Smallpox prevails to a considerable, but not to an alarming, extent. The entire command has been vaccinated four times since the appearance of the disease.

The Presidency of the New York City Board of Health.—An effort is again being made before the New York State Legislature to amend the law which prevents a member of the medical profession from being elevated to the position of president of the New York City Board of Health. No satisfactory reason has ever been presented as to why this restriction should have been made. It is certainly recognized that many medical men in New York City are not, to say the least, inferior in executive ability to the representative men in other walks of life. The education and training of the medical man eminently qualifies him for the position of President of the Board. The medical profession should unite in a demand that this restricting clause be repealed and individual members should write to their representatives in the Legislature demanding their support in the passage of the desired amendment.

International Congress of Medical Ethics.—Among the other congresses to be held in Paris in 1900 in connection with the Thirteenth International Medical Congress will be one under the title of the "International Congress of Medical Ethics." The members of the organizing committee include some of the most prominent medical men in France: Professor Brouardel who was re-elected Dean of the Medical School of the University of Paris, Professor Cornil who is a member of the French Senate, Professor Gariel, and others. Those who desire information as to the proposed proceedings of the Congress and its purposes should address all communications to M. le Dr. Léreboullet, President of the Committee, 44 rue de Lille, Paris, or M. le Dr. Jules Glover, Secretary General, 37 Faubourg Poissoniére, Paris. Further information as to the purposes of the Congress and the questions proposed for discussion are to be made public in the near future.

Canned Food in the French Army.—According to the *Army and Navy Journal* a number of men of the Eighty-second Infantry at Sens were recently seized with vomiting and diarrhea of exceptional gravity of whom twenty were sent to the hospital and one or more died. An inquiry showed that the attack was due to the consumption of preserved food of defective quality. At Havre twenty thousand cans of preserved meat which had been for some time in the stores were opened, and though their contents were undoubtedly wholesome they were thrown into the sea. The *Army and Navy Journal* observes that the French authorities are obviously not up to date. They should have roundly abused every one who ventured to suggest that the canned meat made them sick. The conclusion having been reached that meat preserved in cans should not be kept too long, orders have been issued by the French Government that all canned food bearing the date of 1893 and 1894 and all salt pork dating from years previous to 1898 shall be destroyed.

No Yellow Fever in Louisiana.—The people of Louisiana are congratulating themselves on the prospect of escape from any recrudescence of yellow fever in that portion of the South during the coming summer. In this flattering prospect they see compensation for the discomfort of the low temperature from which they have suffered during the past few months. The thermometer in certain localities has dropped as low as twenty-five degrees below freezing-point. If yellow fever appears within the limits of the State, therefore, the quarantine authorities will have some difficulty in making a satisfactory explanation to the people. We note in the daily press in this connection the deplorable fact that President Edmund Souchon of the State Board of Health and Dr. Quitman Kohnke of the City Board have been indicted for alleged manslaughter in a little town known as East Felinicia for having been the indirect cause of a death in the parish through the introduction of yellow fever from New Orleans as they failed to inform the county parishes of the existence of the disease in that city.

The American Congress of Special Societies.—This Congress will be convened at Washington, D. C., on the second Tuesday in May, 1900. The Executive Committee, composed of one delegate from each one of the fourteen participating societies, at the invitation of its President, Dr. Landon Carter Gray, held its annual meeting at the Union Club, New York, on March 18th. All the members were present. As this committee has the power of self-organization it exercised it in the re-election of Dr. Landon Carter Gray as president and Dr. William K. Simpson of New York City as secretary. The committee also elected officers for the next Congress as follows: President, Dr. H. J. Bowdich of Boston; secretary, Dr. W. H. Carmalt of New Haven; treasurer, Dr. N. M. Shaffer of New York. The committee decided to limit the next meeeting of the Congress to three days instead of four. Two of the afternoons will be occupied by the Congress in general conclave. The first evening will be left open for the individual meetings of the participating societies. The second evening will be devoted to the President's address and reception, and the evening

of the third day to a general banquet. Dr. A. Jacobi of New York and Dr. W. H. Welch of Baltimore were added to the Committee of Arrangements.

CORRESPONDENCE.

TYPHOID FEVER IN PHILADELPHIA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I am glad to see that you hold your slippery Philadelphia critic to the point at issue, namely, that Philadelphia drinks water defiled with sewage, and in consequence sickens and dies from typhoid.

A few years ago the city of Munich was in the same rotten state. A loud, popular outcry, in which the physicians not only of the rest of Germany, but of Munich itself joined, at last stirred the authorities to furnish a pure drinking-water in the city pipes. Notice the comparative result in typhoid fever as shown by the official returns of the two cities for the current year:

	Munich.		Philadelphia.	
	New cases.	Deaths.	New cases.	Deaths.
Week ending Jan. 21...	2	0	320	31
" " " 28...	4	0	427	40
" " Feb. 4 ..	2	0	361	38
" " " 11...	3	0	339	41
" " " 18...	2	0	287	38
Total for 5 weeks.....	13	0	1734	188

Munich has 450,000 inhabitants; Philadelphia has 1,300,000, not quite three times as many. In Munich for this period the average number of new cases a week was 2.6, or 5.7 per million inhabitants. In Philadelphia for the same period the average number of new cases a week was 347 or 268 per million inhabitants. In other words, typhoid fever is just 47 times as prevalent in Philadelphia as in Munich. The death-rate in the same period was as 188 to 0.

A CONSTANT READER.

NEW YORK, March 18, 1899.

THE WHITE VERSUS THE YOLK OF EGG AS A FOOD.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—"Eggs make me bilious," is the familiar reply that so often comes to us when we advise the taking of raw eggs. We usually then rack our brains for other suggestions as to easily taken foods, by which we can increase our patient's alimentation. The reason for this "biliousness" I have long explained to myself by a physiological fact not generally known. In many recent works on medicine it is recommended to give patients yolks of eggs to keep up their nourishment, but a little knowledge of physiological chemistry will show I think that it is a mistake to give the yolk preference over the white. Let us take the analysis of the parts:

	NITROGEN.	FATS.	SALTS.	WATER.
White.....	20.4	....	1.0	78
Yolk.....	16	30.7	1.3	52

The nitrogenous parts are egg-albumen and egg-globulin, both easily digested and assimilated. The fatty substance in the yolk is mainly lecithin. It has long been regarded as a physiological fact that this fat—lecithin—in undergoing digestion is converted by the pancreatic juice into glycerin, phosphoric acid, stearic acid, and a poisonous alkaloid called choline. We are protected, however, against this poison by the bacteria in the intestines, which seize on it and convert it into carbonic acid, methane, and ammonia.

Now surely it must happen that these bacteria are not always on duty, or, perhaps, they have more to tackle than they are able to convert, allowing some of this choline to become absorbed, giving rise to this biliousness. I have repeatedly found that a patient made "bilious" by one whole egg can take a dozen raw whites daily without discomfort, and greatly to his advantage. I have many tuberculous patients gaining by the extra strength these whites give when taken between meals. I find an excellent way to take them is to add a little salt, red pepper, and lemon juice to three whites in a glass, but these condiments are not always necessary. Infants will often do well on them when dissolved (not beaten) in water, and a little sugar of milk added; it should be remembered, however, that the egg-globulin does not dissolve in the water, but is precipitated and should be separated by straining.

I often make use of a physiological principle with success with the help of these whites of eggs. I have found that if a weakly patient on waking takes two whites of eggs his appetite on getting down to breakfast is greatly benefited, thereby illustrating Heidenhein's experiment on gastric secretion.

GERALD BERTRAM WEBB, M.D.

COLORADO SPRINGS, COL.,

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

THE TYPHOID-FEVER EPIDEMIC AT LAST AROUSES PUBLIC INDIGNATION—AN ENDOWMENT FOR THE LIBRARY OF THE COLLEGE OF PHYSICIANS — A CASE OF INTRATHORACIC TUMOR—TYPHOID COMPLICATED BY MANIFESTATIONS OF HEMORRHAGIC DIATHESIS — A CASE OF ACUTE THYROIDITIS — A STATUE OF DR. PEPPER—PERSONAL NOTES—DR. FLEXNER CALLED TO THE UNIVERSITY — BOARD OF HEALTH NOTES AND HEALTH STATISTICS.

PHILADELPHIA, March 21, 1896.

A MASS meeting of citizens of Philadelphia was held at the Bourse Saturday evening to protest against the criminal action of our councilmen in delaying the improvement of the water-supply, and incidentally these same unique specimens of manhood were treated to some compliments which would pierce the hide of anything except a Philadelphia councilman. The meeting was remarkable, for not only physicians, ministers, and lawyers of the first rank, were present, but public officials and politicians joined the throng which crowded the Bourse. The meeting was an outgrowth of various ward-meetings held throughout the city last week. In his introduction, Mr. William Waterall, who presided, said: "This is a profound, a serious question, and surely it will lead to a

revolution. Let us deal with it as our New England friends did, and rise up and break up councils." Mr. Charles Richardson said among other things: "We hear that there are capitalists who want our water-works, and that they are in collusion with persons of influence who are keeping the water-works in such bad order that they may break down at any moment. Of all men, if this is true, they deserve hanging most. We want no more murders; what we want done, we want done now." Mr. Herbert Welsh said that Philadelphia has been ravaged for three months by an epidemic of typhoid fever, which all would admit is the direct result of a polluted water-supply. "If we dare speak the truth we must admit it comes through our own folly and wickedness. By years of indifference and by persistence in a course which was perfectly sure to have this sequel we have courted this calamity." Among physicians who spoke were Drs. H. C. Wood, John H. Musser, and W. W. Keen. Dr. Wood said that at the present rate one person in every four of Philadelphia's population will have had typhoid by the end of the year, and he also pointed out the fact that to say cases were reported as typhoid which were not so, is both childish and ignorant, as the mortality statistics show only too well that a poisoned water-supply means disease and death always. Dr. Keen compared Philadelphia to Havana and characterized it as only a half civilized city. He gave the statistics of typhoid fever during ten years in Philadelphia, and said that, "It is barbarous; it is worse, it is murder. An eminent English scientist said that for every case of typhoid fever some one ought to be hung. The only reason why the members of councils are not hung is because there are not enough to go around."

What a commentary on a city of Philadelphia's fame as a center of medical teaching! Run by a gang of political thieves is it any wonder that such frightful figures as *ninety-five new cases* of typhoid fever are reported during one day? What puerile trash are statements attempting to deny or defend the death-rate from typhoid, or to compare the statistics of New York, Boston, or any other city in the United States! The papers are teeming with accounts of the Windsor Hotel fire, and yet the loss of life in that catastrophe is nothing when compared with the number of persons dying from typhoid. The property loss, too, sinks into insignificance when compared with the cost of caring for the 4000 cases which have developed since January 1st, and with the business losses which will certainly follow when our more civilized neighbors will refuse to come to a plague-stricken city.

The College of Physicians is anxious to increase its library, and with this end in view an effort is being made to secure an endowment fund of $50,000, of which $20,000 has already been collected. Until quite recently the library ranked next to that of the Surgeon-General's Office at Washington, but recently that of the New York Academy of Medicine has forged ahead. An interesting fact in regard to the college is that out of a membership of about 300 thirty-one wrote or edited medical books during the past year.

At a meeting of the College of Physicians, held March 13th, Dr. J. M. Miller reported a case of intrathoracic tumor which occurred in a man, aged thirty-eight years, who was presented at the meeting. Pain in the left side of the chest, and pain, dyspnea, and loss of weight, were complained of, and in addition, during the past eight months a tumor had been visible which extended from the second to the fifth rib, and from the left edge of the sternum, to the anterior axillary line. There was no enlargement of any veins, nor of the cervical or axillary glands. The blood examination revealed a moderate lymphocytosis, and it was suggested that the tumor might be a lymphosarcoma, or possibly a chondroma.

Drs. John H. Musser and Joseph Sailer reported a case of typhoid fever, complicated by manifestations of hemorrhagic diathesis, which occurred in a boy of nineteen years, who had hemorrhages in the mouth and nose, and in the subcutaneous and intermuscular tissues all over the body. These hemorrhages occurred early in the course of the typhoid, and the patient having died, the autopsy revealed an ulcer in a Meckel's diverticulum (the second case reported within a week or ten days) and a patulous foramen ovale.

Dr. H. A. Hare reported a case of acute thyroiditis with thyroid poisoning which occurred in a woman after slight injury to the right side of the neck. The right lobe of the thyroid became enlarged, and fever, palpitation, and other symptoms apparently due to the presence of thyroid substance in the general circulation developed. Most cases have terminated in suppuration and death, although Dr. Musser referred to one in which, after suppuration, the patient recovered.

At a meeting of the committee having in charge the preparation of a memorial to the late Dr. William Pepper, held last week, it was decided to erect a bronze statue of Dr. Pepper on the City Hall Plaza, and Drs. J. C. Da Costa, Alfred C. Lambdin, H. C. Wood, and Edward Brooks were appointed on the subcommittee having the matter in charge.

Dr. Spencer Morris, Professor of Medical Jurisprudence in the Medico-Chirurgical College, was stricken with paralysis just as he was about to deliver the last lecture of the term on this subject last week. He is reported to be much improved though he has not yet regained the use of his left leg and arm.

Drs. Charles E. Harvey and P. A. Bayer have been appointed by Governor Stone members of the State Board of Health and Vital Statistics.

Dr. Louis W. Reid, retiring Surgeon-General of this State, was tendered a complimentary dinner at the Union League Club on Saturday night. The dinner was attended by three ex-Governors, during whose administration Dr. Reid had served, and all spoke of the faithful service he had rendered during the thirty years in which he continuously held this office.

Dr. Simon Flexner, Professor of Pathological Anatomy in the Johns Hopkins University, has accepted the position of Professor of Pathology in the University of Pennsylvania, to succeed Dr. John Guiteras, resigned, and will enter upon his new duties on September 1st. He had already declined offers from several medical schools, notably one in New York, and one here in Philadelphia.

The bill passed by the Senate, abolishing the Board of Health and creating a Bureau of Health, may not prove to be any advantage in the methods of caring for the public health. This bureau will be under the same control as is the Bureau of Street Cleaning, which gave such a delightful example of its efficiency during the blizzard when traffic was paralyzed owing to its negligence in removing snow and dirt. It remains to be seen whether the head of this bureau will take advantage of the opportunities offered and give us really good service or whether it will degenerate into a foul politicians' nest like its sister departments.

The total number of deaths occurring in Philadelphia for the week ending March 18th, as reported at the Health Office, was 520, an increase of 36 over those of the corresponding period of last year. Of this number 127 occurred among children under five years of age. The total number of new cases of contagious diseases was 571, reported as follows: Diphtheria, 59 cases, with 9 deaths; scarlet fever 35 cases, with 1 death; *typhoid fever*, **477** *cases, with* **44** *deaths.*

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

JONNESCO'S METHOD—DEVIOUS MANIFESTATIONS OF EPILEPSY—RELATIONS OF THE COLON TO INTRA-ABDOMINAL TUMORS.

CHICAGO, March 21, 1899.

AT a meeting of the Chicago Medical Society, held March 15th, Dr. Carl Beck presented a contribution on the value of resection of the sympathetic ganglia of the neck in the cure of epilepsy, and reported several cases in which he had operated. In reviewing his results, he summed up by saying that the method suggested by Jonnesco, and so highly praised by him and his followers, is hardly of any value, and that the few changes for the better that are observed are either accidental or such as are noticed in almost any case following surgical interference. It will be remembered that it was in 1897 that Jonnesco recommended total extirpation of the sympathetic ganglia of the neck on both sides for epilepsy, Basedow's disease, hysteria, chorea, tumor of the brain, progressive paralysis, and many other similar diseases. In all three cases of genuine epilepsy reported at that time the cure was said to be perfect, but they were only observed for a short time. Navratil of Budapest also reported three cases of operations similar to those of Jonnesco and Donath, and described the results, which were negative. Dr. Beck is inclined to favor the removal of the cervical sympathetic ganglia for the treatment of Basedow's disease, believing it would prove of value. It is less dangerous and less difficult than any other surgical method suggested for the treatment of this disease; but as for the cure of epilepsy, he is satisfied that Jonnesco's method is of doubtful value.

Dr. Sanger Brown read a paper at the same meeting on the devious manifestations of epilepsy. He expressed the conviction that the main pathologic feature in epilepsy consists in a sudden disturbance of equilibrium between the several forces of the central nervous system. He regards all neurons directly connected with end organs as peripheral, and all others as central, although the latter are frequently further subdivided into projection, intermediate, etc., this equilibrium being soon completely restored, and a permanent tendency to recurrence remaining. Few observers, who have given the subject much attention, will dissent from the view that by far the most potent etiologic factor consists in a predisposition inherent in the cerebral tissues to undergo those changes which give rise to epileptic phenomena. Some ingenious arguments have been advanced to the effect that the main causative element consists in a vice of metabolism, resulting in an excess of some noxious substance or substances accumulating in the tissues of the brain, and thus exciting this abnormal activity. But even if this is admitted, it is not unreasonable to assume that this metabolic vice owes its origin mainly to influences derived from the nervous system, so that in either case an inherent pathogenic tendency of the central nerve elements has a similar etiological significance. The simple fact, however, that therapeutic measures projected on the basis of an autotoxic etiology have been notably barren of results, so far, at least, rather discredits this theory. Individuals are frequently met with, however, who, on the one hand, have been repeatedly exposed to influences usually regarded as especially likely to act as exciting causes of epilepsy, without developing the disease, and, on the other hand, innumerable instances are observed where the disease develops without any appreciable exciting cause whatever. thus powerfully magnifying the probability of an inherent predisposition. Several cases of epilepsy were reported in which the manifestations varied very materially.

At a recent meeting of the Chicago Medical Society, Dr. M. L. Harris read a paper on relations of the colon to intra-abdominal tumors. He said that one of the first and most important points to be determined in the diagnosis of a tumor of the abdomen is the particular organ or tissue from which the tumor takes its origin. Could this always be accurately determined, the diagnosis would often be much simplified. The old method of subdividing the topography of the abdomen into regions by arbitrary lines so that a tumor found occupying any particular region could be referred to an organ normal to that region, is very unsatisfactory, for the reason that some organs are not always found in the same region, and, again, owing to the facility with which a tumor may be displaced from one region to another. The particular point is not to determine the relations of the tumor to the abdominal topography, but its relations to the viscera themselves. To facilitate this a new subdivision of the abdominal cavity is proposed, based upon definite anatomical outlines. Taking the inferior or caudal layer of the transverse mesocolon and the internal or mesal layer of the ascending and descending colons as a fixed anatomical boundary, the abdominal cavity is subdivided into four areas or regions, namely: The central region, surrounded by the mesocolons; the superior region, lying above the transverse mesocolon; and the right and left external regions, lying external and posterior to the longi-

tudinal mesocolons. This boundary is not recognizable through the intact abdominal wall, but attached throughout to its free border is the colon which can, at all times, be easily outlined. The best method of outlining the colon is by distending it with ordinary air. This is easily done and occasions no trouble. While the boundary here mentioned is in a manner fixed, it may be easily displaced by a tumor. The various tumors common to each of the subdivisions were then mentioned, and numerous cases cited illustrating the characteristic displacement of the colon which is produced by particular tumors. By distending the colon with air and recognizing its characteristic displacement, one is often able to refer a given tumor to the particular organ from which it takes its origin, and thus materially facilitate a correct diagnosis. The following points were emphasized: First, the great importance, clinically and diagnostically considered, of the subdivisions of the abdominal cavity as outlined. Second, the colon, or some part of it, bears a characteristic relation to most intra-abdominal tumors, and an accurate knowledge of such relation is of greater diagnostic importance than any other single point.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE PRINCE OF WALES' HOSPITAL FUND — LONDON HOSPITALS WHICH RELY UPON VOLUNTARY CONTRIBUTIONS FOR THEIR EXISTENCE — DEATH OF PROFESSORS RUTHERFORD AND STRUTHERS.

LONDON, March 10, 1899.

THE Prince of Wales' Hospital Fund Association has just held its second annual meeting, and the Treasurer, Lord Rothschild, reported that $152,500 had been distributed among the London hospitals during the past year. The existence of this association, nobly beneficial as it is, calls attention to the extraordinary condition of affairs which obtains in the financial status of nearly all the London hospitals. With a few exceptions they are all chiefly dependent, and many of them entirely so, upon voluntary subscriptions from year to year for their running expenses. A few are richly endowed, but many have practically their entire capital invested in buildings, ground, and fittings, and must literally beg their living from the charitable public. So far the public has nobly responded, and the great London Hospital in Whitechapel makes its boast in large letters across its front that it is "supported entirely by voluntary contributions," but it is a singular and most anomalous state of affairs in the richest city of the wealthiest nation in the world. In some respects it does not work badly, as it is a good thing for the hospitals to be compelled to "earn their salt" and make their work prove their value to the public, and it keeps a larger class of the people in touch with hospital needs and hospital progress than an endowment or a government subsidy would. On the other hand, the drawbacks are many. It is little short of scandalous to permit such a precarious "hand-to-mouth" existence on the part of the most vital and important institutions of the community. It makes the rivalry between the hospitals intensely keen and bitter as all are drawing upon the same purse, and each feels that the others' gain is like to be its own loss. Sad to say this feeling even extends to the medical staffs, and the "Bart's" man knows no more of Guys' or St. Thomas' and their methods than he does of the Allgemeine Krankenhaus; no man can belong to the staffs of two of the teaching ones at the same time; the calling of a teacher from one hospital to fill a chair in another is a thing almost unheard of, and the jealously between them is almost incredible in men who are in all other respects educated, broad-minded gentlemen.

What makes this unfortunate attitude more serious is that the entire medical teaching of the metropolis is in the hands of the medical schools attached to the great hospitals, the faculty of each consisting entirely of members of the staff of the particular hospital, with the exception of a few purely scientific chairs. And finally, this dependence upon public favor makes the hospitals both extremely subject and sensitive to all sorts of irresponsible criticism. Some busybody discovers a case of supposed "heartless treatment" and reports it with artistic embellishments to a newspaper, the dear public promptly sympathizes with the patient, and a serious injury has been done not merely to the reputation but also to the income of the hospital, an injury for which there is no redress, and which no amount of official investigation and formal proof of the baselessness of the charge can more than half undo. Hence, members of the staff are often unpleasantly hampered in methods of treatment or in letting self-limited or harmless diseases run their normal course for fear of the bray "experimenting" being set up by the "antis" and their kindred.

Death has again been busy within the ranks of our profession. The celebrated Professor William Rutherford of Edinburgh, familiarly known in medical circles as "Bili Rubin," died on February 21st of influenza. He had been professor of physiology in the University of Edinburgh for twenty-five years, and was widely known both at home and abroad by his valuable original researches, especially that, as his pet name implies, upon the constituents of the bile and the effect upon their excretion of various drugs.

Almost the same day there passed away in the fulness of years and reputation his old teacher in anatomy, Sir John Struthers. Born in 1824, he became an extramural lecturer in the University of Edinburgh about 1848, and soon won such reputation that he was called into the faculty where he gave nearly forty years of continuous service. He was not only a great teacher, but a thinker of great insight and originality, and had advanced views upon the descent of animal forms strongly suggesting the Darwinian hypothesis long before the appearance of the "Origin of Species."

Soon after Professor Kanthack's death a strong desire was expressed by his pupils and friends in favor of some sort of a memorial to his life and services to science. As soon as it transpired that the professor had devoted practically his entire income to the enlargement of his scientific work so that his young widow was left in quite straitened circumstances the memorial committee promptly

decided that the memorial should take the form of a fund, the interest of which should be placed at Mrs. Kanthack's disposal during her life-time, and after her death be devoted to the establishment of research scholarships. And the entire profession will, we think, cordially approve of the committee's action. It is, however, a striking comment, not to say reflection upon the endowment of research in England, that such a state of affairs is possible in the finances of admittedly one of the most brilliant and promising of her original investigators. As was related in a former letter poor Kanthack was actually obliged at one time to give up his laboratory work and attempt to embark in private practice at Liverpool for the sake of a living.

A handsome donation has just been made to Guy's Hospital for the benefit of its medical school by Sir Frederic Wills. The amount is $25,000, and comes in response to Mr. Arthur Balfour's eloquent appeal for the endowment of medical education and research. Lord Iveagh's noble example is bearing excellent fruit already.

The Erasmus Wilson Lectures of the Royal College of Surgeons were delivered last week by Dr. Y. Gregor Brodie, upon the "Chemical and Physiological Properties of Diphtheria Toxin and Antitoxin."

The new laboratories in connection with the Middlesex Hospital Medical School have just been completed and equipped, and will be opened this week with a conversazione.

A singular case of urticaria has been reported by Mr. Hutchinson at his clinic. The patient, a member of Parliament, had been troubled for years by violent attacks of "nettle-rash" at very irregular intervals, each of which lasted for weeks, making his life a burden, and the cause of which had baffled discovery. Upon careful questioning it was developed that the attacks most commonly occurred after eating salmon, but not exclusively, nor did they always follow indulgence in this piscine delicacy. He was, therefore, instructed to experiment carefully with salmon cooked in various ways, and soon found that he could eat it cold, pickled, or escalloped with impunity, but that boiled salmon always brought on an attack. This in England is religiously served with parsley sauce, but happening one day to eat some without this condiment he was surprised to find no unpleasant after-effects, and acting upon this clue found that the real cause of his trouble was the parsley, and that if this were taken in or with any other dish urticaria promptly followed. By scrupulously avoiding this herb in every form the disease was completely got rid of, and he has had no attack of it now for several years.

A most interesting case of syphilis was also presented, in which the groins of the patient were filled with large, flat-topped cauliflower-like, soft warts, bathed in pus, and closely resembling the papillary out-growths of yaws. Mr. Hutchinson said that he regarded yaws as the parent of syphilis, developing in the tropics, and chiefly in the dark-skinned races, and brought back by explorers to temperate climes. Fifty years ago a disease known as "sibbens" or "button-scurvy" was comparatively common in the north of Scotland and Ireland, and was absolutely indistinguishable from yaws. This was clearly proven to be a neglected form of syphilis, and under prompt mercurial treatment has now entirely disappeared.

Dr. Vivian Paore delivered last week the first of a series of lectures upon "The Soil in Relation to Disease." He stated that the group of "soil-diseases" was being rapidly diminished of late years, and one after another attributed to animal or insect hosts, as for instance, diphtheria, the plague, and malaria. The latter, he quaintly remarked, might now be classed with hydrophobia, as due to the bite of an "animal," merely an arthropod, instead of a mammal.

The bacteria and insects of the soil are our best and most invaluable scavengers, and he exhibited the corpses of a number of rabbits which had been buried some months before in various soils and substances which clearly showed that the most rapid decay took place in those buried in rich garden soil, and only three inches below the surface, next in those buried in the same soil a foot deep, then in those buried in ashes, while those in sand, in quicklime, and in ordinary lime had undergone scarcely a third of the decomposition. Moreover, the remains of the bodies buried in ordinary soil and sand were almost entirely free from odor while those in quicklime, lime, and ashes stank abominably.

KELOID FROM ACNE—SOME FOREIGN BODIES REMOVED FROM THE MALE BLADDER—A RAPID METHOD OF MAKING A DIAGNOSIS OF TYPHOID FEVER—INDICATIONS FOR THE RADICAL OPERATION IN HERNIA—GASTRIC ECTASIA WITH TETANIC SYMPTOMS—INTERMITTENT HYDROPS OF THE KNEE—A MASS OF HAIR IN THE STOMACH WEIGHING ONE POUND—INOCULATION OF TUBERCULOSIS AT CIRCUMCISION—AN IODID ERUPTION UPON THE INTERNAL ORGANS—METHODICAL EXERCISE AS A TREATMENT FOR DEAFNESS.

AT the Berlin Medical Society, January 11th, BUSCHKE showed a negro, aged thirty-four years, from whose neck he had removed a large keloid. Two years before his face and neck broke out in large acne pustules which were treated in various ways with considerable benefit. On the back of his neck, however, a tumor developed which at the time of operation had an irregular rough surface. It was hard at the periphery but somewhat softened in the middle. There were also several ulcerations in the skin over it. Microscopically it was found to be a keloid, and the history left no doubt that it developed from the acne pustules. It was removed and the gap covered by a Thiersch graft. Three months later another keloid was already forming in the scar.

BUSCHKE showed a patient from whose bladder he had removed a lead-pencil by suprapubic cystotomy. It had been in the bladder two weeks, had fallen into three pieces and had become partially encrusted. The patient denied having used the pencil for sexual excitement, and stated that he had gone to sleep with it in his hand, and upon waking up was unable to find it.

POSNER mentioned another case of masturbation in

the male by the introduction of a foreign substance into the urethra. Articles which have been introduced for this purpose are rarely found in the male bladder although common enough in the female bladder. He had removed from the bladder of this patient a rubber tube 56 cm. (22 inches) long and 3½ mm. (¼ inch) thick. By means of a lithotrite the tube was extracted from the bladder without difficulty and the violent cystitis quickly disappeared.

At the session of January 25th, PIORKOWSKI gave a demonstration of a rapid method of distinguishing typhoid bacilli from colon bacteria. He found that the amount of gelatin in the culture media which he employed was so slight that the typhoid bacilli took on in twenty hours a perfectly characteristic form of growth. For this purpose he prepared the medium as follows: Normal urine of a specific gravity of 1020 was collected for two days, the reaction having in that time become alkaline. One-half per cent. of pepton and 3.3 per cent. of gelatin were added and the whole cooked over a water-bath for an hour, and filtered. The filtrate was poured into glasses and sterilized at 100° C. for fifteen minutes, and again the next day for only ten minutes. Upon this medium in twenty hours colonies of the bacteria coli, kept at an even temperature of 22° C. appeared yellowish and round with sharp edges; while the colonies of the typhoid bacilli, appeared as if threads were extending from a center. So delicate was this reaction that the omission of the urine from the culture medium or the failure to keep the culture glass at the required temperature was sufficient to prevent the typhoid colonies from assuming the form of growth above described. The typhoid bacilli were obtained from the stools of typhoid patients by simple dilution. In almost all of the tests the number of typhoid colonies far exceeded that of the colon bacteria.

GRAWITZ mentioned the attempts which have been made for years to diagnose typhoid fever by examinations of the blood, by splenic puncture, by examinations of the stools, and recently and with more success by the serum reaction. Even this reaction fails, however, in many cases and often does not appear until several days after it would be most desirable to have a diagnosis. In one of Piorkowski's cases it did not appear until after the correct diagnosis had been shown by the bacillary growth upon the medium referred to.

ROTTER spoke of the indications for radical operation in hernia. Modern statistics prove that the mortality from hernia operations in the hands of the best men, is only about 0.3 per cent., and that recurrence after Bassini's operation is less than 5 per cent. He had only 1 recurrence in 67 cases. Hence operation was to be advised not only to those patients who have an irreducible hernia, or one that a truss will not hold in position; but to all patients with inguinal hernia, who wish to be free from the annoyance of a truss, the surgeon is justified in saying, that in the present condition of surgery, one can promise permanently to relieve the trouble by an operation practically without danger.

He advocated the method of Kocher, especially for operations upon young children, in whom the dressings are apt to become soaked with urine. This fouling of the wound does little damage if the wound is a simple incision, but in the sutured planes of the patient operated upon according to Bassini, more serious mischief is likely to follow a soaking with urine. Recurrence in young children is very rare after any operation. He had never seen an instance of it after any method, and in a number of cases he had simply tied off the sac high up. The most essential point in the perfect cure is primary union. The poor results which were at first obtained by Kocher's method were due to the fact that the twisting of the sac led to its necrosis and to suppuration. He called attention to the fact that Kocher himself did not advise his method for large herniæ, nor for those with thick sacs. Bassini's operation ought always to be performed with absorbable sutures, not with silk.

February 8th, ALBU showed two patients with dilated stomach who suffered from tetanic symptoms. The first was a mason who in repairing a roof, fell to the ground and was picked up unconscious. He must have swallowed some gravel, for the following year his stomach was washed out, and a small stone came out through the tube. His gastric troubles continued, and three years after the accident, there were attacks of hemorrhage, and almost constant vomiting. The stomach was washed out and twenty-two stones were recovered, facetted in such a way as to indicate that they had lain together in the stomach for a long time. The stomach was so dilated that in a fasting condition it was always possible to wash out from one to three quarts of fluid, with remnants of the meals of several days previous. At this time symptoms arose which were looked upon as tetanic. There was headache, failure of the memory, dizziness, itching of the hands, and often cramps of the fingers. Regular lavage helped the subjective symptoms somewhat.

The second patient had a marked gastric ectasia from pyloric stenosis from a small scirrhus tumor as was proved by subsequent operation, for the tumor was too small to be felt. There was loss of weight, and an almost total absence of hydrochloric acid in the gastric juice. One day just before lavage, the patient had a typical tetanic attack, with the body stretched in opisthotonos, and the fingers in the characteristic position of the gynecologist. The electrical irritability of the nerves of the upper extremities was much increased. The attack passed off in a few minutes. The tumor was removed, the patient gained twenty pounds in six months, and all trace of tetanus disappeared.

At the Vienna Medical Club, January 18th, BUM described a case of intermittent hydrops of the knee, occurring in a man, aged thirty-seven years, who had exhibited neurasthenic symptoms for seven years. Periodically for several months the right knee would swell up with fluid, reaching the maximum of its distention in three days, and then gradually subsiding. There was no pain associated with the phenomenon. All measures, general and local had failed to affect the swelling.

SCHLESINGER mentioned a similar case which had come under his notice. The patient was a man not in the least neurasthenic, but for six years from November to March, every other year, the attacks had come on

every ten days. The swelling lasted two or three days, and was associated in its beginning with an increased frequency of micturition and an increase in the daily amount of urine. He also mentioned an instance in which a mass of hair weighing a pound had been removed from the stomach of a woman by laparotomy. The tumor before operation was readily palpated in the left hypochondrium, and was thought to be of the stomach, but its true nature was not suspected until the stomach was opened.

It was free in the cavity of the stomach. Such cases occur only in women, and owe their origin, almost beyond doubt to a habit of biting off and swallowing the ends of the hair. The only treatment is operative, for no other means are calculated to remove the cause.

At the Imperio-Royal Society of Physicians of Vienna, February 3d, NEUMAN showed a baby whose penis had been inoculated with tuberculosis at its circumcision. Several other babies who had been circumcised by the same rabbi had been infected in a similar manner, and the source of infection was beyond a doubt in the mouth of the officiating priest as he had the practice of taking the penis in his mouth in order to stop the bleeding. The difference between tuberculosis and syphilis in such cases is made clear in the course of time, as the tubercular ulcers and infected glands always suppurate.

NEUMANN described the results of an autopsy performed upon a man aged thirty, who died of nephritis and cerebral hemorrhage, while taking iodid of potassium. The drug had produced upon the skin a profuse eruption, and it was interesting to observe a similar eruption upon the kidney, brain, and pyloric portion of the stomach. The seat of the eruption upon the pyloric region was of a special interest since this portion of the alimentary canal is so prone to the development of ulcers and neoplasms.

At the session of February 17th, URBANTSCHITSCH spoke of the value of methodical exercise for deafness. It has been observed that those who hear with difficulty are improved by a single evening in the theater. Such improvement is much more marked if systematic exercises such as listening to a wagon in the street, or to the voice of another individual, are regularly carried out. In such exercises the better ear must be stopped, otherwise the patient simply listens with this ear, while the deaf ear grows worse and worse. Since a person who hears with difficulty is accustomed to divine the meaning of a sentence from those words or syllables which he hears, it is better to use a foreign language in these exercises, or a collection of words without meaning, and the patient should repeat back each word. Words heard indistinctly should be practised over and over again. The distance between the people should be gradually increased, and the rate of speech varied, etc. It goes without saying that the patient must not see the lips of the speaker. These exercises are exhausting, and should not be continued for more than five minutes at a time. The amount of improvement is sometimes great, while sometimes there is no improvement at all, depending on the nature of the trouble.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Regular Meeting, Held January 23, 1899.

THE President, DR. PALMER COLE, in the Chair.

DR. EDWARD R. DUNHAM read a paper, entitled

SIMPLE BACTERIOLOGICAL PROCEDURES APPLICABLE TO THE TESTING OF DRINKING-WATER.

He said in abstract: Eleven years ago when I began to pay some attention to the bacteriology of water its sanitary condition was determined bacteriologically by counting the colonies that would develop from a certain amount of it, usually one cubic centimeter when mixed with some suitable culture-medium. The empirical rule then in vogue as to the sanitary condition of water from a bacteriological standpoint was if one cubic centimeter of the water examined contained no more than 250 bacteria it was good; if more than that it was suspicious; if it contained 1000 it was condemned. This rule, of course, was extremely unsatisfactory in practice. It did not take into account whether the bacteria found were pathogenic or not. We may have a water with 3000 bacteria to the cubic centimeter that would be perfectly innocuous because the micro-organisms were all of harmless varieties; while we may have water containing less than 300 bacteria to the cubic centimeter extremely dangerous because the microbes are all, or nearly all of some pathogenic variety intensely virulent for man.

Then it was thought that value might be given to the bacteriological examination of water by looking for known pathogenic bacteria in it, and as typhoid is the most common of the pathogenic water-borne bacteria the presence or absence of this it was hoped would constitute a good criterion as to the availability of water for drinking purposes. But the differentiation of typhoid bacilli from certain others, especially the colon bacillus, became in course of time more and more complicated. What were considered absolutely distinctive marks lost their value as such. The growth on potato held its ground as a distinguishing peculiarity for some time but it, too, became of a doubtful value and finally the method of differentiation became so involved and required so much time that it became useless. Three to four weeks were required and then a negative result was only relatively conclusive since pathogenic germs might just have been missed in the specimen taken. The bacteriology of water for practical purposes fell into discredit and the necessity for further developmental work became evident.

It seemed worth while to study the possible sources of water-contamination systematically. The life-history of all water is briefly this: It is taken up as vapor from the sea; falls through the air as rain; flows over the surface of the earth in rills to streams and rivers, or filters through it to appear as springs and so eventually enter the rivers and complete the cycle of change by getting to the sea once more.

While in the state of vapor the water is of no interest to the bacteriologist. Falling as rain it becomes contaminated with the bacteria it washes from the air. These

bacteria are, as might be expected, strictly aerobic. It might happen that some of them would be facultative anaerobics, *i. e.*, live normally in the presence of oxygen and yet have the faculty of continuing to live and multiply even in the absence of that gas. In distilled water which had been exposed to the air of the laboratory and the atmosphere out of doors for some time I found no facultative anaerobic micro-organisms. The method employed to demonstrate this was as follows: Petri dishes were prepared in the usual way for the examination of water and then instead of allowing the microbes to develop as usual with free access of air they were put beneath a bell-jar with a water-seal. From this after the inoculated Petri dishes had been put in the oxygen of the air was removed by the presence of a mixture of pyrogallic acid and caustic potash. An hour after the plates were put in all the oxygen had been consumed and as the results show none of the bacteria had time to develop during this short interval. In distilled water exposed to the air as stated above no anaerobic bacteria were found. All of the bacteria washed out of the air are strictly anaerobic. These observations were confirmed by examination of water taken from cisterns and collecting trenches such as may be found in Massachusetts, thoroughly protected from the infiltration of soil-water by cement, and where no contaminating surface-water could enter. Samples taken from these collections of rain-water always had nothing but strictly aerobic bacilli.

The next source of contamination of water in its cycle to the sea is from the soil. A number of samples of distilled water were mixed with measured small quantities of soil and after being shaken up with gelatin cultures were permitted to cool and the bacteria allowed to develop. Some of the plates made were allowed free access to air, others were placed in an atmosphere of nitrogen in the apparatus described. In the air-plates an average of over 30,000 colonies of aerobic microbes were found to have developed from a gram of soil taken from Madison Square, while only some 500 colonies of anaerobic micro-organisms developed from the same amount. Mixture of the water with soil taken from Bellevue Hospital yard led to the development of nearly half as many anaerobic as aerobic microbes. When sewage taken from the main sewer in Twenty-third street was mixed with distilled water the number of anaerobic colonies was ninety-six per cent. as much as that of the aerobes that developed. When the sewage was diluted with water up to one to one-thousand and then twenty-four hours allowed to elapse the result was practically the same and ninety-four per cent. as many aerobes as anaerobes were found to be present. With sewage taken from the ordinary sewer of a small country town instead of New York sewage the result was practically the same. The conclusion is obvious that any considerable number of anaerobic bacteria in water is strongly suspicious of sewage contamination.

This principle applied to Croton water gave the following results: In 1897 about twenty-two per cent. of the bacteria found in drinking-water at the spigot in New York City were anaerobic. In 1898 the anaerobic bacteria numbered but about twelve per cent. Enough certainly to give color to serious suspicion of sewage contamination somewhere along the line.

But so far the methods suggested for the examination of water are merely quantitative and so are open to most of the objections of the older methods. The application of some qualitative method was necessary in order to point out with assurance the presence of dangerous and infective material and in general to point out the probable source of the micro-organisms that occur. The bacilli from the air it was found are mostly chromogenic. Those from the soil belong principally to three classes: There is, first, the family of the hay bacillus; second, that of the bacillus figurans, and third, that of mucoides. The presence of the hay bacillus shows that the water has washed the surface of plants or been in contact with vegetables. In general these three classes of micro-organisms are characteristic of surface-water in country places.

The presence of fecal matter in water because of contamination with sewage is best detected by the presence in it of the colon bacillus and putrefactive bacteria. The test for putrefaction is not difficult. If a small amount of the suspected water be added to a one-per-cent. peptone solution and putrefactive bacteria are present they will decompose the solution and set free H_2S. This may be detected by its blackening action upon a piece of paper previously coated with carbonate of lead which is allowed to hang down into the flask in which the putrefaction is accomplished.

For the colon bacillus the most delicate and satisfactory test seems to be the setting up of fermentation. If the suspected water contains colon bacilli it will cause fermentation in a two-per-cent. solution of glucose. The gas given off is the best sign of this and it may be tested and shown to be CO_2. There are other micro-organisms that cause fermentation and that might be present in water, but their differentiation is not hard. Incubator temperature causes colon bacilli to multiply very rapidly. Sometimes at the end of twenty-four hours almost a pure culture of those bacilli will be found. Other fermentative bacteria are rather inhibited at incubator temperature.

These tests applied to Croton water give the following results: The bacillus mucoides can always be found but means nothing except the percolation of a certain amount of the water through soil. The blackening of the carbonate of lead paper in the peptone solution after the addition of the Croton water shows the presence of bacteria of putrefaction. The fermentation-test is also positive, due to the presence of colon bacilli. This would seem to show that there is sewage contamination of Croton water. Any one who has ever been on the Croton watershed would not be surprised at this. Of course it may be urged that the presence of these putrefactive and fermentative bacteria are due to the washing in of barnyard refuse. This does not improve the matter much, however, as on sanitary as well as on esthetic grounds the presence of barnyard refuse in our drinking-water is not desirable. At present our water-supply is tested chemically and our water is decided to be drinkable. Since there is at present no special prevalence of intestinal d.s-

orders it is probable that this is a relatively safe decision. The chemical tests are, however, lacking in delicacy and the conclusions from the bacteriological observations I have detailed to you show that our water-supply is on the border-line of safety and that present conditions are by no means ideal for a great city's water-supply.

As colon bacilli and the putrefactive bacteria do not live except in the presence of organic matter it is evident that a certain amount of this is always either in solution or suspension in the water, for I have been able to demonstrate beyond a doubt that colon bacilli will not live and multiply to any extent in water free from such contamination.

DISCUSSION.

Dr. Palmer Cole said that of course present conditions on the Croton water-shed are not ideal; that any one who knows the locality realizes at once; but he was glad to think that at present the water is not dangerous and that dilution of noxious matter present plays so important a rôle in keeping it so. In a few years another immense Croton-water dam will be added to those already present and then the still further dilution will greatly add to New York's safety. He had lived on the shores of a lake during certain summers, where he knew that the lake water was being used as drinking-water and with no serious results, yet where he felt sure that the drainings from the houses of all the effete material of the household must eventually find their way into the lake after being filtered through the soil. Filtration then even under natural conditions could play a great rôle in the purifying of water.

To the question as to whether the samples of Croton water tested were taken from the ordinary drinking-water of New York Dr. Dunham replied that they were and at times when the health department had not pronounced it to be in any worse condition than at others. Every now and then there is a little scare on the part of the New York Board of Health authorities because the nitrites in Croton water were found to be increased. This is taken ordinarily to mean the presence of organic matter and to imply sewage contamination. Any contamination of this kind present, however, is so diluted by the immense volume of water that reproduction of bacteria is practically inhibited. The water in its present condition is not dangerous. The results of the tests he had given were only meant to show that the elements that would prove dangerous if present in larger quantities are really present and that the ideal city water has by no means been reached. The idea had been not to disturb people as to present conditions but to endeavor to restore bacteriology to a place in the testing of water by which it may give even more delicate results than chemistry.

Dr. E. M. Foote said with regard to the tenacity of life of the bacillus coli communis, that it had been found by Von Baracz still living after nearly a year in portions of intestine that had in animals been cut off from the rest of the intestine and closed by sutures though left *in situ* in order to determine what happened to portions of intestine thus cut off.

Dr. Dunham said with regard to the purifying effect of filtration that it was marvelous. The water flowing from the Seine sewage-farms near Paris is clear and pure and contains but few bacteria.

Dr. Cole said that he understood that trout would live in it. Dr. Dunham said he knew of an institution in Massachusetts where the sewage of the establishment was used for manure. The drinking-water comes from a well near the farm. This is thoroughly protected from surface or superficial soil-drainage and though the chemical tests show the presence of organic matter, evidently sewage derivatives, no bacteria can be found. Repeated negative examinations had been made and a careful watch was kept for the first sign of bacterial contamination but so far without result.

REVIEWS.

The Principles and Practice of Hydrotherapy. A Guide to the Application of Water in Disease. By Simon Baruch, M.D. New York: William Wood & Co., 1898.

The author of this volume has for many years been known to the medical profession as an ardent advocate of the use of water in the treatment of disease, and no doubt the results of his study and experience as set forth in this volume of more than 400 pages will be welcomed by his professional brethren who, convinced of the usefulness of hydrotherapy, desire instruction concerning the most approved methods of its utilization. The subject is considered in considerable detail, not alone the application of water generally and in individual diseases, but chapters are devoted, entirely unnecessarily we believe, to the "Functions of the Skin," "Anatomy and Physiology of the Skin," "Physical Properties of Water," and "Hydrotherapy in Different Countries." The book is a pioneer of its kind in this country, and as such it should be received. No doubt the author has good reasons for believing that the medical profession has been somewhat apathetic regarding the adoption of water as an agent of great importance in the treatment of almost every disease, but we venture to believe that there has not been such lethargy and "strong feeling of repulsion" as one might be led to think from reading this book. The motto of the volume is a quotation from Dr. H. C. Wood: "Therapeutics developed by empiricism or clinical experience alone cannot rest upon a secure foundation." Why not? On what is the use of morphin based in the relief of pain? Do we in any way understand how mercury acts in the cure of syphilis? Upon what is thyroidtherapy in the treatment of myxedema based? Is it not empiricism and clinical experience?

The author makes altogether too much strife in an endeavor to establish the *rationale* of the action of water on what he is pleased to call a scientific basis, which consists largely in the citation of pulse-tracing and muscle-curves during and after the application of water in different ways. Moreover, his combativeness is manifest in almost every page of the chapters devoted to this part of the subject. For in-

stance, in speaking of the skin as an organ of excretion, he says: "These well-authenticated observations prove incontestably the importance of the skin as a secreting and excreting organ in health and the vicarious utility of this function in disease." Who has ever denied that the skin is an important secretive organ in health, and why quote a catalogue of experiments to prove it? In all fairness it must be stated that the first chapters devoted to the physiological effects of water, the anatomy and physiology of the skin, the physical properties of water, the *rationalé* of the action of water in health, etc., are extremely disappointing and in no way enhance the author's reputation. The chapters on the practice of hydrotherapy are very much more acceptable and to those unacquainted with the modes of applying water they can be unhesitatingly recommended, although there is much to be criticized even in them.

A chapter on the hydriatic prescription is made up largely of "pointing a moral" by recording the mistakes on "justly eminent teachers" and of "otherwise well-informed gentlemen" and a plea for the exact dosage of hydratic procedures. Naturally one can sit in judgment on others if it pleases him. *Chacun à son gout.* But we must demur to the statement that one can write a prescription for a hydric application with the exact dosage of a prescription calling for strychnin. No two patients suffering from chronic disease will be benefited by the same sort of hydric application. Every case is a law unto itself and no one knows what the exact technic for a given patient should be until one or more trials are made. He can then write a hydriatic prescription if it affords him any pleasure, but the technic may have to be varied the next day or the next week as the patient's reactive capacity changes.

In many instances wherein the efficacy of hydriatics is spoken of one cannot help feeling that the author claims too much. The only way to explain that a case of prosopalgia disappeared after one bath is that the patient took to the woods, or left town on the first train, because even hydrotherapy is not a miracle worker.

The index is very incomplete. One example may suffice to show this The author says that hydrotherapy belongs to the most precious antineuralgic remedies, but on attempting to find where the subject of neuralgia is considered in the volume by consulting the index, we find the word is absent.

Although the treatise under consideration is one that deserves to be read and studied, we are of the opinion, after a careful examination of it that nothing can do the subject of hydrotherapy more harm than an overenthusiastic, combative advocacy of it, as if it were the only thing in the world. Hydrotherapy has its limitations and they are very serious. Every one admits its utility, but very few, fortunately, are so wrapped up in the subject that they are unable to see its limitations.

THE DISEASES OF THE LUNGS. By JAMES KINGSTON FOWLER, M.D., F.R.C.P., Physician to the Middlesex Hospital and to the Hospital for Consumption and Diseases of the Chest; and RICKMAN JOHN GODLEE, M.S., F.R.C.S., Fellow and Professor of Clinical Surgery, University College, London. Illustrated. New York and Bombay: Longmans, Green & Co., 1898.

THE authors of this work have not been misled in their attempt to present a "continuous picture of the medical and surgical aspects of pulmonary disease." A careful reading of their book shows a most painstaking effort to record the essentials of present knowledge of the diseases of the lung and pleura from the standpoints, respectively, of the physician and surgeon.

The introductory chapter on the anatomy of the lungs is carefully written, and while making no attempt to give all that is known on the subject, contains more than enough for clinical purposes. The chapter on physical diagnosis is especially thorough and shows the hand of the teacher as well as of the trained observer. The various diseases of the lungs and pleura are next considered, and are discussed fully as to their etiology, symptoms, pathology, and treatment. The surgical treatment of such diseases of these organs as lend themselves to intervention by the surgeon is fully described and is interesting as showing the advances made in recent times in surgery of the chest. Two especially interesting chapters are those on the bacteriologic aspect of pleurisy and on clubbing of the fingers. A chapter on pulmonary osteoarthropathy is included. It is plainly evident that the book is not only complete in the sphere it sets out to cover, but is characterized as well by certain knowledge and by a scientific spirit. The profuse illustrations are especially clear and of important didactic value. The book is to be conscientiously recommended as a serious study of the subject of which it treats.

THERAPEUTIC HINTS.

For "Scrofulous" Adenitis in Children.—

℞	Potass. iodi	. . . .	gr. xxiv
	Tinct. iodi	. . . .	gtt. xxiv
	Syr. gentianæ, Syr. cinchonæ	aa . . .	℥ iii.

M. Sig. One to two tablespoonfuls daily.—*Verneuil.*

For Acne in Young People.—Instead of the frequently employed lotions containing a small quantity of sulphur and a large quantity of glycerin, VEIEL of Cannstatt considers it advisable to increase the sulphur and altogether omit the glycerin:

℞	Sulphuris sublim., Spiritus, Aquæ	aa . . .	ʒ v
	Mucil. acaciæ	. . . .	ʒ iss.

M. Sig. Apply night and morning.

If too irritating substitute a lotion containing from one to fifty per cent. boric acid.

For Tonsillitis.—

℞	Sodii benzoat.	. . . .	ʒ i–iv
	Glycerini, Elix. calisayæ	aa . . .	℥ i.

M. Sig. A teaspoonful every one or two hours.—*Stevens.*

ORIGINAL ARTICLES.

A FURTHER STUDY INTO THE FREQUENCY AND NATURE OF CANCER.[1]

BY ROSWELL PARK, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO; DIRECTOR OF THE STATE PATHOLOGICAL LABORATORY, ETC.

THE object of this paper is threefold: first to emphasize the ever-increasing mortality-rate in this State from cancer; secondly, to epitomize some of the more recent studies in regard to its etiology, and especially the arguments which point more and more toward its parasitic origin; thirdly, to bring to your notice the work already done and in prospect in the new laboratory started under the auspices of this State, and located in Buffalo.

With regard to the increasing mortality-rate, it would consume too much of your time if I were to read tables which have been carefully prepared from the returns of the State Board of Health, but the principal facts brought out can be briefly laid before you. These tables are, of themselves, a convincing argument in favor of collective study, and by public aid, as to the causes of cancer, since they show with regard to another disease whose cause used to be equally unknown that since the discovery of the peculiar organism to which it is due its mortality-rate has steadily declined. I allude, of course, to consumption. Since its cause has been known, intelligent and properly directed efforts have produced a very marked decrease in its ravages. On the other hand, the death-rate from cancer is steadily increasing not alone in New York State, but apparently in all parts of the world. There is, furthermore, every reason to infer that this increase will undoubtedly continue until its minute causes are positively determined. So far as we have been able to learn, cancer is now the only disease which is steadily upon the increase. This, of course, is a statement made without reference to the acute infectious diseases, like bubonic plague, etc., which have their own peculiar way of producing epidemic disturbances. In England and Wales, for instance, where most careful statistics are kept, the cancer death-rate has risen from 1 in 5646 of population in 1840, to 1 in every 1306 of population in 1896; that is, in fifty years the proportion has increased nearly five times. All over this country the increase is quite as alarming, while the figures pertaining especially to our own State are equally significant, and quite incompatible with its increase in population. Thus, for instance, in 1887 there were in this State 2363 deaths from cancer and 11,609 from consumption. In 1898 there were 4456 deaths from cancer and only 12,552 from consumption. This increase in cancer mortality is certainly not due to improvements in methods of diagnosis, but rather the reverse is the case, since many cases which were formerly diagnosed as cancer are now properly classified where they belong in other lists. In none of the other diseases tabulated by the State Board of Health, nor in any Government reports, has there been such an immense increase as in cancer. It is the only disease tabulated which shows a progressive and steady increment by months and by years.

A careful study of all these tables permits one to make the following startling prophecy: If during the next ten years the relative death rates are maintained we shall find that ten years from now, *viz.:* in 1909, there will be *more deaths in New York State from cancer than from consumption, smallpox, and typhoid fever combined.*

It is most interesting, again, to see how cancer is particularly prevalent in certain regions. There is a recent report by Dr. Symons, Medical Officer of Bath, Eng., who has found that in his territory cancer is fifty per cent. more frequent than in neighboring localities. But the most extraordinary and significant topographical and statistical study of recent times is that of Behla, in the concluding numbers of the *Centralblatt für Bakteriologie* for 1898, which pertains to the little town of Luckau, in Germany, where, within the past twenty-three years there have been seventy-three deaths from cancer in an area covered by two or three city squares, as many as four deaths from it occurring in one house, and where the disease has assumed the proportions and the importance of an endemic. To this paper should be given the careful consideration of all who are interested in this study, though, to be sure, similar endemic appearances of the disease have been noted in other parts of the world, and in milder form may be said to have almost prevailed in time past in certain localities in Western New York, where the disease is exceptionally prevalent. Prob-

[1] Read at the Ninety-third Annual Meeting of the New York State Medical Society, held at Albany, January 31 and February 1 and 2, 1899.

ably it is not necessary to do more than to rehearse these very brief facts in order to bring vividly to your minds this great and increasing source of danger to our population.

Next, with regard to the actual nature of this disease. First of all it is possible to sweep aside, with one or two possible exceptions, everything that has been brought forward until within recent years as an explanation of this disease. The old theories of irritation, of perverted nerve-centers, of heredity, etc., cannot for a moment stand in view of the searching scientific methods of to-day. We have gotten as far as this at present that we know that cells act as they do in producing the disease either as the result of some external or internal stimulus. The exact character of this stimulus is not yet certainly demonstrated, though things point more and more toward its parasitic, *i.e.*, its potent living influence. There are so many analogies between cancer and other diseases which are known to be infectious that these alone should be enough of themselves to almost convict, aside from the ordinary revelations of the microscope and the findings of the experimental laboratory. If cancer be an infection it must be acknowledged that, as a rule, it is exceedingly slow. This, however, does not prevent us from accepting such diseases as syphilis, leprosy, and others as in their essential nature parasitic. We know very well that infections vary within the widest limits in their intensity and rapidity of action, from those which kill within a few hours, such as yellow fever, cholera, and the like, to those in which two or three weeks are required, like typhoid fever, or those which ordinarily are much slower yet, like tuberculosis. No valid argument, therefore, can be made against the infectious nature of cancer based simply on the time limit. Whatever of value may be obtained from arguments concerning the nature of the tumors and cancers in the vegetable world is cast on this side, because an unprovoked tumor in the vegetable kingdom is an exceeding rarity. The only statements which help us as they come down to us from the writings of our predecessors are those concerning evident clinical facts, such as the direct transmission of cancer from one part of the body to another. We know now that tuberculosis is not inherited, though the predisposition to it may be, and we believe the same thing to be true of cancer. But anything which points to a direct inoculation from one individual to another is of incontestable value, whether recently observed or a thousand years ago.

Further analogy is found in the undoubted cachexia of its later stages, or let us say the more pronounced stages, of all the infections. Such toxic conditions we rarely get from any conditions save the genuine infections. The supposed intimate relation which injury bears to cancer is of no more importance than that upon which the clinicians, and even the pathologists, used to place so much stress in tuberculosis. There are still those who claim that the predisposing cause of most tubercular joint lesions is previous injury of some character, and there are still those who look for a similar mechanical cause of cancer in virtually every case. What is there about injury, which, by itself, can produce at one time tuberculosis, at another syphilitic gumma, or at yet another cancer, save that either at the moment it has permitted a surface or deep infection, or that directly it has so far changed the vulnerability of the tissues as to permit of their more easy subjection to minute enemies from without? Trauma, therefore, must be disregarded save as it plays a subsidiary rôle.

The occurrence of cancer in certain families and its prevalence in certain localities, especially in the so-called epidemics of cancer which writers in various parts of the world have described, permit of scarcely any other explanation except the transmission from one to another of a *contagium vivum* of some kind.

There are, moreover, numerous analogies between malignant tumors and the infectious granulomata, to which the careful student cannot be blind. The characteristic reaction of the cells, the way in which they group themselves, their internal activities, their behavior in every respect, though not identical, are so plainly analogous that they cannot be disregarded. Moreover, the disease which any organism may produce is not necessarily characterized by the presence of its germs in a selected part, though this statement should perhaps be qualified by saying that at present our technic does not yet permit of their detection. This is particularly true of such diseases as tetanus and scarlatina, and probably of syphilis. This is, perhaps, to be explained by the fact which Orth and others have amply demonstrated, that bacteria can pass through certain tissues to find a resting-place in others at long distances, and yet leave no intermediate traces nor indications of their journey. Syphilis is, for instance, everywhere regarded as a parasitic disease, and is so viewed because the various steps of the infection can be traced, and yet we know less of the actual parasite of syphilis than of that of cancer. Indeed, there are numerous diseases whose infectious nature is established, yet the mechanism of whose infection has only been determined since the identification and study of the organisms at fault. In such diseases, for instance, as malaria and plague, the organism enters and leaves no traces by which to track it, yet no one dis-

putes their parasitic character, and one cannot afford to scoff at the infectious theory of cancer simply because we are still ignorant of the organism or the source of the infection.

Again, certain known organisms are well known to possess what we speak of as selective activities, as, for example, the ordinary pyogenic bacteria, tubercle bacilli and Busse's yeast-cells, which latter are capable of irritating the connective tissue, and thus producing a tumor much resembling sarcoma, which, however, after a time subsides. But this is no more than we see in certain malignant tumors in man, since sarcomata in human beings have been known to undergo spontaneous retrocession.

Then, again, from the standpoint of the histologist it cannot be forgotten that observers in all parts of the world have noted in and among cancer cells appearances which have everywhere provoked a suspicion of the presence of micro-organisms, but which have been variously interpreted. By some these have been called cell degenerations, protozoa by others, and fungi by yet others. It is remarkable to see how closely the pictures of these appearances, drawn by observers with these various and variant views, agree at least in this, that they all show something which does not belong to the cell, but is foreign to its proper structure and development, there being the closest correspondence between them in almost everything save the interpretation of the phenomena. This would indicate that our next advances must be made by improvement in technic. Certainly in time past one disease after another has been shown to be parasitic, the change of opinion being due entirely to advances in technical methods. Far as we think we have gone in this regard, there is yet no visible limit to what may yet be revealed in cancer as well as in other obscure conditions.

Every little advance even brings us something of value. For illustration, take the micro-organisms recently identified by Adami, which produce a peculiar cirrhosis of the liver among cattle of Pictou, or others studied recently by Roux, which are too small to be yet seen by the most powerful lenses constructed, which can only be seen when growing in colonies, and which pass through the fine porcelain that has hitherto been supposed to filter out all germs, and yet which produce well-marked lesions. Doubtless some one will soon make a lens with which these individual forms may be distinguished. As yet no one has done it. Again, there is no prophesying what the future may have in store for us in the way of new culture media and methods and improvements in experimental technic. What we most need now are better lenses, still more media, other stains and improved chemical methods. When we recall what the chemists who concern themselves with aniline dyes have done for the pathologist, we have reason to expect great things of as yet unfamiliar materials. The experience of the past few years in the production of toxins and antitoxins has shown the necessity of much more minute knowledge of chemistry, and its application to this line of research. Numerous advances made of late also in chemical physics must be brought directly to bear upon this subject.

Hitherto, almost all the work done on cancer has been carried on in a most traditional and conventional way, and most of it is, consequently, worthless and must be all gone over again by the aid of the latest improvements. This is particularly true of inoculation work, which must be carried on along three lines of experimentation: (*a*) From animal to animal. This has succeeded in various isolated instances in the past, in the hands of numerous experimenters, and quite recently has been methodically carried out with a large measure of success in several laboratories. (*b*) From the dead human subject to the living animal. A remarkable illustration of this was afforded last year by Jurgens, who successfully inoculated animals with the fragments of sarcoma taken from a patient who had been three days dead, which seemed to indicate very strongly that it is not the human cells which are the infectious agents, but some persistent *contagium vivum* which they may thus carry with them. (*c*) Inoculation into animals of pure cultures of organisms taken from fresh human specimens. In this regard the largest measure of success seems to have fallen to the Italian experimenters, like Sanfelice and Roncali, whose labors in this direction are now quite well known. At Montpelier Bosc seems to have had some remarkable results, and in Gussenbauer's clinic at Vienna striking results have followed experimentation with melanotic sarcoma. Certain it is that our ordinary culture and inoculation methods must be extensively revised and modified. The organisms, whatever they are, certainly do not grow easily or successfully on ordinary culture-media, and new ones still more accurately resembling the human tissues have yet to be devised.

The microscopic picture of a section properly stained and prepared, in which one trained to this work can observe the bodies which we are convinced are parasites, shows everywhere their apparent reproduction *in situ*, as well as their multiplication by their own natural methods, which are probably not those with which we are most familiar, as well as their abundance in numbers, since if seen at all they are there detected in large number and over a wide tissue area. These changes are seen much more markedly

at the margin of the growth rather than in the center, where the contents of the older portions may be easily undergoing various degenerations. There would seem also to be a reasonably definite relation between the age of the parasite and the age of the cell, between the rapidity of growth of the two cellular organisms, and between the rate of development of the parasite and the evolution of the tumor. There is also apparently a pretty constant relation between the hypertrophy of the cellular elements and the parasites which they contain. In those now frequent cases in which it has been possible to inoculate from a spontaneous tumor in a given animal other animals of the same species, one always finds on examining the secondary tumors the same evidences and characteristics of parasitic activity as in the primary tumor. Tumors are frequent among fishes, for instance, and among them one may easily detect the presence of parasitic organisms in which the fluids and tissues of fishes are known to abound. This is true also of the coccidiosis of the rabbit, which has perhaps been too eagerly studied, and from which too stringent conclusions have been drawn. Bosc seems to have had remarkable success by spontaneous and deep implantation of fragments of tumors into animals of the same species, as also by intravenous inoculation, a method also which has given quite startling results in our own laboratory at home. Inoculations from one animal to another of differing species produce lesions varying all the way from sanguinolent effusions to distinct tumors, all of which have this most important experimental result in common that they show how a fragment of tumor known to contain parasites, when inoculated into a healthy animal, produces not the ordinary type of inflammatory phenomena, but a reaction of distinct and special type which almost invariably assumes the neoplastic form. Hanau and Morau have repeatedly succeeded in inoculating spontaneous tumors from rat to rat and have even been able to demonstrate a general cancerous invasion as the result of their experiments. In 1890 Eiselsberg successfully implanted a fibrosarcoma from one rat to another. Although the dog is here, as in most other experiments, the most resistant of all animals, Wehr has succeeded in transplanting malignant tumors of the prepuce or of the vagina, and in producing a general and fatal carcinomatosis, while Klencke has also had positive results with melanosarcoma in horses.

But of still greater interest are the inoculations of cancer from man to man. Bosc alludes to three cases with which, he says, he is personally familiar, where he intimates that this had been done both intentionally and successfully, yet he is discreetly silent with regard to details. Nevertheless, there are numerous instances of veritable auto-inoculation which have come under the observation of observers of large experience. Such, for example, as transplantation of cancer from the tongue to the cheek, the stomach, etc.; and for this matter, *why is not every metastasis as valuable for our purpose as a deliberate transplantation experiment?* Moreover, take the following instances, which are most instructive in their way: Waldeyer and Quincke have reported a case in which cancer followed along the track of the trocar which had been used for tapping a case of ascites due to abdominal cancer, and Sippel has published a case of cancer inoculation along each one of the suture tracks made after extirpating a cancerous ovary. Richardson has quite recently reported a case of invasion of the axilla along the line of a puncture made for the purpose of discovering the nature of a mammary tumor, and a New York surgeon had some time ago a case where cancer developed along the lines of incision made for relieving tension in the endeavor to close a large wound made by removing a cancerous breast, these incisions having been made with the same knife used for operating upon the primary tumor. Indeed, one of the most eminent of my surgical friends has told me quite recently that he will never use the same knife for cleaning out the axilla which he has used in removing a cancerous breast. There is also the celebrated case published by Cornil, in 1891, of a woman having a large tumor of the breast in which a surgeon, name not given, yet known, after its removal inserted a small particle of the growth beneath the skin of the breast on the opposite side. Although the small wound thus made cicatrized without trace of inflammation, a nodule formed at that point within two months, whose subsequent microscopic examination revealed unmistakable cancer, the growth in each instance being a spindle-celled sarcoma, in whose cells mitotic activity was most pronounced.

Note the experiences, also, of other men. Years ago Langenbeck made a watery emulsion of a soft cancer, filtered it, mixed with it the defibrinated blood of a dog, and then injected it into the femoral vein of another dog. Two months later nodules were found in the upper lobe of each lung and a hard vascular tumor in the middle lobe, which proved distinctly cancerous and resembled the original. Follin and Lebert did the same thing with a cancerous lymph-node from the axilla and within fifteen days found in the animal small cancerous nodules in the lungs and liver. Goujon has produced melanosarcoma in small animals within fifteen days after inoculation. In 1893, Mayer published a case of successful inoculation of encephaloid cancer from man

to the white mouse. Bosc has had repeated, though not uniform success, in producing various sized tumors beneath the skin, within the abdomen, etc., and has found the best results when rigid asepsis is maintained and the inoculation made by abdominal section, especially when the fragments introduced are of considerable size and are taken from the actively growing parts of the cancer. Not the least interesting of his observations are those showing the apparent ease with which these parasites, when planted on one side of the diaphragm, traverse it and involve viscera on the other side. This speedy transference between lung and spleen, for instance, he has repeatedly noted and it well illustrates the ease of lymphatic communication through this partition. In all this work it is to be understood that there is practically uniform reproduction of the histological characteristics of the tumor experimented with. So far as I know, there are no observations anywhere reported showing that pieces of healthy tissue introduced into animals under any circumstances ever produced anything resembling a malignant tumor.

There is no reason to think that the parasites which produce sarcoma are essentially different from those which produce carcinoma. The principal differences obtain in that the parasites of sarcoma as a rule present more active changes; in other words, their life history is much shorter and more active. The giant-celled sarcomas seem to be distinguished from the round-celled principally by the presence in the former of relatively larger masses of parasitic organisms.

We may say, then, that malignant tumors are such by virtue of certain specific, *i.e.*, parasitic elements which they contain, and in many respects are analogous to the infectious granulomata, which we now know to be due to other specific organisms. Their peculiar characteristics are in the main due to more or less regular cell proliferation and distinct hypertrophy of cell elements. They manifest a tendency toward alveolar arrangement, with a preference for epithelial cells and the formation of certain cell aggregations, such as pearly bodies and cell inclusions, as well as toward cystic changes by colloid or mucoid degeneration. Practically, all of the characteristics of cancer are explainable by the now well-known activity of parasites, which tend to maintain for the most part an intercellular life, and which rarely penetrate the cells themselves except in search of pabulum or as the result of pressure.

Cancers propagate themselves in various ways: (*a*) By contact as from one lip to the other; (*b*) by continuity of tissue as in cancerous infiltration; (*c*) by transportation as when we see minute ulcerations about the nipple or along the milk-ducts in cases of cancer of the breast, and (*d*) by metastasis to a distance along lymph-tracts, while at the same time no traces of their passage along these vessels can be demonstrated. There is finally a possibility of (*e*) conveyance along the veins or blood-vessels, which certainly is unmistakable in numerous instances. Nepveu and numerous other observers have insisted that they have found cancer parasites in the blood, either from the vicinity of tumors or at a considerable distance. They claim to have seen these in the interior of the red corpuscles.

I have already alluded to the frequency both of tumors and of parasites in fishes. Bosc has referred to a most intesesting case of a young man who, in eating raw trout, had a perforation of the tongue by one of the sharp so-called bones of the fish, and who withdrew a small portion of the broken-off structure. Some days later there was continued irritation and on the fifteenth day there was extracted from a painful, sensitive area of the tongue a considerable fragment of the same bone. From now on there developed at this point an unmistakable epithelioma which grew rapidly and killed him in about a year from the time of the injury. Bosc maintains also that the small fish, which one eats entire without regard to the little bones which they contain, constitute by themselves a source of danger of infection for the stomach and the entire alimentary canal. He shows also that cancer of the stomach is extremely common where people eat freely of this kind of food. If one will take pains to study insect life minutely he may constantly find in the intestinal tract, or in the general abdominal cavity, evidences of cystic degeneration and other alterations due to the presence of micro-organisms which are often at least sporozoa. Throughout those parts of the country where cancer is frequent and where insects and lower animals are constantly present and in contact with the body, as upon the clothing, skin, etc., there would seem to be more or less of actual relation between their presence and the development of external cancers, a relation accentuated by the notoriously uncleanly habits of many of the lower classes. Take the case of a nursing mother with a more or less exposed nipple. It would be possible for one insect upon the skin in the immediate neighborhood of this possible port of entry to elaborate any number of spores or micro-organisms which might serve as infecting organisms. The contaminated fingers and a contaminated water-supply might also serve as means of transport. The rôle which bed-bugs may play was demonstrated by Morau with small animals some years ago and was described in a paper published by myself last year.

Let us ask again, Is cancer actually contagious? Answer in the affirmative would seem to be dictated by such cases as the following: Kuhn has reported the case of a woman who contracted an encephaloid cancer of the finger while caring for a cancerous cow. Hyatt, in 1885, reported a case of inoculation of melanotic sarcoma from horse to man, and Gross claimed to have seen two cases of transmission of cancer from domestic animal to man. Juergens has reported accidental inoculation of epithelioma from a fowl to the thumb. Conversely Budd has reported the instance of a pet dog which contracted cancer of the tongue from licking the cancerous lip of his master. Bosc states that animals living in laboratories where cancer experiments were frequent became themselves affected. Evidences of communication from man to man are numerous. Lusitanus long ago, for example, reported a case of three boys who presented each a cancer of the breast after having for a long time slept with their mother who had a similar disease. Smith has cited the case of a London hospital surgeon who was affected with cancer of the tongue after having taken into his mouth some of the discharge from a cancerous breast. Tranmission to husbands of cancer from wives affected with uterine cancer have been reported by numerous surgeons, and Guéniot has collected reports of twenty-eight such cases. Budd refers to the fact that at least five French hospital surgeons have died of cancer. Emson died of cancer eight months after having injured himself during an operation upon a cancerous patient. Two years ago Guermonprez reported the case of a physician who suffered from cancer at a point where had existed an acne pustule which he had infected during an operation for scraping a cancerous uterus, and the reporter himself suffered for a long time in a similar way. It is notorious that the skin and the various orifices of the body, including the pylorus, the os uteri, etc., are the most favored sites for cancerous development. This is to be explained not alone on embryological grounds but because they are the most exposed of all the parts to infection. One could multiply arguments and statements of this kind indefinitely were he to hunt through literature for the purpose. Surely enough has been already stated to reasonably prove the thesis upon which the second portion of this paper is based.

Lastly, let me invite your special attention to work recently done and projected in our own State. Last year, as the result of persistent efforts on the part of a number of individuals, professional and laymen, both in and out of the Legislature, the Legislature of New York appropriated a small sum for the purpose of "equipping and maintaining a laboratory" devoted to this kind of research. The money was placed at the disposal of the Medical Department of the University of Buffalo, which seems to be located in a region where cancer is more prevalent than in any other part of the United States. The laboratory was at once instituted and put in operation, the writer of this paper being made its Director; and the pathological work was soon placed in charge of Dr. H. R. Gaylord. The equipment of the laboratory is of the very best and the personnel of its working staff admirably adapted to the work in hand. Were this the proper place I could tell you much of their zeal and untiring effort in the work. The primary object of this institution is a determination, if possible, of the nature of the disease, secondary to that, of course, being whatever may be accomplished for its medication and cure. The heartiest cooperation of the profession has been publicly invited and already in many instances obtained. The closest relations exist between the laboratory itself and the clinical opportunities which the university affords, so that by this means there may be the most careful study carried on at the same time of the patient himself and of the specimen removed. The work so far as projected includes everything that may be done in the way of clinical study of cases, especially those which are under the personal observation of members of the laboratory staff, a most careful study of the pathological and histological elements found in every fresh specimen removed, a carefully conducted bacteriological examination with systematic endeavor to cultivate in every known culture-medium whatever living parasites may be obtained. Just so soon as means and space are afforded it is intended to conduct also most minute investigations into physiological chemistry, including chemical and spectroscopic examinations of all the fluids, chemical analysis of secretions, etc. How much of real value may be accomplished by such study is briefly foreshadowed, for instance, in the paper of Moraczewski (*Virchow's Archiv*, vol. 139, page 385) upon the amount of chlorin and phosphorus in the blood of cancer patients, who showed that while in almost all forms of anemia there is a reduction of the amount of phosphorus, in the anemia of cancer there is a relative increase in the amount of chlorin. The value of a careful determination of this and various other similar problems in diagnosis is simply inestimable and is all in the direction of facilitating earlier diagnosis. If we are ever to have a successful internal remedy for cancer we must learn to recognize cases earlier than is at present possible and every method of this kind must be assiduously cultivated. Such a problem as the above, or the alleged presence of sugar in

the blood in sarcoma, or peptone in the blood in carcinoma, etc., need to be all worked out anew. So soon also as the State places sufficient means at command it is intended to institute a series of examinations of whatever specimens may be sent us, just as at present in various city laboratories suspected sputum or exudate is examined for the determination of diphtheria, tuberculosis, etc.

It is, of course, altogether too soon to enter upon any detailed or systematic report of results obtained. To attempt anything of this kind now would be premature and unfortunate. I do want to say this, however, that results obtained already within the past six months have been almost startling, or even dramatic, and give promise of great advance in our knowledge in the future. In virtually every case of cancer yet examined where we have had access to the fresh specimen it has been possible by improvements in technic, which are due to the ability and ingenuity of Dr. Gaylord, to find bodies which cannot be other than parasites present in vast numbers. These are undoubtedly the same bodies which some observers in time past have called cell-degenerations, others fat-globules, but which are now quite generally recognized as parasites; though opinion is still divided as to whether they are sporozoa or fungi. They can now be demonstrated in our laboratory to any one who will take sufficient interest in the problem to come and see for himself. Their life history is now being carefully studied both by culture and inoculation work with results that are in some respects exceedingly satisfying and in other respects exceedingly promising. It will be enough for the present if I say that both cultures and inoculations have been so often successful as to leave no doubt in the minds of those who are doing this work that cancer is unmistakably a parasitic, *i.e.*, an infectious disease.

NASAL CATARRH IN CHILDREN; ITS CAUSE AND TREATMENT.

By CLARENCE C. RICE, M.D.,
OF NEW YORK;
PROFESSOR OF RHINOLOGY AND LARYNGOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

(Concluded from page 363.)

We come now to atrophic rhinitis, and this is by no means an uncommon affection. How frequently we find, even in children five and six years of age, both in dispensary and private practice, evidences that an atrophic process has commenced. We rarely see this condition at a younger age, but from the sixth year on we should say that it is present in some degree in ten per cent. of our cases. We do not often see the extreme condition of atrophy and dryness before young adult life, but in ten per cent. of the cases in children we find that the nostrils are too roomy because of shrunken turbinated tissues, and the mucous membrane generally has a grayish appearance, and is dryer than normal; the secretions, too, are no longer sufficient to keep the nasal passages moist, and we detect a tendency to the formation of small crusts. I know that many writers contend that atrophic rhinitis does not commence much before the twelfth year, but I frequently see the early stages of it in children six years old. The question has never been satisfactorily settled whether atrophic rhinitis may not be a later stage of hypertrophic trouble. It seems to me that in the majority of instances this is not true, but rather that there is in these cases from the beginning a special predisposition to atrophy. If atrophic rhinitis were often a later stage of a hypertrophic process we would all have abundant opportunity of witnessing the period of transition from one process to the other. I believe the same conditions can in one child produce a hypertrophic process, and in another an atrophic one. We frequently see remaining in fairly well advanced cases of atrophic rhinitis, in children twelve years of age, some enlargement of the third tonsil, although there is a strong tendency in these cases to atrophy of all tonsillar tissue. The conditions of life certainly have an important bearing upon the development of atrophic rhinitis because we see it much more frequently in dispensary practice than among the better classes.

The great disturbance of the mucous surfaces during the eruptive fevers undoubtedly determines many atrophic catarrhs. Such a condition as a pharyngeal vault blocked with adenoids which constantly create acute coryzas and cause the nostrils to be filled with a mucopurulent secretion would naturally contribute largely to the causation of atrophic rhinitis. We have here mechanical, physiological, and chemical causes at work which together are quite competent to destroy the epithelial covering, to diminish the blood-supply, to compress the mucous glands, and to produce atrophy. It does not seem necessary to place too great importance upon constitutional tendency when such potent local causes are present to devitalize mucous and submucous structures. Atrophic rhinitis occurs more frequently among the poor than among more fortunate people because in the first instance the nasal passages are apt to be wholly neglected, nor are post-nasal adenoids or enlarged faucial tonsils removed. Once the nostrils are thoroughly closed and the secretions become decomposed nasal bacteria are able

[1] Read before the Section on Laryngology and Rhinology of the New York Academy of Medicine, November 23, 1898.

to attack the nasal tissues. Why is it not possible in the condition of obstructed nostrils just described that in the child of healthy surroundings in whom the nasal passages are partially cleaned, hypertrophic changes take place, while in the neglected patient the extreme unsanitary conditions of the nostrils tends to atrophy?

There is no time in this paper to describe pathologic appearances and symptoms, nor is it necessary, because you are all perfectly familiar with the appearances present in an atrophic rhinitis. There is no question in my mind but that very many cases of atrophic rhinitis could be prevented or aborted by thoroughly treating catarrhal conditions when they first appear in babies and young children.

I have never believed that the term ozena, either in children or adults, should be applied to a special disease. It seems to me rather to be the proper name of a symptom, that is, a fetid odor, which accompanies many conditions. It does not require much consideration in connection with diseases of children, although Carig says that ozena extends back to earliest infancy and that family practitioners are familiar with cases at the age of four. A large number of dissections have been made by Zuckerkandl[1] with the object of ascertaining if ozena might not be a sort of congenital atrophy or congenital anomaly of the nose, but he was not able to substantiate this. Störk believes that ozena results from nasal gonorrhea and so dates from birth, or that it is a manifestation of late hereditary syphilis. The majority of writers prefer to think that it is a symptom of such various causes as a suppurating pharyngeal tonsil, decomposed pus in the accessory sinuses, necrotic bone, foreign bodies, collections of leptothrix masses in the post-nasal space, or the decomposition and retention of secretions anywhere in the nasal passages. Grünwald says that "clinical ozena is made up of a variety of suppurative processes." I see in the writings of many authors a disposition to the belief that atrophic rhinitis and ozena are synonymous, the latter being an extreme type of the most advanced stage of the former. If ozena is a special disease, that is, depending on a special germ and always producing characteristic pathologic changes it has up to the present time not been clearly recognized. Using the word ozena in its original sense of an offensive discharge as first used by German authorities it certainly represents not a disease but a symptom. Bacteriology would naturally decide as to the existence of a special disease called ozena and make the differential diagnosis between it and atrophic rhinitis. Several investigators believe that the bacillus mucosus or the bacillus of Loewenberg and Abel is the cause of ozena. There is no reason, however, why this bacillus should not develop in any purulent or mucopurulent secretion. A theory that ozena is a natural sequence to an atrophic rhinitis is based on the belief that in an atrophic process the bactericidal power of the normal secretions is greatly diminished or lost; hence, in a given case of atrophic rhinitis a bacteriologic test which would show Abel's bacillus in large numbers would be the only scientific method of making the diagnosis between an atrophic rhinitis and the condition known as ozena.

I am sure I have said enough to make it plain that I believe enlargement of the pharyngeal tonsil is more frequently the cause of chronic nasal catarrh in children than any and all other conditions connected with the nose and throat. I was glad to find in Dr. Holt's book, in the chapter on "Adenoids," the statement that "it is a very common and by general practitioners a much-neglected condition and is the source of more discomfort and the origin of more minor ailments than almost any of the pathologic conditions of childhood." This adenoid enlargement is common to all classes of children under all conditions. It is very probable that the exciting cause which creates this enlargement is neglected nasal catarrhs and the acute coryzas accompanying the eruptive fevers, and that as soon as the nasal chambers become blocked by swelling and discharge and mouth-breathing becomes necessary the post-nasal adenoid increases rapidly in size. Enlargement of the faucial tonsils is usually secondary to that of the pharyngeal tonsil. Enlargement of the pharyngeal tonsil is sufficient to cause congestion, thickening, and catarrhal discharge of the entire mucus surface from the nose to the smaller bronchial tubes.

In bringing to a close our remarks in regard to the causation of nasal catarrh in children in its various forms I should like to emphasize my belief that ninety per cent. of the cases of so-called chronic catarrhal rhinitis are caused by enlargement of the post-nasal lymphatic tissue and the resulting nasal obstruction. We believe that true hypertrophic rhinitis in children is rarely seen and that deviations of the septum, except from traumatic causes, are conditions which seldom provoke a chronic catarrh. It is our belief, also, that the presence of post-nasal adenoids is sufficient to constantly occasion acute attacks of rhinitis which eventually become chronic, more often in an atrophic than in a hypertrophic form. In most cases if the adenoids are removed by operation fairly early, the hypertrophic changes which seem to exist in the occluded nostrils will

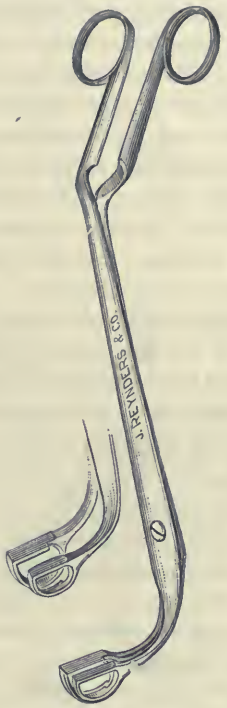
[1] Zuckerkandl, *Normal und patholog. Anat. der Nasenholen*, Wien, 1882.

disappear and the nasal passages will become practically normal.

If, then, post-nasal growths and enlargement of the faucial tonsils are so frequently the cause of the various forms of nasal catarrh in children the treatment would seem to be very clearly indicated. It is almost impossible to use douche or spray satisfactorily for cleansing purposes in occluded nostrils until enlargements of the pharyngeal tonsil have been removed by operation. We have never known any internal medication to be sufficient to reduce such enlargements, and it seems to me a waste of time and a harmful policy to delay operation while attempting to improve the general health of the child even by such excellent remedies as cod-liver oil and iron. You are all so familiar with the disastrous results of long-standing cases of post-nasal adenoid that it is unnecessary to even advocate their removal by proper operative measures, that is by the forceps, or curette, or both. A most excellent discussion on this subject will be found in the "Transactions of the American Laryngological Association" for 1898, in which will be found the views of many experienced physicians. Mouth-breathing children should receive prompt attention, and obstructions should be removed before hearing is impaired, the shape and expression of the face altered, the lung tissue restricted in volume, chronic bronchitis occasioned, and the general constitution impaired for all time. If it is impossible to examine the post-nasal space with a mirror, and it is a difficult thing to do in a small child, I am in the habit of making the diagnosis with the curette itself. If there is no enlargement of tissue no harm is done; if there is, the curette will find it and remove it, and then proper directions can be given to the parent for cleansing the nostrils and delaying irritation. It is a painstaking operation to excise faucial tonsils and to *thoroughly* eradicate post-nasal growths. It is not pleasant to have children brought back after operation still breathing through the mouth, and to find some part of the pharyngeal tonsil remaining.

It is not within the province of this paper to describe in detail the operation for the removal of adenoids. I think it is usually best to give an anesthetic, and I prefer ether because I consider it safer than chloroform. I have performed the operation a great many times, and have had no difficulty with ether. A very important caution in operating is, I think, to proceed slowly, and to wait for hemorrhage to cease from one point before removing tissue in another. As there is an abundance of time it is never necessary to excise both faucial tonsils at once, but is better to wait a few moments until the bleeding from the first has stopped and later the nasopharyngeal tonsil can be removed. A mouth gag should be used, secretion wiped away from the

FIG. 1.



Cutting forceps for the removal of adenoids.

pharynx, and first the cutting-forceps (Fig. 1) should be carried to the roof of the upper pharynx, and a

FIG. 2.

Adenoid forceps.

large portion of the tonsil removed with this. Perhaps the cutting-forceps should be introduced two

or three times until almost all the tissue has been removed, and then the remainder can be taken away with the curette (Fig. 3). There are three ways of determining if all tissue has been removed; I make it a point to use the curette until the surface feels perfectly smooth as the instrument is pushed up and down. The finger, too, will be of assistance in determining whether any tissue remains, and in exceptional cases it will be feasible to use the post-nasal mirror. If the faucial tonsils are very large I think it is better to remove them first in order to get increased breathing space before the nasopharyngeal tonsil is removed. If the operation is thoroughly done and good drainage is established there will rarely be any septic results; but if the tissue is only partially removed it is possible that middle-ear inflammation, or follicular tonsillitis, or inflammation of the lymphatic glands will ensue. I do not often prescribe a nasal wash directly after the operation, because I have never felt that there was any necessity when the operation was thoroughly done and good drainage established.

Perhaps we should say, in passing, that there are a few cases, usually traumatic, in which at the tenth or twelfth year there is sufficient deviation of the nasal septum to require removal of the projecting surface. Once all obstructions are removed the treatment of nasal catarrh resolves itself into proper cleansing and the application of disinfecting, protecting, and sedative remedies. It is quite as important to study *how* the application of medicines can be made to the sensitive mucous membrane of children in the most comfortable manner as it is to select the drugs themselves. We think that with proper instruments for atomizing and for inhalations remedies can be carried to the upper air passages in an efficient manner without the necessity of forcibly swabbing the throat of a resisting child with brushes. Sprays or applications which are strong enough to produce irritation should never be carried into the nostrils. Cleansing with proper alkaline sprays and protecting either with disinfecting powders or oils seem to me to be the proper objects to be accomplished. In some children a simple one-bulb atomizer filled with Seiler's or Dobell's solution accomplishes the purpose, but if this produces sneezing then the nasal douche cup should be substituted, the liquid always warm, and the child's mouth always kept open to prevent the entrance of the medication into the Eustachian tube. Such solutions as Seiler's and Dobell's can to-day be improved by the addition of a small percentage of peroxid of hydrogen or of thymo-formal or some similar preparation. The addition of one-half of one per cent. of cocain to such cleansing washes does not make a perfect chemical combination, but the effect of the cocain is obtained and it reduces swelling and sensitiveness so that the wash can more thoroughly perform its work. Its addition is most necessary in the acute coryzas of children accompanying the eruptive fevers; one-half of one per cent. is sufficient. A teaspoon or a soft bulb ear-syringe will sometimes be found more useful than either the atomizer or the nasal douche cup. I have sometimes been in the habit of using a steam inhalation in children who very strongly resisted all attempts to wash the nasal passages. Of course this is most applicable to children in bed suffering from acute disease. The entrance of the steam liquefies the secretions so that

FIG. 3.

Curette for the removal of adenoids.

after a time they dislodge themselves, unless there is great obstruction from inflammatory swelling or chronic enlargement of tissue. Most of the steam inhalers are of the type of the old croup kettle. The Underwood Company furnish an elaborate one; Whitehall & Tatum's evaporizer No. 3 (Fig. 4) is good and the very cheap benzoinol inhaler may answer the purpose. I am in the habit of using some one of the following preparations—tar, carbolic acid, cresoline, eucalyptol, menthol, terrabine, oil of pine needles, etc. This method of inhalation is particularly admirable for the attacks of catarrhal laryngitis which accompany acute coryza, but I have

been in the habit of prescribing it occasionally for cases of chronic nasal catarrh where the secretions are tenacious and abundant.

After the nostrils have been cleansed a non-irritating disinfecting powder or some one of the solutions of oil can be placed in the nostrils with benefit. The powder I employ most is some one of the compound stearates made by McKesson & Robbins and combined with boric acid, aristol, alum, menthol, etc. The protection furnished by such a powder allays irritation and diminishes congestion and secretion. They should not be used where there is atrophic disease, as they are too drying. In this class of cases oils containing a

Fig. 4.

Steam evaporizer for use in cleansing the nasal passages of children.

weak solution of some one of the volatile substances is preferable. I think we obtain by the rapid evaporation of such drugs as thymol and eucalyptol a cooling of the mucous surface which is really an astringent effect without the irritation of any of the old-fashioned irritating astringents. A few drops of spirits of chlorform can be added to this oily solution. We constantly have trouble with our atomizers in spraying oily solutions. I am not at all satisfied with the ordinary oil-atomizer and see no reason why they should not be manufactured on the same plan as those in use for watery solutions, except that they must be coarser. It does not seem to me of value to endeavor to discover more new remedies for the treatment of nasal catarrh in children, but rather to recognize the importance of finding and removing any obstruction which impedes respiration and which constantly produces the acute coryzas and chronic nasal catarrhs. Once the nostrils are free, cleansing and protection will suffice. Nor is it necessary to enumerate a large number of drugs for the treatment of atrophic catarrh in children because the disease as a rule is not far advanced and cleansing and mild stimulation will usually keep it in abeyance. Empyema of the sinuses tends to rapid recovery as soon as the nostrils are made free, and it is hardly necessary in such a general paper as this to refer to the evident treatment of such cases as syphilitic ulceration and necrosis.

Make the nasal passages sufficiently free for nasal respiration, prescribe the proper unirritating, cleansing solutions, protect inflamed mucous surfaces with soothing powders or oils, and Nature will make strong and successful efforts to restore normal conditions in children.

CLINICAL MEMORANDUM.

A CASE OF ARTERIOSCLEROSIS: NECROPSY.

By HERBERT MAXON KING, M.D.,
of Grand Rapids, Mich.;
Physician to Butterworth Hospital.

On October 15, 1898, there came under my observation the following case which, while presenting nothing particularly new to pathology or symptomatology, is still in some respects sufficiently instructive to make a brief report worth while.

The patient was a man about seventy-one years of age, born in Ireland, who had lived for upward of fifty years in this country. He was a veteran of the Mexican War, had been subjected to almost all conceivable vicissitudes of climatic exposure, had all his life been a hard-working man in the capacity of cook on river steamers, and in military camps, at various times had been in the retail liquor business and, in short, up to the day before he consulted me had always been actively at work, having come to me directly from a military camp where he was employed as cook. He claimed, and I believe truthfully, never to have tasted an alcoholic beverage of any sort, never to have had any venereal disease, nor to have been confined to bed a day by illness.

His family history was very meager; his mother died at the menopause from an unknown cause. His father disappeared during the Civil War and was presumably killed in battle. One brother is living and in good health. He had had another brother and one sister, but knew nothing about them. According to his own statement his illness dated from about two weeks before he consulted me, when he became conscious of rapidly failing strength, great difficulty in the performance of his duties, shortness of breath, occasional dizziness, and muscular weakness (he had previously been a powerful man). During the previous few days he had noticed an increasing distress referable to the region of the heart amounting at times to pain. Upon inquiry I found that during the last few years he had voided urine more frequently than formerly, rising several times during the night for the purpose, but I could not determine that the amount passed in twenty-four hours was increased to any appreciable extent.

Upon examination I found him to weigh upward of 200 pounds, five feet nine inches in height, well propor-

tioned, broad shoulders, thick neck, small round head and, considering his age, of excellent muscular development, but with rather an excess of adipose. The special senses were not impaired. Aside from a sense of anxiety and "nervousness," which increased to a painful degree upon the approach of sleep, his mind and nervous system seemed normal. At all points the lungs gave a resonant percussion-note and were normal to auscultation. The area of heart dulness was slightly increased, but owing to the amount of fat intervening I could not definitely locate the apex-beat except when he stood inclining forward; it was then in the fifth interspace and within the nipple line. Auscultation of the heart revealed the most remarkable feature of the case. The first sound was replaced or obliterated by a loud, distinctly musical murmur occupying the whole systole and ending abruptly with the second sound. At the apex the musical quality of the murmur was most apparent, resembling in fact the ring of a low-pitch tuning-fork. This musical quality gradually changed as the stethoscope approached the point of maximum intensity, *i.e.*, the second right interspace close to the sternum where it was lost in a loud systolic churning sound, but at other points along the great vessels of the neck, subclavian arteries, thoracic aorta and even at the sides of the chest as low as the diaphram, the musical murmur could be distinctly heard. The spleen, liver, and kidneys were not palpable. The skin was anemic with that peculiar pallor nearly always met with in chronic heart and kidney diseases. There was slight edema of the lower extremities. The tongue was slightly coated but moist. He said that appetite and digestion were normal. The radial pulse was 40, very small, and not easily compressible. Temperature normal. The urine voided at the time of the examination was highly colored and albuminous. The centrifuge sediment contained a few hyalin and granular casts, leucocytes, and some kidney epithelium. The quantity of urine was too small to obtain the specific gravity. Quantitative analysis of the blood resulted as follows: Erythrocytes, 3,350,000 to the c.mm.; leucocytes, 7500; hemoglobin, 60 per cent.; color index, 0.89 per cent.

A provisional diagnosis of aortic stenosis and cardiac hypertrophy with an acute exacerbation supervening upon chronic diffuse parenchymatous nephritis was *allowed* after considerable hesitation, and with, I confess, much doubt. I did not think it probable from my observation that the myocardium was seriously affected, but I was by no means certain that there was not an infectious endocarditis notwithstanding the absence of temperature and leucocytosis.

The patient was kept under as close observation as was possible but allowed to go home and visit me at my office for two days, during which time I was unable to procure a sufficient quantity of urine to make a complete analysis or even to determine the specific gravity. He grew perceptibly weaker, his pulse falling to 36, but temperature still normal, and on the morning of October 17th, he went to the hospital. That night he was very restless and slept at intervals during a few moments, waking suddenly with great anxiety and sense of smothering.

On October 18th his pulse fell to 22 in the forenoon, never rising higher than 28, while his temperature reached 99.2° F. His skin, nails, and lips were frequently cyanotic. I had ordered all his urine saved, and the first twenty-four hours' urinalysis resulted as follows: Quantity in twenty-four hours, 12 ounces; reaction, acid; color, very dark; transparency, clear with considerable sediment; specific gravity, 1025; total solids, 330 grains; chlorids, 16 per cent. bulk; sulphates, 2 per cent.; phosphates, 8 per cent.; urea, 15 grains per ounce, 180 grains in 24 hours; albumin, 5 per cent.; peptones, absent; sugar, absent; bile, absent; indican, negative; diazo reaction, negative. Microscopic examination: Centrifuge sediment — Casts, few granular and hyalin, with an occasional epithelial; blood, absent; pus, present in considerable amount; crystals, urates, few; epithelial cells, from kidney and bladder.

From this urinalysis I was obliged to modify my diagnosis of the kidney lesion, and left it an open question to be decided at the autopsy. On the morning of October 19th the patient had what appeared to the nurse to be a mild uremic convulsion (probably muscular spasm from interference with circulation) and the edema increased slightly. His pulse was 40 all day, temperature normal, cyanosis at times marked. From this time on his condition grew rapidly worse. The urine, however, showed improvement under diuretic treatment. On October 20th, the quantity was 14 ounces; specific gravity, 1025; total solids, 385 grains; urea, 231 grains; albumin, 7 per cent. October 21st, quantity, 21 ounces; specific gravity, 1022; total solids, 508 grains; urea, 388 grains; albumin, 5 per cent.

Periods of mild delirium alternating with periods of consciousness, during which there was extreme anxiety and "nervousness," continued throughout. Of pain, however, the patient never complained, and the only subjective symptom was the "smothering sensation" which he invariably referred to the region of the heart.

On the night of October 23rd the patient was violent, but more from fear and anxiety than from delirium. On the morning of the 24th he seemed unusually calm and was quite rational; pulse was 40, temperature normal. A few minutes after an observation for temperature and pulse, while in the act of rising from the bed with the aid of the orderly, his heart suddenly ceased beating and death was instantaneous.

The autopsy was held four hours later, before rigor mortis had set in. Unfortunately, circumstances made a complete examination impossible and the brain was left unexamined, which, in view of the anatomic diagnosis, would probably have offered points of interest.

Of the thoracic viscera the heart and aorta were of main interest. The walls of the left ventricle were hypertrophied to 1½ times the normal thickness. There had been very perfect compensation in the left heart, as shown by absence of dilatation. The aortic valve was atheromatous, one segment being hard and immobile while smaller atheromatous patches and plates were plentiful about the opening and on the other segments. This accounts for the stenosis, and if the pa-

tient had lived long enough would probably have eventually permitted regurgitation. The right heart, especially the auricle, was much dilated, and the walls very thin, rupturing while the heart was being removed. The aorta was dilated to twice its normal size and had undergone atheromatous degeneration, elasticity having been completely destroyed. The atheromatous plates were large and projected from the surface. At death the ventricles were in diastole and consequently contained clots. The atheroma and dilatation of the aorta and the condition of the valves explain the peculiar musical quality of the murmur. The orifices of the coronary arteries were both patent and permitted the free passage of a probe to a considerable distance. Sclerosis of these arteries was not evident macroscopically. The other valves were apparently normal. There was much fat about the heart but no pericardial adhesions. Aside from a considerable hypostasis the lungs and pleuræ were normal.

Microscopically, sections of the coronaries showed sclerotic changes—a thickening and projection of the intima into the lumen of the vessel with hyalin deposits narrowing the caliber, and a slight increase of connective tissue in the media. While these changes were not as pronounced in the sections as they sometimes are they served to show the nature of the arterial degeneration going on thoughout the body.

Of the abdominal viscera, the liver and spleen were not enlarged nor macroscopically imperfect. In short, nothing of practical interest aside from the kidneys was demonstrable. The kidneys were enveloped in much fat, but were neither materially enlarged nor shrunken. The capsules were non-adherent. There was considerable congestion present but no evidence of any chronic inflammatory process unless certain whitish areas which could be seen on gross section could be mistaken for cicatricial tissue, which the microscope proved them not to be. Microscopically, within the area of these patches the parenchyma was shown to have undergone extensive hyalin degeneration. The tubes were here obliterated, as were the glomeruli. Elsewhere in both kidneys there appeared to be a very normal condition of the parenchyma, and the function of the organs was certainly not organically interfered with sufficiently to have caused death or uremia. On the other hand, the arteries and capillaries everywhere showed sclerotic changes and the hyalin deposits which interfere so materially with osmosis and allow the transudation of albumin from the circulation into the urine. Thus the diagnosis of nephritis was, strictly speaking, incorrect.

Chronic interstitial nephritis does impair, and finally destroy the parenchyma of the kidney, although itself merely a local manifestation of a general arteriocapillary fibrosis. In this case, however, the disease as affecting the kidney at the time of death was comparatively insignificant and had nothing whatever to do *directly* with the cause of death except as the kidney vessels through the common sclerotic changes added their share to the general resistance to circulation and consequent impediment to the heart's action.

It has been demonstrated that the loss of resiliency in the arteries, such as is induced by sclerotic changes, immensely increases the work of the heart. With the advance of this degeneration, therefore, it becomes only a question of time when the heart must fail and death ensue from simple inability on the part of the heart-muscle to overcome the resistance, and this may occur, as it often does, when post-mortem gross appearances are very misleading and fail to disclose sufficient morbid changes to cause death. In the case presented, "heart failure" was undoubtedly the immediate cause of death, and for the reason stated, notwithstanding the compensation in the left heart.

The anatomical diagnosis, therefore, was arteriosclerosis, under which head is included atheroma and dilatation of the aorta, aortic stenosis, hypertrophy of the left heart, dilatation of the right heart, hyalin degeneration of the kidney, and arteriocapillary fibrosis. The etiologic factors were age, and a life of hard work and exposure. Among the points of interest in the case may be mentioned: First, the misleading significance of the albumin and casts in the urine. Second, the peculiar musical quality of the murmur occasioned by the aortic atheroma; and third, the comparatively sudden and rapid breaking down of an apparently splendid physique as induced by the progressive arteriocapillary degeneration after compensation had failed to meet the requirements. Strictly speaking, of course, this is only an instance of a perfectly natural death, but I am of the opinion that the occasional study of the process of even so common a law of Nature is fraught with instructive interest.

MEDICAL PROGRESS.

Embolic Gangrene of the Hand in the Course of Purulent Pleurisy,—Desbonnets and Bosquier (*Presse Med.*, January 21, 1899) saw a man, aged forty-two years, with effusion in the left pleural cavity. Fetid pus was aspirated from it. The right arm was livid from the fingertips to the elbow and was extremely painful. There was no pulsation in the radial artery. A week later the hand was black with dry gangrene due, as the authors thought, to an embolus from the lung. The pus from the pleural cavity was found to contain no other micro-organisms except tetragenic micrococci.

Delivery of a Child through the Placenta —Bourlet and Mariage (*Jour. des Sciences Med. de Lille*, January 7, 1899) report a case of confinement in which a successful termination was obtained by an unusual procedure. They found a placenta previa and as the condition of the mother was good tampons were introduced and it was decided to await the natural course of events. Later the hemorrhage was so considerable that the placenta was torn through and podalic version was performed. Soon afterward the placenta was delivered spontaneously. The uterus contracted well and there was no cause for alarm on the part of the mother. The child appeared dead. Traction upon its tongue produced no results, but after artificial respiration had been carried out for thirty minutes its color changed and it began to breathe regularly. It

was fifty-five minutes before the child breathed independently of the artificial respiration. An examination of the placenta showed that the child had been delivered right through its center.

Pulmonary Embolus after an Operation for Hernia.—BAYER (*Centr. für Chir.*, February 18, 1899) reported an unusual complication which followed a radical operation for a reducible inguinal hernia. The wound healed by primary union. On the day following the operation the patient had an even temperature of 39° C. (102° F.). On the next day there was expectoration of fresh and clotted blood. In the lower lobe of the right lung, posteriorly, there was an area of dulness and bronchial breathing. These signs lasted for a week and then gradually disappeared. The case was diagnosed as one of pulmonary embolus resulting in hemorrhagic infarction. As the hernia was not adherent the blood-clots must have started from the separation of the veins associated with the cord.

Volvulus of the Sigmoid Three Times Relieved by Operation.—FOOTE (*Bost. Med. and Surg. Jour.*, March 9, 1899) had the unusual experience of operating upon a patient with volvulus of the sigmoid three times within eighteen months. The patient was a young man with a voracious appetite and of constipated habit. The sigmoid was an unusually large and long one, and on each occasion was twisted from right to left. At the last operation the lower portion of the sigmoid was drawn across the abdomen and stitched to the peritoneum and fascia through an incision made just above the anterior superior spine of the ilium. The patient made a good recovery and up to the time of report (two months after the operation) there was no sign of recurrence.

Resection of the Transverse Colon.—SCHWYZER (*The Med. Dial*, January, 1899) removed the whole transverse colon for carcinoma, uniting the hepatic and splenic flexures by silk sutures. The tumor involved the mesocolon and gastrocolic ligament to such an extent that it was necessary to resect in addition to the structures named a portion of the stomach and a part of the head of the pancreas. The whole omentum was, of course, sacrificed. The patient made a somewhat slow but complete recovery and in two months from the time of operation he had gained seventeen pounds in weight. He was free from pain and his bowels were acting perfectly.

Diabetic Gangrene.—GUSSENBAUER (*Wien. med. Blat.*, February 2, 1899) believes that the gangrene of diabetes is not due to the presence of sugar in the affected tissues but to the ill results which follow infective processes in the diabetic. Infection of the skin in these patients is a common accident. There is usually itching and scratching, and by this means pyogenic organisms obtain entrance. In the healthy such an invasion is followed by a strong reaction on the part of the tissues of the body, but in the diabetic person the blood has lost in large measure its power of resistance, and instead, therefore, of an acute inflammation with necrosis and casting off of the slough in the skin as is seen in the ordinary boil in the diabetic individual the necrosis takes place slowly and assumes alarming dimensions. If the gangrenous parts are thoroughly removed with the knife and the principles of asepsis and antisepsis are rigidly adhered to, both at the time of operation and afterward, the wound will heal absolutely without reaction even though extensive gangrenous portions have been removed. Gangrene of the lower extremities in diabetics is like gangrene elsewhere in their bodies in that it is nothing but an infective process arising from some break in the continuity of the skin.

THERAPEUTIC NOTES.

Treatment of Carbolic-Acid Poisoning.—HARNSBERGER (*Charlotte Med. Jour.*, February, 1899) saw a boy, aged sixteen years, within thirty minutes of the time that he had swallowed 1.5 oz. of carbolic acid. He was in a limp and comatose state, the pulse being imperceptible. A pint of cream was at once poured into the stomach which was kneaded in order to mix thoroughly the cream and the carbolic acid. Dry heat and friction were applied to the legs and arms. In two or three hours consciousness returned. The administration of cream and unskimmed milk was continued at short intervals for several hours. The patient entirely recovered in two days. Harnsberger has found that an adult can take 4 drams of pure carbolic acid mixed with cream and glycerin, or with alcohol, without any toxic symptoms developing.

Suture of a Perforated Ulcer of the Duodenum, with Recovery.—TAYLOR (*North Car. Med. Jour.*, February 5, 1899) reports one of the very few instances in which perforated duodenal ulcer has been successfully sutured. The patient was a girl, aged seventeen years, who had at different times complained of indigestion. Perforation occurred about three hours after supper, and operation was performed twelve hours later under the supposition that the appendix was involved. This prolonged the operation, but when the perforation was found it was quickly sutured. Convalescence was retarded by suppuration along the numerous gauze drains but was ultimately complete.

Operative Treatment of Varicose Veins of the Leg.—MARTIN (*Therap. Gaz.*, February 15, 1899) believes that the three methods of operative treatment of varicose veins of the leg at present in vogue all have their proper application. If the varix is of moderate degree and the vein is dilated high up, high division between ligatures performed under cocain is worth trying. If this fails multiple ligation or multiple small excisions are indicated. If the veins are enormously distended and tortuous, and particularly if they contain sacculations and thrombi, total excision is indicated. All of these operations should be followed by two-weeks' rest in bed with the leg placed upon a splint. The patient should wear a carefully applied bandage for at least a month.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 1, 1899.

EXPECTANCY OF LIFE AFTER TRACHEOTOMY, IN AMERICA.

In our column of "Notable Books," two weeks ago, reviewing Professor Landouzy's "Les Serotherapies," we laid special stress on that distinguished authority's teaching that practically no children that have been tracheotomized live to be adults. We are glad to learn from letters of Drs. Jacobi and "H.", published this week, that in America clinical experience with tracheotomy has no such ultimately fatal prognosis. Despite all that our much-lamented compatriot O'Dwyer did for laryngeal stenosis by his invention of intubation it is still at times absolutely necessary to perform tracheotomy. It would be discouraging to the surgeon to foresee that this meant inevitably a shortened life to the little sufferers even in the event of present recovery. We would welcome the details of others' experiences with tracheotomy for they will serve the very useful purpose of setting an extremely practical and important subject in its proper light, one, too, in which American ideas have been of special service to medicine and to humanity.

COMPARATIVE LONGEVITY OF DOCTORS.

Some recent French statistics show that out of every 1000 persons who have reached the biblical term of seventy years there will be found 43 clergymen, 40 farmers, 33 workmen, 32 soldiers, 29 lawyers, 27 professors, teachers, or educators, and only 24 doctors. It has, of course, long been known that the mortality among doctors is much higher than among other professional men and that their expectation of life at any given period is much less. As the collection and collation of statistics grows more exact, however, this difference against the doctor proves to be greater than was at first thought to be the case.

Infectious diseases and pulmonary affections are the two forms of fatal illness that especially add to the mortality among physicians. The statistics emphasize the necessity of care on the part of the physician in the handling of such cases; familiarity with contagious disease begets a contempt for its dangers. Physicians as a rule are notably careless of their own health. The exactest precautions in these matters, far from savoring of cowardice, are the expression of the highest qualities of that natural instinct for self-preservation which must characterize the members of the race who survive as the fittest, if they are to properly fulfil their mission in the struggle for life.

THE INCREASE OF CANCER.

Those are startling words that occur in Dr. Roswell Park's article on "A Further Study into the Frequency and Nature of Cancer" in this week's issue. *If the present increase in the death-rate from cancer continues, ten years from now, i.e., in 1909, there will be more deaths in New York from cancer than from consumption, smallpox, and typhoid fever combined.* But that the statement comes from so worthy and conservative a source, one of our best known American surgeons, who is besides recognized as a special authority on cancer and whose investigations on the subject have added so much to our knowledge that was valuable and suggestive, we should be inclined to doubt the possibility of there being any truth in the somber prophecy.

Dr. Park is not, however, alone in his conviction that cancer is rapidly on the increase. The best English and French authorities on the subject are

agreed that the affection is much more prevalent among their respective countrymen and women than it was twenty years ago. Billroth pointed out in the early '90s how rapid was the increase of cancer cases in recent decades in the Vienna General Hospital. Nothnagel in 1897 confirmed this report for later years, and in the volume on "Intestinal Diseases," in his system of "Specielle Pathologie und Therapie," reports a conversation with Billroth just before the great surgeon's death, in which they were agreed that the increase in the frequency of cancer was noticeable, not only among hospital patients and the poorer classes, but also in their private practice and among the wealthy patients. Nothnagel finds that the experience of the last five years has only confirmed this impression.

It is evident then how important a subject the etiology of cancer is becoming. State aid has been asked for its investigation and it is clear that the object is an eminently proper one. A great question of public health, one that is every year becoming more urgent and serious, is involved. If, as Professor Park's investigations and his copious gleanings from medical literature all over the world seem to indicate, the cause of cancer is a parasite, its discovery and the investigation of its biological history would probably confer upon mankind one of the greatest blessings that medical science could bestow. The subject is a most interesting one to medical men, and while no effort should be spared to make the personal observations of every cancer case as complete as possible so that it may be of scientific medical value, every member of the profession should encourage by every means in his power the present earnest effort to make the serious investigation of the etiology of cancer one of the great problems that our Empire State shall solve for her own and the world's benefit.

THE TREATMENT OF SYPHILIS.

WE publish in this number a brief résumé of the discussion on syphilis that occupied the attention of the New York Academy of Medicine at two of its stated meetings and at an additional special meeting during March. It contains some excellent practical and thoroughly up-to-date points on this ever-old yet ever-interesting subject. Some remarks made by Dr. R. W. Taylor at the first meeting, on the early treatment of syphilis, are worthy of special attention. This well-known syphilographer insists that the popular French method so widely adopted in this country of treating the patient with small doses of insoluble mercurial preparations is often a delusion. After a certain length of time these preparations fail to be completely absorbed in the digestive tract and enough of the precious drug so potent against syphilitic processes fails to be supplied to the organism. Dr. Taylor does not found his ideas, as to the failure of absorption that eventually ensues when this method is continuously employed, on any purely theoretic or empiric grounds. He has been able to demonstrate the truth of his position by finding the drug in considerable quantities in the excreta.

In recent years we have heard more and more of the necessity of lengthening the time that a patient should be under treatment for syphilis. From two to two and one-half years it extended to three and then to four or more, and now syphilographers, especially the French, insist on five or six years of primary treatment with occasional succeeding courses of treatment. More recently there have not been wanting good authorities who say that a syphilitic patient should practically be under medical supervision for the rest of his life, and at least for a number of years should take a course of specific treatment each year.

Far be it from us to discourage the thoroughly careful and solicitous interest in a patient that all this implies. Syphilis is an extremely serious ailment, but under favorable circumstances it is completely curable. The best proof of this is to be found in the fact that there are in medical literature a number of reports of cases of infection a second time showing that the virus of the first attack had been completely eradicated. It is noticeable that most of this insistence on the necessity for long-continued treatment comes from France where the esthetic sense relating to the convenience and comfort of the patient demands the simpler, less troublesome, oral medication. From Germany, where the treatment by inunction is almost universal we do not hear so much of the necessity of almost lifelong treatment.

Dr. Taylor's suggestion that inunctions of mercury will, in the course of prolonged treatment, more efficiently keep the tissues saturated to the

therapeutic degree with mercury than the simpler method by the mouth should be borne in mind. In a recent number of *Volkman's Vorträge* Professor Neisser of Breslau, the discoverer of the gonococcus, and a thoroughly advanced yet conservative investigator of venereal diseases insists that the schmier-kur (treatment by inunctions) is better than any other method. The recommendation is all the more striking as Neisser considers that now it may no longer be maintained that the mercury is mainly absorbed directly through the skin in this method as was formerly taught. Its presence on the skin leads to its constant vaporization by the body-heat and then it finds its way into the system through the lungs. The patient is kept persistently surrounded by vapor of mercury. Neisser's recommendation that the patient shall keep indoors a good deal and that the schmier-kur is better given in winter than summer, because of the constant warmth of living-rooms at this season, are interesting and practical suggestions.

PHILADELPHIA PHYSICIANS AND TYPHOID.

We publish this week in our correspondence column, the statistics of the incidence of typhoid fever in Philadelphia during the past thirteen years. Except for the four years 1888 to 1891 there has been a practically constant increase in the number of cases that have occurred in successive years. Notwithstanding this increase there has not been, as is correctly pointed out by Dr. Cleemann of Philadelphia, a corresponding increase in the death rate per 100,000; on the contrary there has been a notable decrease in the percentage mortality from the disease. Whereas more than 25 per cent. of typhoid-fever cases terminated fatally in 1886, and more than 20 per cent. in the years before 1890, there is now a mortality of scarcely more than 10 per cent. from the disease. This decrease is practically a constant one and reaches a climax in the last year. We do not know of a higher compliment that could be paid to the medical profession of Philadelphia than that contained in the simple statement of these statistics. They speak for themselves and in no uncertain tones.

Few such opportunities for the study of typhoid fever have been given to any set of medical men as those Philadelphia physicians have enjoyed during recent years and they have been improved. It seems almost invidious to particularize, yet some of the work seems to deserve special mention. The work done at the German Hospital with the bath treatment for typhoid did more to introduce this priceless therapeutic measure to the American medical profession than any other application of this method. Dr. Keen's work on the surgical complications of typhoid is one of the few modern monographs that seems destined to be a classic in medical literature. If we may judge from advance-sheets Dr. Hare's book on the "Medical Complications of Typhoid" soon to be issued will be worthy of a place beside it.

It is clear then that anything that we have said in criticism of the medical profession of Philadelphia has not been meant to apply to them as physicians but as citizens of a great city, the custody of whose public health must be their special care and charge. Surely if the profession had as a unit done its civic duty during all these years and aroused the public conscience as it was obligated to do, the present awful condition of things with regard to typhoid would not obtain. Unfortunately the immersion in the duties of an exacting profession often keeps medical men from taking that interest in public affairs that they should. This cannot, however, be accepted as an excuse when there is a serious question of public health at issue.

Philadelphia must have improvements in her water supply. What they shall be is a subject for experts, who know the conditions, to decide but they should come without further delay. It was thought a few years ago that the new reservoirs which had been constructed would allow of the subsidence of floating particles during the storage of the water and so free it from infective material. This hope has been found illusory. We understand that the consumption of water is now so great that very little if any time is allowed for subsidence in the storage-reservoirs and that even with continuous pumping the water department is barely able to supply sufficient water to Philadelphia's increased population. It is evident then that the present state of affairs will continue from bad to worse unless something effective is done. It must be done at once. There can be no sufficient excuse for delay. Palliation is impossible, the attempt at it is criminal in

the face of the statistics: for the present year up to March 25th the deaths from typhoid 463; during the last week 563 cases and 38 deaths. Precedent and procedure and politics and red tape and bribery and chicanery must all hide their diminished heads before this horrible slaughter of Philadelphia's citizens.

ECHOES AND NEWS.

Dr. A. Martin Leaves Berlin.—On April 1st Dr. A. Martin removes to Greifswald, to take the chair of gynecology at the Greifswald University.

Influenza in Paris.—During the week ending March 23d, there were 238 deaths above the average. Grip is held responsible for the increased death-rate.

Appointment by Governor Roosevelt.—On March 22d Governor Roosevelt appointed Professor Walter Francis Wilcox of Ithaca, N. Y., a member of the State Board of Health. The appointee is Associate Professor of Social Science and Statistics in Cornell University.

Gold Medal for Professor Dewar.—The first gold medal ever given by the Smithsonian Institute at Washington, D. C., is the Hodgkins' medal which was on March 20th sent to Professor James Dewar, F.R.S., of London, in recognition of his discovery of the process by which air may be liquefied.

Dr. Senn on the Army Beef.—Dr. Nicholas Senn testified before the Beef Inquiry Board at Chicago, Ill., on March 21st to the effect that the beef and bacon served to the troops in Cuba had a bad effect on their health, that the beef was not roasted, but simply boiled and cooked too much and that it was not adapted to a daily ration, was tasteless and lacked nutritious qualities.

Guarding against Yellow Fever.—The Surgeon-General of the Marine Hospital Service on March 20th detailed assistant surgeons to the various fruit ports of Central America. The surgeons detailed carry with them instructions concerning the investigation of possible yellow fever on out going vessels. All vessels receiving certificates from the surgeons will be allowed to land their cargoes in the United States without being delayed by preliminary disinfection.

The Medico-Chi Can Grant Degrees in Dental Surgery.—The Medico-Chirurgical College of Philadelphia petitioned the courts for leave to amend its charter so as to grant diplomas and degrees in dental surgery. This was resisted by the Philadelphia Dental College on the ground of want of authority to do so. The Common Pleas Court decided in favor of the Medico-Chirurgical and the Dental College appealed from the decision. The Supreme Court in an opinion by Justice Dean, has just confirmed the decision of the lower court, and dismissed the appeal.

Lord Lister Honored.—Lord Lister has been elected Foreign Associate of the Paris Academie de Medicine. "The honor," says the *British Medical Journal*, "is the highest which it is in the power of the medical profession of France to bestow. It must be all the more gratifying to the distinguished man on whom it has been conferred from the fact that the vote for him was unanimous. Professor Koch of Berlin was elected at the same time, but in his case several of the members of the Academie de Medicine abstained from recording their votes."

Professor Koch Going to South Africa Again.—Professor Koch is said to be fitting up an expedition to go to South Africa, especially to German East Africa. His intention is to study malaria and kindred diseases more fully, especially with an eye to prophylaxis, immunization, and treatment. With malaria under control Professor Koch insists that the tropics would be perfectly habitable for Europeans and Caucasians generally. He aims also to investigate more fully and locate the exact limits of the plague focus that he found on the shores of Lake Victoria Nyanza during his previous visit to Africa.

The "Medical Record" Plays with Fire.—We are not a little amused at the New York *Medical Record* for its complimentary reference in its last issue to its "classical contemporary." Would it not be well for our distinguished neighbor, when criticizing others on so delicate a subject, to take care of its own fences in the matter of the proof-reading of Latin quotations? The quotation "ad majoram (*sic*) scientiæ gloriam" is not quite the form in which the "classical contemporary" used it. We would humbly suggest to the *Record's* appreciative Latinist that the phrase *bene facta male locata male facta* would more satisfactorily express the sense which it was intended to convey if it had read *bene facta male locuta male facta. Non ne?*

State Appropriations for Hospitals.—On March 21st it was reported from Albany that the annual appropriation bill, which has passed the Assembly, has been materially changed in form by the Senate Finance Committee. Heretofore no appropriations have been included in this bill for the maintenance of the State hospitals, and money for this purpose has been levied by special tax. It has been decided by the Senate Committee to place appropriations for hospitals in the annual appropriation bill, and provision for $5,000,000 for the care of the insane has been inserted in this bill. There is also another change. Hereafter it must be designated just what amount of the appropriation given to each institution shall be expended for salaries, maintenance and expenses; this has not heretofore been done.

School of Public Health.—The Council of New York University has set apart buildings near First Avenue, between Twenty-fifth and Twenty-sixth streets, for the use of a "School of Public Health." There is a bill in the Legislature at Albany to provide $25,000 for the maintenance of the school for the year beginning October 1, 1899. It is proposed to promote public sanitation in various ways, especially to instruct properly accredited medical and lay sanitary officers throughout the State in methods and appliances for the prevention of disease.

The public will be instructed in sanitary matters by university extension work. It is expected that a hygienic museum will be established for the collection and exhibition of all forms of sanitary appliances and models in plumbing, ventilation, disinfection, heating, clothing, and other kindred subjects to be open to the public.

The Chlorin Treatment of Diphtheria.—The chlorin treatment of diphtheria has been submitted to a test experiment at the Willard Parker Hospital, New York City, during the past six weeks. Every alternate patient ill with diphtheria received the chlorin treatment and every alternate one the antitoxin treatment. In connection with the chlorin treatment tonics and general sustaining remedies were used. Dr. Winters supervised the chlorin treatment, and Dr. Berg the antitoxin. The mortality was higher, and the patients generally seemed to be decidedly worse with the chlorin treatment than those with the antitoxin. It is the opinion of those who witnessed the results that the chlorin solution seemed harmless, but useless. It produced neither good nor bad results. The course of the disease presented the picture so familiar previous to the discovery of antitoxin.

A Case of Typhus in Massachusetts.—A Russian immigrant who landed at the port of New York about fourteen days before his symptoms appeared is reported to be lying ill of typhus at Chelsea, Massachusetts. There is no question but that the disease is epidemic in many parts of Southern Russia, the famine that has threatened the country for some months having made numbers of the people especially irresistive and liable to contract what has been under similar circumstances often called famine fever, but which is really the dread typhus. An incubation period of more than three weeks is unusual for the disease but is not unheard of. It is clear then that great caution is needed in permitting immigrants from these Russian districts to land at any of our ports and that the longest possible incubation period of the disease be allowed to elapse before they are permitted the liberty of the country. While typhus has only very exceptionally been known to rage as an epidemic among a cleanly, well-fed folk experiments in this line are eminently dangerous.

First Aid to the Injured on Railways.—We called attention some months ago to the fact that in other countries, notably France and England, railroad men were being trained in the proper giving of first aid to the injured in railway accidents, and that properly prepared and packed surgical materials were readily and quickly available for the emergencies of railroad traffic. We are pleased to note that now the importance of the system as we presented it has appealed practically to at least one corporation. It is announced that the managers of the Chicago, Milwaukee and St. Paul Railroad (we welcome the opportunity to give them due credit for their truly humanitarian action) are about to start a systematic course of instruction in the principles that underlie the giving of medical and surgical first aid to the injured. We hope that other American railroads will recognize that it is a duty they owe the traveling public to see that in case of accident, the injured shall receive prompt, well-directed, trained assistance and not the ignorant, meddlesome interference now so common.

The Operation on the Pope.—There has been a good deal of indefiniteness in the statements in the daily press as to the exact nature of the cystic tumor for which an operation was recently performed on Pope Leo. The Roman correspondent of the *British Medical Journal* gives the following details: For upward of twenty-five years the Pope had had a cystic tumor in the left flank immediately above the crest of the ilium. It was hematic in character and the size of a large lemon (correspondent says citron, but this is evidently a mistake) or fetal head. It had never given any trouble until recently when considerable pain developed in it, and toward the end of February the Pope was taken ill with malaise and rise of temperature. His physician, Dr. Lapponi, decided that he was suffering from inflammation of the cyst and called Professor Mazzoni in consultation, who enucleated the cyst March 1st. The operation was done under local anesthesia as it was not thought advisable to administer chloroform to one of the Pope's age (he completed his eighty-ninth year the day after the operation, March 2d). The Pope bore the operation very well, but it was deemed inadvisable to stitch the edges of the wound because of the pain it involved so they were brought together with plaster. His temperature fell after the operation, and the wound healed slowly but satisfactorily.

American Medical Association.—The officers of the sections at the Columbus meeting will be as follows: *Practice of Medicine*—Frank Billings, Chicago, chairman; Carroll E. Edson, Denver, secretary. *Surgery and Anatomy.*—W. J. Mayo, Rochester, Minn., chairman; M. L. Harris, Chicago, secretary. *Obstetrics and Diseases of Women.*—A. H. Cordier, Kansas City, Mo., chairman; W. D. Haggard, Jr., Nashville, Tenn., secretary. *Materia Medica, Pharmacy and Therapeutics.*—Thomas H. Stucky, Louisville, Ky., chairman; Leon L. Solomon, Louisville, Ky., secretary. *Ophthalmology.*—Casey A. Wood, Chicago, chairman; Charles H. Williams, Boston, secretary. *Laryngology and Otology.*—Emil Mayer, New York, chairman; Christian R. Holmes, Cincinnati, secretary. *Diseases of Children.*—Henry E. Tuley, Louisville, Ky., chairman; L. D. Boogher, St. Louis. secretary. *Physiology and Dietetics.*—J. Weir, Jr., Owensboro, Ky., chairman; Lee Kahn, Leadville, Col., secretary. *Neurology and Medical Jurisprudence.*—Frederick Peterson, New York, chairman; Hugh T. Patrick, Chicago, secretary. *Cutaneous Medicine and Surgery.*—W. T. Corlett, Cleveland, Ohio, chairman; J. M. Blaine, Denver, Col., secretary. *State Medicine.*—Arthur R. Reynolds, Chicago, chairman; W. P. Munn, Denver, Col., secretary. *Stomatology.*—George V. I. Brown, Milwaukee, Wis., chairman; Eugene S. Talbot, Chicago, secretary.

The "Cure for Pneumonia."—The newspapers reported

some three weeks ago that a cure for pneumonia had been discovered by Professor Wasserman working in Professor Koch's Laboratory in Berlin. The item proves to be the usual newspaper canard with perhaps a shade more of foundation than there is ordinarily in newspaper accounts of supposed new discoveries in medicine. What Dr. Wasserman did publish was an account of some researches on immunity with regard to the pneumococcus which he has been conducting for some time. We gather from the *Deutsche Medicinische Wochenschrift* of March 2d, in which his article appeared, that his aim was to find the comparative immunizing value of the blood-serum and of extracts obtained from the different organs and the bone-marrow of immunized rabbits. He concludes that the organs contain no productive substances while the bone-marrow is rich in it, holding more even than is contained in the blood-serum. The protective substances are formed, therefore, in the bone-marrow whence they pass into the blood to be mainly carried in solution in the serum. Dr. Wasserman lays no claim to have made any discovery which can be utilized in the treatment of pneumonia in human beings. His paper is, like preceding papers of his that concerned themselves with the immunizing substances produced in tetanus, a distinct contribution to the general subject of immunity, but much more work will have to be done in this line before his discoveries can be utilized practically in therapeutics. Dr. Wasserman himself would, we are sure, from what we know of the thoroughly scientific character of his work have been the last to produce the impression the newspapers have given the results of his recent investigations.

William W. Van Arsdale, M.D.—At a special meeting of the Medical Board of Mt. Sinai Hospital, held March 18, 1899, the following resolutions were adopted:

The Medical Board of Mt. Sinai Hospital has learned with sorrow of the death of Dr. William W. Van Arsdale which occurred at Atlantic City on March 17, 1899. Dr. Van Arsdale had endeared himself to all the members of the medical staff by the lovable traits of his character and earned their respect by his eminent professional attainments and efficiency.

Resolved, That in the death of Dr. Van Arsdale the Medical Board has lost one of its most valuable and respected members, the institution a skilful surgeon and able scientific worker; that the sympathy of the members of the Medical Board be extended to his family in their sad loss; and finally, that these resolutions be spread on the minutes and published in the MEDICAL NEWS, *Medical Record, and New York Medical Journal.*

Resolved, That a copy of these minutes be sent to his family. (Signed.) Arpad G. Gerster, M.D., William F. Fluhrer, M.D., Committee.

Sixth International Otological Congress, 1899.—This congress is to be held in London, August 8th to 12th, under the Presidency of Dr. Urban Pritchard. The British Organization Committee, which numbers over 70 members from Great Britain and the Colonies, has Mr. A. E. Cumberbatch for its treasurer, and Mr. Cresswell Baber for its Secretary-General. The meeting will be held at the examination hall of the Royal College of Physicians of London, and Royal College of Surgeons of England, and the following details have been arranged: On Monday evening, August 7th, a preliminary reception will be held by the president elect. On August 8th, 9th, 10th, and 11th, the congress will be in session, and will be followed on Saturday, August 12th, by an excursion for members and their friends. The official languages of the congress are English, French, German, and Italian. The subscription, to include a copy of the transactions, is fixed at £1, to be paid to the treasurer, Mr. A. E. Cumberbatch, 80 Portland Place, London, W., before the opening of the congress. The subject chosen for special discussion is "Indications for Opening the Mastoid in Chronic Suppurative Otitis Media," which will be introduced by Professor W. MacEwen of Glasgow, Dr. H. Knapp of New York, Dr. Luc of Paris, and Professor Politzer of Vienna. A museum of specimens and instruments relating to otology, shown by members, will be a feature of the meeting. Communications regarding the museum should be addressed to Mr. A. H. Cheatle, 117 Harley Street, London, W. Intending members of the congress are requested to send their names to the Honorable Secretary-General as soon as possible, and in any case *not later than May 1st.* Titles of communications, together with a short abstract of the same, to be sent to the Honorable Secretary-General by the same date. According to the regulations of the congress, no papers shall exceed fifteen minutes in reading, therefore all long communications should be read in abstract.

Protests to the Legislature.—Protests against restricting the work of the New York Health Department in the production and sale of antitoxin have been recently made as follows: To the Committee on Cities of the Assembly and Senate of the State of New York.

WHEREAS, the Department of Health of New York City during the last few years has established a high standard of work in the prevention and treatment of infectious diseases, especially diphtheria, with the resulting reduction in mortality of zymotic diseases from thirteen per thousand to five and a fraction, and the reduction in the deaths from diphtheria and croup from 2870 in 1894 to 922 in 1898, and

WHEREAS, the scientific investigation carried on in the laboratories of the Department of Health have been of great value to the medical profession and to the people, not only of this city but of the whole country, and

WHEREAS, the products of these laboratories have been regarded by the medical profession of this city of very high standard, and

WHEREAS, Assembly Bill No. 451 if enacted would materially restrict and limit the work of the Department, and

WHEREAS, it is not in our opinion in the interest of the public good and should not become a law,

THEREFORE, we, the members of the Medical Board of New York Hospital, respectfully protest against the

passage of this Act, as inexpedient, harmful, and opposed to the interests of the people of the City of New York. (Signed) George L. Peabody, M.D.; A. Brayton Ball, M.D.: F. W. Murray, M.D.; W. H. Draper, M.D.; R. F. Weir, M.D.; Samuel W. Lambert, M.D.; Louis A. Stimson, M.D.; William T. Bull, M.D.

March 11, 1899.

The undersigned members of the Medical Board of Roosevelt Hospital desire to enter a protest against the passage of Assembly Bill No. 451 as a measure which would restrict and limit the admirable work of the bacteriological laboratories of the Department of Health of New York City and as a measure which is not in the interest of the people of New York City. (Signed) George L. Peabody, M.D.; George H. Tuttle, M.D.; Charles McBurney, M.D.; Francis Delafield, M.D.; W. H. Draper, M.D.; Robert F. Weir, M.D.; Wm. H. Thomson, M.D.

March 11, 1899.

CORRESPONDENCE.

A DENIAL THAT TUBERCULOSIS FOLLOWS TRACHEOTOMY, AS CLAIMED BY LANDOUZY.

To the Editor of the Medical News.

Dear Sir:—In a review of Professor Landouzy's "Clinical Lessons in Serum-therapy," which recently appeared in the Medical News the question of the expectation of life after tracheotomy is discussed, and the statement made that tuberculosis nearly always carries off tracheotomized patients within a comparatively few years after the operation. To quote further, "He now repeats the conclusion, and in the light of his riper experience and continued observation on the subject, it must carry great weight. Simon, of Paris, who has passed his life among children, does not know of a single living adult who had been tracheotomized as a child."

Such statements cannot go unchallenged, at least in New York. The undersigned is acquainted with a medical man who has been in active practice for the past fifteen years, and who, when but a few years old, had a rapid tracheotomy done upon himself with a penknife by the attending physician. He is in excellent health, and does not present any evidence of tuberculosis.

A miss of eighteen presented herself but a few months ago, and was introduced as a patient upon whom the writer had performed tracheotomy about fourteen years ago. The adopted mother with considerable pride stated that the young lady had an excellent voice and sang in a choir.

Third instance: rapid tracheotomy by Dr. D., fifteen years ago; tardy recovery because of infection of wound; the young lady was in excellent health when last heard from, about half a year ago.

In view of the reputation of the authors referred to, and the weight which their statements carry, the above experience may be of interest and worthy of a brief notice.

H.

209 East 17th Street, New York,
March 20, 1899.

THE LONGEVITY OF TRACHEOTOMIZED CHILDREN.

To the Editor of the Medical News.

Dear Sir:—As you characterize on page 340 of your issue of March 18th, Landouzy's book on "Serum Therapy" as one of "unusual interest," there is a possibility that unsophisticated readers may take his statements, many or all, as absolutely correct. At all events, it may be difficult to distinguish between those which may be taken for granted, and such as permit of modifications.

The distinguished author expresses the opinion that "in practically all cases tuberculosis carries off tracheotomized patients within a comparatively few years after the operation," and Simon is quoted as not knowing "of a single adult who had been tracheotomized as a child" (Medical News, p. 342). It is not for me to look for an explanation of the singular experience of the two famous teachers. My own, however, differs from theirs. A young man whom I tracheotomized in 1861 turned up suddenly, having for many years lived in Texas, with an extensive necrosis of the humerus some fifteen years ago, and was operated upon by Dr. F. Lange. After his recovery he returned to his State. Some four years ago I met quite accidentally a man whom Dr. Ernst Kraikowizer had operated upon forty years previously. During the last two years two gentlemen came up to me—one on a railroad train, the other in the residence of a patient—to show their cicatrices and renew an acquaintance interrupted some thirty-five years. I admit I saw nothing surprising in their being alive, nor can I see the reason why a child with laryngeal diphtheria should not share the average opportunities, after recovery.

NOT A CASE OF HYDROPHOBIA.

To the Editor of the Medical News.

Dear Sir:—In the edition of the Medical News, dated March 18th, there appeared the report of a case under the heading: "An Interesting Case of Hydrophobia; Recovery."

It seems to me that this title is rather confusing as all undoubted cases of hydrophobia have been fatal. To prove that a case was one of hydrophobia we must either find by tests that the offending animal which bit the patient was mad, or by making tests from the brain or spinal cord of the victim prove him to have died from rabies. These tests are made by inoculating other animals, and are the only sure means of proving the absence or presence of rabies. If we cannot do this we must at least prove that the person has been bitten within six months, and by the symptoms of the disease demonstrate that the case was probably hydrophobia. If the patient dies we may presume it to have been a case of hydrophobia, but without more proof we could not report it as an undoubted case of the disease. If the patient should live it seems to me we should have to assume the position taken after the recovery of a case of supposed tuber-

cular meningitis, that is, that there was a mistake in the diagnosis.

In the case reported as hydrophobia the history of the bite is obscure and occurred at least a year or two before the disease developed. No authentic case reported of man or animal has had an incubation period of more than six months. Then there was no history of the offending dog. The history of the case is not like one of true hydrophobia, as people do not in that disease have to be held down, make no attempt to bite, and have no *fear* of water.

I should say that the case was one simulating hydrophobia, or of hystero-epilepsy. Yours truly,

FOLLEN CABOT, M.D.

NEW YORK, March 24, 1899.

TYPHOID IN PHILADELPHIA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your remarks upon my letter of the 12th inst. you did not reply to my challenge to furnish facts or statistics to prove your assertions with regard to the typhoid mortality in Philadelphia that "matters have grown worse not better in the last fifteen years," and "the last year is the worst of the ten." Instead, you refer me to the Philadelphia health reports to give the impression, I presume, that these reports confirm your careless utterances.

This is what I find, bringing the statistics down to the end of "the last year," 1898. (Annual report Board of Health of Philadelphia for 1897, page 70.):

Years.	Deaths.	Ratio per 100,000 Inhabitants.	Ratio for 5 years.
1884	662	71.3	....
1885	610	64.2	....
1886	618	63.6	....
1887	621	62.4	....
1888	785	77.2	65.7
1889	736	70.7	....
1890	666	63.6	....
1891	683	64.0	....
1892	440	40.2	....
1893	456	40.8	55.8
1894	370	32.4	....
1895	469	40.2	....
1896	402	33.8	....
1897	401	33.0	....
1898	566*	44.6	36.5

These figures show that up to the end of last year the typhoid mortality of Philadelphia in the previous fifteen years quite steadily, and in an increasing ratio, decreased from 65.7 in the first period to 55.8 in the second, and to 36.5 in the last. This contradicts your first assertion. It is also demonstrated that there were three years in the last ten "worse" in their mortality than last year, namely, the earlier years, 1889, 1890, and 1891, the numbers 736, 666, and 683 being respectively greater than 566. This contradicts the second assertion.

RICHARD A. CLEEMANN, M.D.

PHILADELPHIA, March 20, 1899.

* The report of the Board of Health of Philadelphia for 1898 not having yet been published, the figures for that year were obtained from the Registration Office. The whole number of deaths reported from typhoid fever during 1898 was 639, but 73 of these were of soldiers in the hospitals who had been brought from distant camps, and are to be subtracted to arrive at the true number of deaths to be credited to Philadelphia.

[When we received the above we asked our correspondent to send us statistics giving the total number of cases of typhoid fever that had been reported in Philadelphia for each of the last fifteen years. He did so for the last thirteen years, the others not being available, but asked that these statistics be not incorporated in his letter. We give them below. We think they make perfectly clear what is the basis for our statements that the condition of Philadelphia with regard to typhoid has *grown worse, not better, in this last fifteen years, and that the last of the years is the worst of them all.* After all, it is the number of cases of typhoid that occur, not the deaths from the disease, which shows the infective quality of Philadelphia's water and the need for reform. One awful year, 1889, approached last year in the number of cases reported, and the years just before and after it are notably above the average, but otherwise there is shown to be a steady progressive rise in the number of typhoid cases. This increased incidence of the disease is much more than proportionate to the increase in population during the same period. The decrease in the death-rate per 100,000 during these fifteen years, as given by Dr. Cleemann, only shows that Philadelphia physicians have known how to take advantage of their wonderful opportunities (the best that have been vouchsafed to any set of medical men anywhere in recent years) to make great practical advances in the treatment of the disease, and so lessen the mortality.—ED.]

Years.	Cases.	Years.	Cases.
1886	2079	1893	2519
1887	2488	1894	2357
1888	3573	1895	2748
1889	4631	1896	2490

STEAM STERILIZATION.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—The valuable article on sterilization written by Dr. Theodore Dunham which appeared in the MEDICAL NEWS of March 4, 1899, has been of much interest to surgeons, and has aroused the question in the minds of some of us if the sterilizers in general use in our hospitals are entirely satisfactory. I think in regard to most of these sterilizers that the question can be answered in the affirmative.

A series of experiments made some six or seven years ago when pressure steam sterilizers were first introduced into the Presbyterian Hospital, showed the same results as those obtained by Dr. Dunham when sterilizers of a cylindrical form were employed. It was found that when the sterilizer was in the shape of a cube the results were different, and numerous tests made at that time proved to us that even when the steam was introduced at the bottom the registering thermometers placed at the bottom, in the center, and at the top, at the expiration of ten minutes, showed practically the same degree of heat. Since the publication of Dr. Dunham's paper it was thought that perhaps these observations were not correct, and in consequence I have recently made the following tests of the steam sterilizers which we now use in the

Operating Pavilion of the Presbyterian Hospital. These tests were repeated on three occasions and the results were indentical:

(*a*) A registering thermometer was placed on the floor, another on a shelf in the center, and another at the roof of the sterilizer. At the expiration of ten minutes after the gas-stove was lighted each thermometer registered 240° F. (*b*) The thermometers were arranged as before, but the sterilizer was filled with dressings, the center thermometer being tightly rolled in a bundle of gauze and placed in the metal box. At the expiration of ten minutes the upper and lower thermometers registered 240° F., and the one enclosed in gauze registered 238° F. (*c*) The thermometers were placed as in *b*. At the end of twenty minutes each thermometer registered 245° F.

For some years I have been using in my office a sterilizer of German make in which the steam, as Dr. Dunham suggests, enters at the top of a cylinder and emerges through a tube at the bottom into a vessel filled with cold water. The temperature does not reach as high a point as that in the hospital sterilizers of American manufacture but the heat is uniform throughout. Some experiments which have been made for me by exhausting the air by means of an air-pump, before turning the steam into the sterilizer, have convinced us that there is no special advantage in any such contrivance.

Dr. Dunham has wisely chosen a subject which I feel sure is of great interest to surgeons, and many of us feel indebted to him for his investigation in this special line of work, which is of such vital importance to all operators.

Yours very truly,

ANDREW J. McCOSH.

NEW YORK, March 24, 1899.

THE BERLIN TUBERCULOSIS CONGRESS.[1]

To the Editor of the MEDICAL NEWS.

DEAR SIR:—The "German Central-Committee for the Erection of Sanitaria for Consumptives" has issued a call for a Congress to be held in Berlin, Germany, May 24 to 27, 1899, for the purpose of discussing the subject of tuberculosis. The Congress will meet in the new building of the Imperial Diet, and is under the patronage of Her Majesty, the Kaiserin, while Prince Hohenlohe, the Imperial Chancellor, will serve as Honorary President. All of the German States, also local authorities, medical faculties and societies, and all corporations interested in fighting tuberculosis have been requested to send delegates; all foreign countries represented at the Imperial Court have also been invited to take part. The United States Embassy has been requested to extend a cordial invitation to American physicians to become members of the Congress, and the same invitation has been extended through other missions to physicians of other nationalities.

As basis for discussion papers will be presented as follows: (1) "Distribution and Extent of Tuberculosis," by Geheimrath Koehler, Director of the Imperial Health Office, and Geheimrath Krieger of Strassburg; (2) "Etiology," by Professors Robert Koch and B. Fraenkel of Berlin; (3) "Prophylaxis," by Professor Gerhardt and Generaloberartz Schjerning of Berlin; (4) "Therapy," by Professors von Ziemssen of Munich, and Schroetter of Vienna; (5) "Sanitaria," by Herr Gaebel, President of the Imperial Insurance Office, Berlin, and Dr. Dettweiler of Falkenstein.

Following the presentation of the two leading papers (limited to twenty minutes each) in the respective divisions, there will be a general discussion, speakers being limited to ten minutes each. All papers and remarks are to be in German, although the chairman is empowered to make exceptions during the general discussion.

All persons interested in this subject of tuberculosis are eligible for membership; membership cards (20 marks—nearly $5) are to be obtained at the office of the Congress (Bureau des Organisations-Komites, Wilhelm Platz 2, Berlin, W.) and entitle the holder to a copy of the "proceedings." An early registration is requested.

The writer has been requested to furnish a list of Americans to whom special invitations to the Congress should be sent. He has complied with this request, so far as his personal and professional acquaintance with specialists in this line has permitted, and has also suggested to the committee that invitations be sent to the various medical societies and faculties. There are undoubtedly many American practitioners especially interested in tuberculosis, and possibly some laboratory workers, whom he has overlooked. Should any such person desire to attend the Congress, yet prefer to receive a personal invitation, the writer will be pleased to forward the name of such person upon proper introduction to the Executive Committee of the Congress. As "proper introduction" will be considered a letter from any recognized medical, scientific, or veterinary faculty, or society.

CH. WARDELL STILES, PH.D.,
Scientific Attaché, U. S. Embassy.

BERLIN, GERMANY.

[1] Written at the request of Dr. Pannwitz, General-Secretary of the Congress, and forwarded simultaneously to several American journals. The medical, veterinarian, and scientific press is requested to call the attention of its readers to this Congress.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

THE BILL FOR AN APPROPRIATION FOR PURE WATER DEFEATED—THE RELATION OF THE BILE TO INFECTIOUS DISEASES—SURGERY OF THE BILIARY PASSAGES AND GALL-BLADDER—THE RED-CROSS SOCIETY IN CUBA—SALARY POSITIONS IN THE BUREAU OF HEALTH AND THE NEW MAYOR'S POWER—A NEW CORONER AND A NEW CORONER'S PHYSICIAN—OBITUARY—HEALTH STATISTICS.

PHILADELPHIA, March 27, 1899.

SELECT Council on Friday last defeated the bill to appropriate $3,200,000 from the $11,200,000 loan for the improvement, extension, and filtration of the water-supply, notwithstanding the presence of a delegation of twenty-five or thirty members of the Citizens' Emergency Committee on Water and resolutions and communications from every important commercial, educational, and scientific association in the city. It is the opinion of those in a position to know that the beginning of any measures

looking to the relief and improvement of the water-supply has, by this action of councils, been put off for many months. Of the thirteen councilmen who voted against the measure nine are known to favor the infamous Schuylkill Water Bill, whereby the city's rights were to be bartered away, and a set of men more inimical to the city's welfare would be hard to find. The work of securing pure water must now be begun all over again involving weeks or months of delay and each week means 400 or 500 preventable cases of typhoid, each week exceeding the preceding. Over 500 deaths have occurred since January 1st and this week's number of cases exceeds any number so far recorded, but when will the limit be reached? What will the spring and summer bring forth? If an average cost of caring for one patient is placed at $200, surely a low average, and 400 cases occur each week, it means that every month of this year has so far cost the population of Philadelphia about $320,000, or for January, February, and March about $1,000,000 in round numbers. And yet Select Council (save the mark) refused to spend $3,000,000 which the city, by popular vote, demanded last year. Your correspondent honestly believes that serious trouble with the populace will eventually compel the politicians to come to terms and the day of rioting and uprising seems not far off if we are to place any credence in the press.

Dr. A. C. Abbott, City Bacteriologist, at a joint meeting of the Pathological Society and the Academy of Surgery, held March 23d, read a paper on "The Relation of the Bile to Infectious Diseases." He said that at the outside the bile has no germicidal action and is of doubtful antiseptic value. It is antitoxic, protecting against the disease from which the animal it is taken from is suffering. Sometimes organisms persist in the bile, however, when they no longer exist in any other organ. One function of the bile, that of preventing putrefaction, is accomplished, according to Dr. Abbott, more by the stimulation of peristalsis which hastens elimination before putrefactive changes occur than by any direct antiputrefactive action. It does not prevent the growth of bacteria and itself quickly undergoes decomposition. Frazer has shown that it can neutralize venoms and that inoculations of bile are preventive against them. Koch found that bile from animals suffering with rinderpest (?) when injected into other animals prevents the disease. Two explanations are given of the way in which this is accomplished: First, by attenuation of the micro-organisms, and secondly, Koler's explanation that no attenuation occurs but immunity is due to the growth of these specific organisms at the point of inoculation and by their growth the bile causes a tissue-wall to be built around them through which they cannot escape. Dr. Abbott thinks much is to be learned by different means of studying the bile, treating it as a living substance instead of a dead, just as a study of "dead" blood would fail to reveal the true character of living blood.

"Surgery of the Biliary Passages" was the title of an article by Dr. John B. Deaver in which he divided into classes the many pathological conditions found in the gall-bladder and its ducts. He presented statistics from 40 cases of his own, 10 of which were in males and 30 in females. Of the 40 cases 14 were due to cholelithiasis, the most common affection. Of the 40 there were 34 recoveries, 5 dying from shock and 1 from hemorrhage. An interesting statement by Dr. Deaver was that 50 per cent. of women with "corset" livers have gall-stones. Out of 100 post-mortems held at the German Hospital 6 subjects were found incidentally to have gall-stones. Dr. Deaver outlined his method of operation, one feature being his belief that an incision through the rectus muscle leaves less chance of a subsequent hernia and another, his infallible rule to leave a temporary fistula.

Dr. Joseph McFarland in the discussion said that post-mortems in general show gall-stones to be present in about seven per cent. of all cases. He said the largest number of gall-stonse ever found was 7802 and the largest single stone was 6 inches long by 2½ inches in diameter.

Dr. W. M. L. Coplin and Dr. Mears discussed the question. In answer to a question concerning the supposed agglutinative action of bile after typhoid infection Dr. Abbott said he had not studied it. No mention was made of the interesting communication of Cushing last spring in which he discussed this agglutinative reaction and its possible relation to the formation of gall-stones by the clumping forming nuclei for their production and one case which he reported where typhoid bacilli were found in the gall-bladder though there was no history of typhoid fever.

The Philadelphia Red-Cross Society has been asked to forward three ambulances, one wagon, and a pair of mules for work in Cuba. The work which was interrupted by the war to a certain extent is to be vigorously pushed and a Red-Cross Hospital will be established in Havana it is hoped.

When Mayor-elect Ashbridge resigns the office of coroner, on March 31st, Deputy-Coroner Dugan is to take his place. The appointment was made at the request of Mr. Ashbridge, for Mr. Dugan has been connected with the Coroner's office for nearly twenty years. The position of coroner's physician, which Dr. Henry W. Cattell resigned on his appointment as director of the Ayer Clinical Laboratory at the Pennsylvania Hospital, is to be filled by Dr. William S. Wadsworth, now Resident Pathologist at the Presbyterian Hospital and Assistant-Demonstrator of Physiology at the University of Pennsylvania.

Officials in the Board of Health, or as it is now, the Bureau of Health, are wondering when the ax will fall. The position of Chief Medical Inspector which Dr. J. Howard Taylor now holds at a yearly salary of $2300, and that of City Bacteriologist, filled by Dr. Abbott with $2000 a year, are two of the most important positions which medical men fill. Besides these are numerous assistants at salaries ranging from $2000 down to $700, and the position of Physician to the Municipal Hospital, for which Dr. Welch receives $2000 yearly. Counting the civilian positions the political power with which Mayor Ashbridge has been invested may be imagined for these positions are, of course, more numerous than the medical ones.

The total number of deaths occurring in Philadelphia,

as reported at the Health Office, for the week ending March 25th, was 530. The total number of new cases of contagious diseases was 58, reported as follows: Diphtheria, 49 cases with 18 deaths; scarlet fever, 29 cases with 2 deaths; *typhoid fever, 563 cases with 38 deaths.*

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE FINANCIAL STATUS OF THE GREAT LONDON HOSPITALS—THE NEW "ORDER OF MERCY"—SPREAD OF INFLUENZA—THE NEW SCHOOL OF TROPICAL MEDICINE—THE "LANCET" UP IN ARMS.

London, March 16, 1899.

The unsatisfactory condition of the financial status of the great London hospitals, which we noted in our last letter, has been extensively commented upon by the public press during the past week. The situation at present is that there is a yearly discrepancy of some $500,000 between the even reasonably regular income of the ninety-three great hospitals—which consists chiefly of voluntary subscriptions—which has to be made up by legacies, bequests, and special donations, the aggregate of which often varies as much as $400,000 between one year and the next. The Prince of Wales' Fund was started two years ago for the purpose of making good this deficit, but so far is it from doing it that its utmost annual income, both from the interest of its sinking fund and from regular annual subscriptions, barely reaches $150,000, or less than a third of the deficit. Worse still, there is a growing conviction that much of this money instead of being clear gain, is actually drawn from the former voluntary contributions of the hospitals, attracted by the glamor of royalty and the interest of the last new thing. This has become so obvious, even to royalty itself, that H. R. H. has just launched another crusade in supplement of the original fund. This is to be known as the League of Mercy, and is to consist of a grand central council and president, with a sub-council and president for each of the parliamentary districts of London and the surrounding counties, nearly 100 in all. Each of these is to have under them thirty vice-presidents, who in turn are to be the heads of committees of twenty, each number of which is to secure annually twenty shillings from as many luckless mortals. Its a sort of mixture of the House that Jack Built and the celebrated stamp scheme. It may benefit the hospitals—pray for the peace of the community.

The feature which is expected to make it "go" is, of course, that the league is thoroughly lorded and ladied, and, as far as the supply will permit, earled and countessed all over, so that, as the irreverent Radical *Daily Chronicle* remarks, it forms "the foundation of a very fashionable body, a sort of philanthropic Primrose League, affording fine opportunities for association with the aristocracy."

We wish the League every success in its noble aim, but we can hardly persuade ourselves that this mixture of fashionable philantrophy and "beggary under arms" is either the dignified or the adequate way for a great world-city to approach the problem of the support of its hospitals. The League is also to establish an Order of Mercy, with a medal which is to be awarded for gratuitous personal services in the relief of sickness, suffering, poverty, or distress, and altogether the paths of righteousness and pure charity are to be made as flowery as possible, and virtue is to be no longer left in the disgracefully destitute condition of being its own reward.

And still the influenza spreads in London in spite of beautifully mild, bright, sunny weather for two weeks past. All practitioners report the type of the disease as quite mild, and yet the death-rate keeps steadily rising from 22 four weeks ago, to 50, 74, and last week 113 deaths per week. One cannot help suspecting that as in previous epidemics influenza, like charity, covereth a multitude of sins of careless diagnosis, and that even where it is the precipitating cause of death it acts simply by striking some previous weak point in the defences of the organism, or lighting up some smouldering internal mine like tuberculosis, fatty heart, or granular kidney. No disease in the realm of nosology threatens so much and does so little or produces so large a percentage of vivid fear of dissolution with so low a death-rate.

For the most part in this epidemic the nervous symptoms seem to predominate, and many cases are scarcely recognizable until the characteristic stage of depression sets in, and, fortunately, as might have been expected from the the general absence of catarrhal symptoms, few "secondary infections" with pneumonic and bronchitic inflammations are reported. In fact, curiously enough, the total death-rate is still below the mean average for these weeks of the year, and no marked increase in the mortality from respiratory diseases has yet occurred.

Perhaps there is something in the English prejudice in favor of private enterprise and against State aid of even public schemes. While the great Chamberlain School of Tropical Medicine, which was trumpeted abroad nearly six months ago, is still meandering through the Circumlocution Office with no prospect of emergence before next October, the private Jones School at Liverpool, initiated nearly two months later, is making arrangements for its formal opening at an early date. They have just received a letter from Koch regretting that he cannot accept their invitation to be present at the ceremony, but cordially wishing the movement success, and informing them that a similar institution is about to be established in Germany.

One of the most humorous incidents of last week was the editorial protest of the *Lancet* against the alleged throwing of the Mahdi's remains into the Nile at Khartoum. It will be remembered that after the capture of the city Lord Kitchener found it expedient to order the destruction of the tomb of the Mahdi in order to at one stroke put an end to the constant prospect of a "Holy War" for the recovery of such a sacred shrine of worship, and prove to the True Believers that their alleged prophet was unable to protect his own remains from desecration. What was done with the remnants of the body is not stated, but rumor hath it that they were cast into the Nile, although it has since transpired that the skull

and several bones are now in the possession of certain officers of the victorious expedition. Of course, the Irish in Parliament, and what Kipling calls "the poor little street-bred people, who fluster and fume and brag," have been lifting up their voices in horrified protest against "desecration of the ashes of a martyr," "outrage upon the most sacred sentiments of humanity," etc. Now comes the *Lancet*, however, also in the interests of humanity, and protests, not on account of the Mahdi, but on *account of the Nile*, the crystal purity of whose crocodile-laden waters it regards as polluted by the reception of a "demd, unpleasant, decaying body," in the language of the immortal Mr. Mantalini. Such a bad example to set before an ignorant people whom we are endeavoring to train up in the paths of sanitary righteousness! As if it would for a moment occur to the devout Soudanese that any water could possibly be polluted by the sacred relics of their adored Prophet! Or, as a matter of fact, if a few pounds of carefully embalmed remains of nearly ten-years' standing could make the slightest appreciable difference in the Nile flood or to anything in it or near it, except for a few moments of bitter disappointment to the crocodiles.

The lecture season at the Colleges of Physicians and Surgeons is now in full course. Last week Dr. Brodie completed his lectures on the "Chemistry of Toxins and Antitoxins" at the College of Surgeons, and this week Dr. Parsons is giving his course on the "Comparative Anatomy of the Joints of Vertebrates." At the College of Physicians Dr. George Murray is giving three lectures upon "The Pathology of the Thyroid Gland."

ANAEROBIC GERMS IN PURULENT PLEURISY—REMARKABLE POLYDIPSIA AND POLYURIA—DEATH DURING TREATMENT WITH SUPRARENAL CAPSULES IN ADDISON'S DISEASE—AN UNOBSERVED SYMPTOM OF TABES—THE PROPER STRENGTH OF A SALINE SOLUTION FOR INJECTION IN DISEASED CONDITIONS—CAPITONNAGE FOR HYDRONEPHROSIS AND FOR CYSTS OF THE LIVER—INFLAMMATION OF THE OMENTUM DUE TO THE USE OF SILK LIGATURES—THE PLACE OF SILK IN ABDOMINAL SURGERY.

AT the Medical Society of the Hospitals, February 3d, RENDU called attention to three cases of purulent pleurisy of a putrid character in which the bacteriologic examination showed the presence of anaerobic micro-organisms either alone or in combination with aerobic germs. He obtained excellent results in the treatment of the patients by irrigations with solutions of permanganate of potassium, a substance well calculated to destroy anaerobic forms of life on account of the oxygen so easily set free from it.

AUSSET showed a boy, aged four years, who suffered from polydipsia and polyuria and an indefinite general eruption. He drank about ten quarts of water per day, passing nearly as much through his kidneys, but there was no dilatation of the stomach, and the urea in the total amount of urine passed in the day varied from 10 to 20 grams (160 to 320 grains). There was no rise of temperature and no physical signs of hysteria, unless a quick temper be accounted such. He inherited both from his father's and his mother's families, and an emotional impressional temperament. On the whole, the speaker was inclined to set this case down as one of hysteria.

VARIOT mentioned that a patient of his, a child of three years, was in the habit of drinking three liters (quarts) of fluid per day. The stomach was much dilated. There was a well-marked history of polydipsia on the mother's side of the family, and an older sister who died at fifteen months was polydipsic and polyuric. The patient died, and at autopsy there were found the lesions of sclerosis at the summit of the liver, similar to those found in hereditary syphilis.

SOUGUES, GUINON, and RAYMOND all thought the patient presented was a degenerate rather than a hysterical individual.

BARTH said that he knew a young man aged twenty years, who, in the early years of his life, drank about twenty liters (quarts) of fluid per day. He had never shown any of the signs of hysteria

At the session of February 24th, RENDU reported that a patient who had long presented the symptoms of Addison's disease had been put upon the treatment by suprarenal capsules, one fresh calf's suprarenal weighing 10 or 12 grams (about one-third of an ounce) being eaten each day. On the day following the administration of the first capsule the patient complained of pain on micturition and anorexia, and the urine contained much albumin. Nevertheless, the treatment was continued, and in a week, when the general state of the patient was apparently good, he suddenly died, but without uremic symptoms. The death was looked upon as a simple coincidence, although there was no reason why there should not be a certain danger in this method of treatment, just as there is in thyroid therapy.

BECLERE looked upon the appearance of nephritic symptoms during the treatment as a pure coincidence. He had completely cured a patient of Addison's disease by the administration for a long time of large doses of suprarenal capsules, and there had never been any evidence of toxic symptoms.

GILLES DE LA TOURETTE said that a manifestation of tabes which has hitherto escaped notice is the expression of the eyes. In such patients the eyes are bright, but are almost without expression. The speaker regarded this peculiarity as an early sign of the disease. The symptom is independent of the state of contraction or dilatation of the pupil of the eye.

At the Biological Society, February 4th, VAQUEZ and BOUSQUET announced that experiments have shown that a solution of sodium chlorid to have the least effect upon the blood-cells should have a strength of one per cent., and not .7 per cent., as is usually employed. The latter is called the physiologic solution because it contains the same amount of sodium chlorid as is found in the serum in health. Frequently in patients suffering from Bright's disease, eclampsia, and diabetes the amount of chlorid of sodium is 1.1 per cent., or even 1.7 per cent.

While the injection of an artificial serum slightly different from the serum present in the blood-vessels is not dangerous, it is easy to see that the injection of serum one-third less concentrated might interfere considerably with the osmotic tendency.

At the Academy of Medicine, March 7th, Albarran presented a young woman upon whom he had performed a new operation for the radical cure of hydronephrosis by means of implication (*capitonnage*). He reduced the capacity of the sac by suture, and by anastomosis between its lowest portion and the ureter, any obstruction to the flow of water was guarded against. The hydronephrosis was due to calculus. This was removed while the large pouches which had resulted from the obstruction to the flow of water were folded and stitched with catgut in such a manner as to greatly reduce the size of the kidney. By this method no renal tissue was sacrificed. Two months later an anastomosis was made between the pelvis of the kidney and the ureter. At this second operation it was shown that a very considerable degree of retraction had followed the implication (*capitonnage*). Three months later it was shown by ureteral catheterization that the affected kidney held only 8 grams (¼ ounce) of fluid, whereas it had formerly held 400 grams (over 13 ounces).

At the Surgical Society, January 18th, Delbet showed a patient upon whom he had performed implication (*capitonnage*) four months previously for a hydatid cyst of the liver. The entire pouch was sutured. The day after the operation the patient presented grave symptoms which were ascribed to intra-peritoneal hemorrhage, but which were really due to a hydatid intoxication. The patient entirely recovered. This is the sixth case which has been so operated upon by Delbet. The results in every instance were satisfactory.

At the session of February 1st, Delbet contrasted the results of this method of treatment with those obtained by permanent drainage (*marsupialisation*). In eight patients so treated three were troubled with a fistula for two months or more, while another, whose wounds healed, suffered from the formation of a fistula at a later period. It is evident, therefore, that drainage of a hydatid cyst is not the best form of treatment, and in all cases in which it is possible Delbet avoids drainage of any sort.

At the session of February 15th, Monod called attention to the bad results which may follow the use of silk ligatures upon the omentum. He performed a radical operation for hernia upon a male patient, resecting a large portion of the great omentum and ligating its stump with silk. He made a good recovery and left the hospital in one month apparently in perfect health. Two weeks later he come back with intense pain in the left side of the abdomen where there was a well-defined swelling, extremely painful, situated just below the left costal margin. In the center of the swelling peristaltic motion could be made out. By a second laparotomy Monod relieved the obstruction to the transverse colon caused by the epiploitis.

Reynier said that the epiploitis had doubtless been caused by a septic ligature. In order to avoid such accidents he employs catgut rather than silk.

Tuffier mentioned a case in which a large part of the omentum was resected during a radical operation for hernia. There was a large tumefaction in the left flank, but this subsided without suppuration, and in six weeks had entirely disappeared.

Guinard mentioned three cases of epiploitis following resection of the omentum. In two cases an abscess formed and was opened intraperitoneally. In the third case resolution took place without suppuration.

Pozzi said that such cases as those cited show that the use of silk in abdominal surgery is a dangerous practice. He considered it equally reprehensible to ligate the adnexa with silk, expressing the opinion that a large part of the morbid phenomena which are attributed to ovarian castration are due in reality to silk ligatures. For three years he has not used silk in abdominal surgery excepting for intestinal sutures.

Hartmann thought that the ill effects mentioned might not have followed if a smaller silk had been employed.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, March 2, 1899.

DISCUSSION ON SYPHILIS.

The President, Dr. William H. Thomson, in the Chair.

The first paper of the evening on

THE TREATMENT OF SYPHILIS IN ITS EARLY STAGES

was read by Dr. L. Bolton Bangs. He considers mercury not a specific for syphilis nor a direct antidote to its poison, but an excellent remedy for the symptoms. The most necessary thing in the treatment of syphilis is to keep the patient at the very highest level of health. Patients must live carefully and hygienically. This is the first essential. Some recover from the disease without this hygienic care but they are constantly running a great risk. At one time we thought potassium iodid as valuable as mercury but we know now that mercury sets up a fatty degeneration of the morbid products of syphilitic processes and thus leads to their absorption, while the iodids only increase absorption. Hence potassium iodid is indicated only in nervous lesions where fatty degeneration is unusual and would be harmful in states in which absorption is disturbed. Other absorbent remedies are also good on this same principle and their use should be recommended; hot baths, douches, massage, etc., all have a place in the treatment.

It must always be remembered, however, that it is patients with syphilis, not cases of syphilis that we have to treat. Every patient will have a special idiosyncrasy; in some the mouth will be often and seriously affected, in others the skin or bone and nerve lesions will manifest themselves early, etc.

As to the initial lesion Dr. Bangs always advises its

excision if it is favorably situated for removal. At least a mass of infective material is thus removed. Mercurial preparations lead to the absorption of the initial lesion so treatment should be begun at once. There are those who hesitate as to this and wait till the development of secondaries. Immediate treatment, however, keeps the patient in the best condition. As soon as we are certain of the presence of the disease begin to combat it, and as the primary and secondary lesions are the same histologically, begin treatment at once. Care is needed and the vulnerability of the patient must be consulted. There are at work in him the poison of the disease as well as the toxic drug.

As to the method of administration of the drug, by the mouth seems the best. It should be pushed to its physiological effect but should not be allowed to disturb the stomach. After a while the doses should be increased, because continuance begets custom. After administration by the mouth the method by inunctions comes next but it is hard to get patients to obey directions in this matter. When the symptoms are rapid, fulminant, and there is breaking down of tissue, subcutaneous injections should be given, but with the greatest care as death has been known to result from them.

As to length of treatment, so long as the epitrochlear glands are enlarged, in a case that has been followed from the beginning and the enlargement is known to be due to the syphilis, treatment should be persisted in. If a number of glands throughout the body are enlarged, even without a history of syphilis, suspect its presence and treat for it. Treatment should last at least three years.

DR. R. W. TAYLOR then read a paper on

THE TREATMENT OF SYPHILIS IN ITS EARLY STAGES.

This subject practically resolves itself into the treatment of secondary syphilis. Vicious methods of treatment crept in in the first half of the century; too much mercury was administered. An unfortunate, because too radical, reaction against this began about thirty years ago. The pendulum, as usual in matters therapeutic, swung too far and Ricord's methods were too much condemned and rejected. This reaction is with us yet in the treatment of syphilis by small doses of the insoluble preparations of mercury by the mouth. All these metallic compounds must be converted into peptonates and albumenoids to be absorbed and this causes a great strain on digestion. After a while they are not absorbed and this can be shown by careful analysis of the patient's excreta. They do great good at first but gradually become inert. He has for some time, therefore, given up the French interrupted method of treatment.

Treatment is indicated when the heterologous new-cell formation has begun and when the syphilitic toxins are being elaborated in the system. These processes begin when the secondaries make their appearance, so that this is the time and not before this to begin treatment. Until generalization of the syphilitic process in the system has occurred the mercury has very little to work on and does very little good. For mercury does not foster resistance to syphilitic poison in the system by anticipation but on the contrary creates a tolerance to its own action and so dulls its subsequent effect, when acuity of effect is most desired. Second, it does not suppress but retards and disturbs the order of symptoms, and this nearly always has an unfortunate effect on the subsequent course of the disease. Third, the patient should be allowed to see for himself the eruption and the enlargement of the glands. He will then realize thoroughly the constitutional nature of the disease and will follow the instructions for treatment; without the actual presence of these general symptoms he will scarcely be persuaded to submit to the inconvenience necessary for proper therapeusis. Fourth, errors as to the specificity of a supposed primary lesion are possible, even in an expert syphilologist's hands, so that it is always advisable to await the absolutely confirmatory secondary symptoms. Many a case of indurated sore has proved not to be specific and premature treatment in these cases hangs an awful cloud over a patient's life for nothing. Fifth, there is no benefit to be gained by very early treatment. Without it the course of the disease is more orderly, its symptoms more manageable; finally a very important consideration, there will be no haunting doubt left in the physician's mind as to the absolute character of the disease, if he has seen the unmistakable secondary symptoms.

When the general rash appears then is the time for treatment. In ninety-five per cent. of the cases the backbone of the disease may be effectually broken by vigorous yet judicious treatment at this time. Treatment for six months at this time is more effective than a whole year of treatment later on. It is to be remembered that syphilis runs a much severer course in delicate, nervous, anemic individuals, in the tuberculous, etc., and general treatment calculated to improve these conditions may have a place while waiting for secondaries to make their appearance. In women all syphilis seems to run a milder course and this is especially true of nervous syphilis.

It is syphilitic patients, not cases of syphilis that are to be treated, so that no iron-clad therapeutic routine for every case should be adopted. Treatment must be especially managed so as not to produce disgust or annoyance in the patient for he is already disposed by his condition to sufficient discouragement. At the beginning protoiodid of mercury in the usual doses may be given or the tannate of mercury in ½-grain doses three times a day, which has given excellent results. A fair estimate as to its effect may be obtained in fourteen days or so and the advisability of continuing the method decided. As the rash declines inunctions should be advised, as at this period the patient will be more willling to submit to the inconvenience of local treatment and so becomes accustomed to the method.

Papular and pustular lesions of hairy localities should be treated separately because of the dangers they involve of reinfection. About a dram of mercurial ointment should be used each day for fifteen days and then an interval of fifteen days allowed. The study of the excretions shows that mercury is eliminated for a month after such a course of treatment. Rest, of course, is important, not absolute rest but sufficient to keep in the

best possible general condition. A vacation at the seashore, hot and Turkish baths, but without the cold plunge, and all general hygienic measures are, of course, excellent. The administration of potassium iodid must not be delayed too long. It may be employed at first in the intervals of the mercurial treatment. It increases absorption and prevents that cell proliferation which leads to specific bone disease, pleurisy, etc.

After a year patients will seem perfectly well but no chances should be taken, and treatment should be continued in the second year for two to three months at a time with intervals of six to eight weeks so that there will be eight months of active treatment during the year.

The speaker was of the opinion that after careful, persistent treatment in this way for two to two and a half years the patient may be pronounced perfectly well. When symptoms are rapid and there is an early malignant character manifest in the disease so that tissues begin early to break down and continue to do so despite ordinary treatment, then subcutaneous injections of bichlorid must not be forgotten. They give excellent results under such circumstances and must be recognized as an efficient addition to our therapeusis of syphilis.

The next paper was on

DIFFERENTIAL DIAGNOSIS OF SYPHILITIC ERUPTIONS AND SIGNS IN THE SKIN OF FORMER SYPHILIS,

illustrated by lantern-slides and was read by Dr. George H. Fox. The illustrations gave a series of characteristic lesions of the disease as seen in a large clinical service. The multiform character of the disease was shown, yet the typical something present in practically every case despite all its multiformity, that betrayed the specific nature of the lesions was clearly brought out. The symmetrical arrangement of the cutaneous syphilides was especially illustrated. Gummatous and ulcerative lesions were pictured and the characteristics that distinguish syphilitic ulcers from lupoid or simple ulcerative processes pointed out.

The persistent circinate character of individual syphilitic lesions was brought out and the tendency of groups of lesions to arrange themselves frankly as circles, advancing at the periphery and healing at the center, or as arcs of circles or in serpiginous curves was fully illustrated. The diagnostic value of lesions in the upper third of the leg and around the knee and of scars in this region, especially when symmetrical, was pointed out. In cases without a history of syphilis the diagnosis may be made from this point alone.

Dr. R. H. M. Dawbarn in his paper on

STIGMATA OF SYPHILIS IN CHILDREN

said the mortality of congenital syphilis is so great that the best hope of treatment lies in early diagnosis of the disease. In the list presented at the last International Medical Congress at Moscow, out of 2000 cases only 25 per cent., 1 out of 4, syphilitic children survived, while out of 40 cases of acquired syphilis in children recently reported all are now living and well. The earlier treatment is instituted the better the prognosis, hence the necessity for earliest possible diagnosis. Dr. Dawbarn has collected from his own experience and the abundant literature of the subject, some 27 stigmata of syphilis that aid in early diagnosis, many of them serving to arouse suspicion of the existence of the disease when circumstances are such that it is running a latent course. Not all of them are present in any one case; most of them are not pathognomonic of syphilis, but serve only in connection with other signs to confirm the diagnosis.

Twenty-Seven Stigmata of Congenital Syphilis.

1. The description given by Diday. The syphilitic child is wrinkled and drawn in features, with a yellowish-brown *café-au-lait* color, though with it all the child may not be poorly nourished, but on the contrary may be plump and rounded.

2. Thick umbilical cord, often over long and slow to fall, leaving the child liable for a longer time than usual to septic infection through the navel.

3. Pemphigus, consisting of bullæ and blebs, at times invading the palms and soles, consisting usually of lesions vesicular in character which may be small discrete elevations but sometimes large and confluent.

4. Erythema-syphilitic roseola, invading first usually the lower abdomen, coming on commonly about the third week. Then the copper-colored patches, syphilitic pennies, as they have been called, though syphilitic farthing-pieces would be a better name. They are oftenest about the size of the babies' finger-nails. Cutaneous syphilides however, occur in only 25 per cent. of the cases of congenital syphilis.

5. Condylomata.

6. Coryza. An attack of snuffles is always suspicious in the new-born; when it persists it is almost pathognomonic. A well-known woman novelist has given great publicity to the phrase "a little old man with a cold in his head," so picturesquely descriptive of the syphilitic child.

7. Laryngeal symptoms, especially a hoarse cry.

8. Mucous patches.

9. Stomatitis especially when it becomes generalized. Hold considers a general stomatitis as a constant symptom of congenital syphilis.

10. Do not be deceived into a false sense of security as to syphilis by the absence of enlarged glands. Lymph nodular enlargement is usually absent in congenital syphilis.

11. Hemorrhages, subcutaneous or from mucous membranes.

12. White pneumonia, though this is a post-mortem sign and the specific nature of the pneumonia can only be suspected during life.

13. Hepatic enlargement but without jaundice.

14. The spleen is enlarged in over half the cases. It has been known to reach four times its normal size in three weeks.

15. The ground-glass cornea is pathognomonic. Other eye lesions occur, as iritis, but the keratitis is of most value.

16. Middle-ear disease. It is to be remembered that the Hutchinson triad of symptoms is the notched teeth,

the specific keratitis and deafness, or middle-ear symptoms without known cause.

17. Alopecia, so that the infant looks like a badly plucked fowl.

18. Orchitis.

19. Neuroses, especially epilepsy and any and all forms of palsy.

20. Bone lesions. The first and most important, the syphilitic osteochondritis of the epiphyses. Child's bones are sore. It is tender when handled. Later rickets not infrequently develops.

21. Syphilitic periostitis, the syphilitic nodes of Parrott.

22. Syphilitic dactylitis.

23. Peculiar onychia.

24. The teeth come early and decay easily and soon. It used to be said that it was unlucky for a child to be born with teeth. The foundation for the old saw would seem to be that the irritation of the osteogenic and kindred systems set up by the syphilis toxins causes early development of the teeth. Needless to say that the unluckiness of the symptom is evident in this case.

25. The Hutchinson teeth. In the permanent set of teeth the upper central incisors are pegged, apt to be separated and are notched, the enamel having disappeared from the central portion of the cutting edge. They do not always occur after congenital syphilis but only where there has been a good deal of severe and generalized syphilitic sore mouth.

26. Irregularities and asymmetry of the bony skeleton. This is often very noticeable and endures through life, constituting a stigma by which congenital syphilis may be suspected though there is no history, long years after any acute manifestations of the disease have disappeared.

27. Other enduring stigmata of congenital syphilis are bosses on the skull nodes on the long bones especially easy to recognize on the surface of the tibia, chronic fissures of the corners of the mouth or the whitish contracted cicatrices they leave after them; scars on the upper third of the legs, the remains of old syphilitic ulcers, especially significant if symmetrical.

Meeting of Thursday, March 9, 1899.

(Continuation of the Discussion on Syphilis.)

The first paper of the evening, entitled

SYPHILITIC AFFECTIONS OF THE HEART AND LUNGS,

was read by DR. LEONARD WEBER. Syphilitic affections of the heart are more frequent than those of the lungs and by a fortunate coincidence the treatment of syphilitic cardiac affections is much more successful than pulmonary syphilitic complications. Heart affections, as Adler has shown, occur alike in hereditary and acquired syphilis. In general syphilitic affections of the heart they do not occur so infrequently as is thought. The gumma or gummi, as Virchow insists it should be called, occurs quite often in the course of the disease, and endo- and peri-arteritis and endocarditis occur at times, as also a fibrous interstitial myocarditis. Gumma is the only characteristic lesion. Ehrlich has shown that hemorrhage may occur into the heart substance displacing the fibers, hampering their function, and leading to fracture of the fibers during exhaustive efforts at contraction.

Wherever there is visceral syphilis vascular syphilis also occurs and usually some syphilitic affection of the heart. The diagnosis of cardiac syphilis without external stigmata of the disease is practically impossible. When in doubt it may be made *ex juvantibus*. In young patients with irregular hearts and tendency to dyspnea with no history of rheumatism or other infection it is well not to forget syphilis. Potassium iodid and mercury will often do good. Sometimes these syphilitic heart cases in the young simulate neurasthenia very closely, or genuine neurasthenia with cardiac symptoms develops in consequence of the constitutional disease.

Among the pulmonary affections due to syphilis may be considered a proliferating tracheitis. The speaker had seen three cases of lung syphilis in women who had borne dead syphilitic children. White pneumonia and gumma of the lung are seen post-mortem but cannot be diagnosed with any probability during life. We need for the assured diagnosis of syphilitic conditions in the lungs the discovery of the syphilis bacillus so that we may demonstrate it in the sputum as we do for tuberculosis now.

PROFESSOR J. GEORGE ADAMI of McGill University, Montreal, then read a paper, entitled

SYPHILITIC AFFECTIONS OF THE LIVER IN ADULTS AND IN CHILDREN.

For the pathologist there is no distinction between the secondary and tertiary lesions of syphilis, though the division of the disease into these stages may still be useful to the clinician. Apart from the granulomata characteristic of the disease there is a generalized tissue disturbance that must be borne in mind. Syphilis in infants is congenital, not inherited. It is acquired by the fetus, not present in one of the germinal elements. As the analogy of syphilis with tuberculosis becomes more complete this fact becomes surer. There are a number of observations that go to confirm this view.

The maternal blood is carried first to the liver; if syphilis were acquired by the fetus we would expect to find this organ often affected. As a matter of fact Chiari of Prague in 122 out of 144 cases of congenital syphilis did find syphilitic affections of the liver in children examined carefully for this purpose. This view of the acquirement of so-called hereditary syphilis may seem heretical, but Professor Adami holds firmly to it. The continuation of the idea of real heredity in the matter seems but the perpetuation of a vulgar error. It is absurd to think of the germ of syphilis as latent in the ovum until the fetal period begins. Even if it were so the presence of syphilis would not be due to heredity but would be an epiphenomenon manifesting itself in a special ovum.

The most usual and earliest focal lesion in the livers of children is a collection of round cells. Comparatively early in the disease miliary gummata develop. When the liver exhibits what are usually called tertiary lesions the skin may be passing through the secondary period. Fibrosis of the liver develops relatively early. Flexner

working along the lines laid down by Adami gives bacteria a place in sclerotic changes in the liver and they play a rôle in the early development of fibrosis in syphilitic hepatitis. The fibrosis may be the result of an attempt to wall off and protect the organ from invasion or may be due to the irritation of toxins produced during the course of the disease.

Changes in the liver of children due to syphilis are much easier to classify and recognize with assurance than those of adults because the etiological problem is simpler. Other and sometimes unknown factors have not been at work and besides the time of their development can reasonably be presumed from the age of the child. The varieties of syphilitic liver affections in children are about as follows: (1) Those due to granulomatous processes or to interstitial change. (2) Minute multiple miliary gummata or isolated large ones. (3) Fibrous changes due to the irritation of toxins.

In later life the classification of syphilitic affections of the liver is not so easy. It is evident that when the secondary cutaneous lesions make their appearance lesions of the same general character are to be looked for in the viscera. These visceral changes are not, however, very noticeable or we would know more of them. Autopsies at this stage of the disease are rare and so far only the gross morbid appearances of the internal organs have been studied, the early visceral lesions being as a rule microscopical in character and not noted. This is a line of work in which great things are to be hoped for from the present universal attention to minute pathological histology.

Fagge has reported a case of indurated liver in the adult, a cirrhotic change not unlike the condition that develops in syphilitic children. It must be borne in mind that the liver is an excretory organ and as such especially liable to be flooded with the toxins of any diseased processes at work in the body. The presence of these toxins as they develop in a catarrhal hepatitis may give rise to jaundice though, of course, the jaundice may be obstructive in origin due to the pressure of enlarged glands in the hilum of the liver or to syphilitic nodular involvement of liver tissue.

Tertiary syphilis of the liver after gummatous inflammation gives rise to scars and fibroid puckerings of the organ which represent the lesions of an obsolete syphilis. In very old cases the obsolescence of the lesions has sometimes gone on to such a degree that reabsorption of the fibrous tissue has taken place so that only the puckerings remain as larval substitutes for the old process. Gummata may be large or may be small—miliary in size and may be found in the second year or may be met with long years after infection.

The hepatic lesions in the adult may be summed up about as follows: (1) Gummata. (2) Miliary lesions gummatous in character. (3) Parenchymatous hepatitis. (4) Interstitial hepatitis causing syphilitic cirrhosis. (5) Obsolete gummata. (6) Puckerings of liver substance, the stigmata that remain after obsolete gummata, though all trace of the fibrous tissue that existed here after the formation of the scar that followed the gummata has been removed by absorption. (7) Tumor-like outgrowths of liver substance simulating very closely on palpation malignant growths, and not rarely leading to mistakes of diagnosis. Usually in these tumorous formations there is an outer layer of normal hepatic tissue surrounding gummatous deposits, the pathological material at the center of the lesion being sometimes broken down or in certain stages of degeneration.

In general in adults the tendency of syphilis is toward the production of focal lesions; in children the fibroses predominate and the tendency is to the production of diffuser pathological conditions. The liver is especially affected in nearly all cases because of its importance as an organ of excretion. Hence the toxic products of the disease are delayed here during the metabolic process and effect the injury of tissue noted. In the fetus the liver first receives the blood from the placenta and so is especially liable to be affected by the disease-products from a syphilitic mother. In the liver more than anywhere else it becomes clear that it is impossible from a pathological standpoint to draw any hard and fast lines between secondary and tertiary symptoms of syphilis.

(To be continued.)

REVIEWS.

Affections Chirurgicales du Tronc. By Dr. Polaillon, Chirurgien de l'hotel-Dieu; Professeur-agrége a la Faculté de médecine de Paris. Paris: Octave Doin, 1898.

The first volume of this treatise on surgery of the trunk, published in 1896 and devoted to the thorax and its contents, has been reviewed in these columns. The two concluding volumes of this series now under consideration deal, respectively, with the surgery of the abdomen and its viscera, and the pelvis and its contents.

The work partakes of the nature of a statistical account with summaries and short observations of the most important cases. Both volumes are replete with rare and commonplace affections, many of which have been previously reported in current French periodicals.

Treatment, more than etiology or pathology, is considered, and above all, there is a striking absence of bacteriologic data; yet this deficiency is compensated for in part by the careful clinical data, being the experience of the author and his assistants for a period of nineteen years. It is, therefore, from the clinical standpoint that these two volumes commend themselves to the surgeon.

Report on the Investigations into the Purification of the Ohio River Water at Louisville, Kentucky. By George W. Fuller, Chief Chemist and Bacteriologist to the Louisville Water Company. New York: D. Van Nostrand Company, 1898.

This work, which deals principally with the bacteriological and chemical investigations of Ohio River water, both before and after filtration, is one of vast scope. All modern filters have been carefully tested and the results obtained are of vast importance to the specialist inter-

ested in the water-supplies of lage cities. It is remarkable to note what enormous advances the filtration of waters has made since the introduction of the process in London seventy years ago, and what perfection it has attained in that comparatively short interval of time.

Several chapters are devoted to a subject of considerable importance to large and small towns having need of water filtration, dealing also with the cost of the various systems and their respective efficiency. Much space is devoted to the methods of electrical purification. Chapter XV., on the "Description of the methods and devices of the water company, tested during 1897, and a record and a discussion of the results accomplished therewith," gives us the whole plan of Mr. Fuller's experiments, and the form in which they are presented is very clear and impressive.

The conclusions reached by Mr. Fuller after his most careful researches, are that the employment of coagulants, subsidence and filtration "is applicable to the satisfactory purification of the Ohio River water at Louisville," but he does not recommend the direct use of either the Warren, Jewell, or Western Systems. The appendix deals with the methods used for collection of samples and for analysis in a most concise manner. The work is well indexed, and the plates, which complete the volume, are most ably executed.

MANUAL OF ORTHOPEDIC SURGERY. By STEWART LE ROY MCCURDY, A.M., M.D., Orthopedic Surgeon to the Presbyterian Hospital and East End Free Dispensary, Pittsburgh. Pittsburgh: Published by the Author, 1898.

THE author is to be congratulated upon having produced in this small convenient volume of 336 closely printed pages more than a summary of the subject without a sacrifice of clearness in view of the terse style adopted. Definitions are concise, and classifications complete but little discussed.

The following are some of the features derogatory to the general merits of the work: The illustrations are poor and many familiar ones produced from other works are not duly credited. Among typographical errors we note "kyphose" for "kyphosis," and "coxa vera" for "coxa vara," and the the misspelling of the proper names of Burns for Bruns and Mikrelicy for Mikulicz.

Though cognizance has been taken of most of the advances in orthopedy yet gouty arthritis, habitual dislocation of the shoulder-joint, and achyllodynia receive no mention. The names of such authorities as Tallerman-Sheffield in hot-air treatment, and that of Kassowitz in connection with rickets are passed over. The treatment recommended is sound, yet we must challege such scientific vagaries as are mentioned on pp. 63 and 69, *viz.*: that tubercular abscesses can be cured by the external applications of ointments. The chapter on infantile scurvy (Barlow's Disease) is rather confused, and much of the matter therein contained is foreign to it, and belongs under the head of rickets where it is found wanting. In connection with congenital dislocation of the hip nothing is said of Lorenz's method of bloodless reduction unless we infer the author to hold the method of Paci as identical with it, which then is certainly a faulty conception. With due allowance for these deviations in this first edition we endorse this manual as worthy of the perusal of the student.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIV. NEW YORK, SATURDAY, APRIL 8, 1899. NO. 14.

ORIGINAL ARTICLES.

STYPTICIN (COTARNINE HYDROCHLORATE) IN UTERINE HEMORRHAGE.[1]

BY H. J. BOLDT, M.D.,

OF NEW YORK;

PROFESSOR OF GYNECOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL; GYNECOLOGIST TO THE POST-GRADUATE HOSPITAL, TO ST. MARK'S HOSPITAL AND TO THE GERMAN POLIKLINIK; CONSULTING GYNECOLOGIST TO BETH-ISRAEL HOSPITAL.

PHYSICIANS are consulted nearly as often about uterine bleeding as about any other gynecologic disorder, and hence it is an important question as to how such symptoms should be treated. No remedy has yet been found which will act as a universal panacea therefor; nor can this be expected, because of the different indications for the employment of remedies. The fault is not with a respective drug, which is unvarying in its action under similar circumstances. The error is with the doctor, in failing to recognize the respective indications and on that account selecting the wrong agent to meet them.

For about eighteen months past I have been using stypticin (cotarnine hydrochlorate) in my practice, and during the past ten months have recommended others to try it on various occasions when there has been profuse menstrual and irregular bleeding from the uterus. After giving this agent a conscientious trial for the time mentioned I find that some of my experience accords with that of other physicians who have reported their observations, while in some instances it is at variance. Stypticin[2] is a convenient name given to the hydrochlorate of cotarnine by its discoverer, Professor Martin Freund of Frankfurt-on the-Main, on account of its hemostatic properties. Cotarnine is a fractionation product by oxidation of narcotin, an alkaloid obtained from opium. Woehler demonstrated that narcotin, under the influence of oxidizing agents, can be separated into an acid, "opianic acid," and a base, "cotarnine," after the following formula:

$$C_{22}H_{23}NO_7 + O + H_2O = C_{10}H_{10}O_6 + C_{12}H_{13}NO_3\,H_2O$$

Narcotin. Opianic acid. Cotarnine.

As thus obtained, cotarnine is easily converted into its hydrochlorate (stypticin), which occurs usually as microcrystalline yellow powder, with an intensely bitter taste, and soluble in water, the solution becoming darker on exposure to light. Freund came to the conclusion that inasmuch as the course of the chemical decomposition by which cotarnine is obtained is similar to that followed in forming hydrastinin, its physiologic and therapeutic actions must also resemble those of the latter.

Hydrastin, $C_{21}H_{21}NO_6$, is separated into opianic acid and hydrastinin, $C_{11}H_{11}NO_2\,H_2O$—showing that cotarnine is, chemically, hydrastinin, in which, for one atom of displaced hydrogen, the methoxyl group OCH_3 has been substituted. This having been determined, physiologic, and therapeutic experiments were made. For the latter the new drug was referred to Dr. Sigmund Gottschalk of Berlin, who read a paper on the subject before the Gynecological Congress in Vienna in 1895.[1]

Physiologic Action.—For the details of experiments as to the physiologic action I refer to the valuable contribution of Edmund Falk[2] of the Pharmacological Institute of Berlin, and cite only his conclusions:

"1. In cold- and warm-blooded animals it produces paralysis by its action on the motor sphere of the spinal cord. In the warm-blooded a complete paralysis occurs late, usually only prior to death.

"2. It produces in the warm-blooded, by its action on the cerebrum, a mild narcotic state, but not sleep nor complete narcosis.

"3. In rabbits and dogs it is productive, by both internal and subcutaneous administration, of intestinal peristalsis and fecal evacuations.

"4. It has no direct primary influence in the warm-blooded on the heart, circulatory system, or blood-pressure. The effect on the heart, pulse, and blood-pressure are of secondary nature, through the influence of cotarnine on respiration: only in very large doses with long-continued artificial respiration, a weakened heart-action is produced.

"5. Its action on the respiratory center after transitory irritation is paralytic; respiration is, therefore, increased at first, but subsequently rapidly sinks to a quietus.

[1] Read at the Ninety-third Annual Meeting of the New York State Medical Society, held at Albany, January 31 and February 1 and 2, 1899.

[2] Cotarnine hydrochlorate: Yellow crystals soluble in water. Hemostatic, uterine sedative. Uses: Uterine hemorrhage, dysmenorrhea, fibroids, subinvolution, climacteric disorders, etc. Dose: 1–2½–5 grains, four times daily, in capsules or pearls. Injection (urgent cases): 1-3 grains in ten-per-cent. solution. — [Merck's 1899 Manual of the "Materia Medica," page 74.]

"6. Fatal termination is produced by paralysis of the respiratory center, but can at any time be kept in abeyance by artificial respiration."

Ronsse and Walton[1] explain the similar therapeutic properties of stypticin and hydrastinin on the theory that both drugs augment cardiac activity, and by their oxytocic properties. According to these observers the difference between hydrastinin and stypticin is that the former causes circulatory modifications more rapidly, acting on the heart and abdominal vessels at the same time, while the action of stypticin seems limited to the heart and is much later. They also find that stypticin slows the action of the heart in the frog and rabbit, whereas it exerts an accelerating influence in the dog; hence they utilized the latter animal in their later experiments. They find, contrary to the opinion of Falk and Marfori[2], that stypticin exerts a tonic action on the circulatory system. Comparing it again with hydrastinin they find this acts as a stimulant on the heart, like camphor and ether, whereas stypticin can be compared in its action on the heart to digitalis; hence the difference in their indication when these drugs are to be used in the control of hemorrhage. All observers agree that stypticin causes fatal termination by its paralyzing effect on the respiratory center.

Personal Observations.—After thus having stated the principal observations recorded as to the physiologic action of stypticin, I beg to place before you my personal experience with its therapeutic employment, most of which was made before seeing the literature on the subject. It was due to a simple request on the part of Dr. W. Freudenthal to try stypticin in cases of uterine hemorrhage, because he had seen good results from it in bleeding from the respiratory tract. The drug was supplied to me through the courtesy of Merck & Co., and a small quantity also by Professor Freund, to both of whom I hereby express my appreciation therefor.

I shall first classify the conditions in which the drug has been used by me, and then give further details:

1. Prolonged and profuse menstruation in unmarried anemic subjects, without any discernible change in the pelvic organs—nine cases.

2. Fibromyomata causing meno- and metrorrhagia —four cases.

3. Inoperable cancer—five cases.

4. Para- and perimetritis after abortion—three cases.

5. Para- and perimetritis after full-term deliveries—two cases.

6. Profuse and prolonged menstruation in multiparæ without anemia and without changed endometrium, but moderate enlargement of the ovaries —eight cases.

7. Irregular bleeding after the puerperium without retention of decidua or placenta, these having previously been removed with the curette—twelve cases.

8. Irregular bleeding after the puerperium with retention of small areas of placental tissue—two cases.

9. Hemorrhagic endometritis—eight cases.

10. Fungous endometritis—two cases.

11. Retroflexion with chronic endometritis—two cases.

12. Chronic metritis and endometritis — seven cases.

13. Irregular bleeding in multiparæ at the menopause—five cases.

14. Irregular bleeding without any discoverable cause—one case.

15. Subinvolution, present six weeks to four months after delivery—eleven cases.

16. Perimetritis and parametritis due to traumatism—three cases.

17. Bleeding during pregnancy—three cases.

The material for these observations was derived from my clinics and private and consultation practice. A few instances of patients who presented themselves in one of the clinics and did not return for observation are excluded from the list. The method of administration employed was principally per os, and the doses varied from half a grain to five grains until during the past two months, when subcutaneous injections were used almost entirely.

Having enumerated the classes, it is superfluous for practical purposes to give the details of each individual case, and I deem it sufficient for all clinical ends to describe one case of each group, and then to give the results of the respective class as a whole.

1. *Menorrhagia in Virgins without Detectable Changes in the Pelvic Organs.*—A. J., aged twenty years. Menstruation began at thirteen; had been regular for 5 months at intervals of 3½ to 4 weeks; then ceased for nearly a year, when the flow became re-established. At the sixteenth year the intervals were only 3 weeks, the flow continuing 5 to 8 days, being profuse and painful. Two days before the anticipated flow half grain doses of stypticin was administered at intervals of 12 hours. When the flow appeared the drug was given in ¾-grain doses at intervals of 4 hours during the first day without effect; on the second day 2½ grains was prescribed at intervals of 2 hours for three days, with the result

[1] Ronsse and Walton, *Archiv Intern. de Pharma.*, vol. iv, Fasc. iii and iv, 1898.

[2] Marfori, "Sur l'action biologique de la Cotarnine," *Arch. Ital. de Biol.*, xxviii, 2, p. 19.

that the flow diminished on the same day. No amelioration of the dysmenorrhea during the continuance of the flow. Total consumed, 15 grains.

The other eight patients of this group were put on doses of 1.5 grains every 2 hours for 4 doses at the first sign of the flow, with somewhat similar beneficial effect as to the quantity of the blood lost; but there was no marked decrease of the dysmenorrhea in either of the other two patients who also suffered from this symptom. In three patients the treatment was necessitated again at the subsequent period, with similar result; two remained symptomatically well, and in four the control was lost.

2. *Fibromyomata.*—In only one instance the flow was somewhat diminished, with a decrease of pain at the time of menstruation; in the others the effect was absolutely negative, despite the administration of 1.5 grains of the drug subcutaneously in the lumbar region.

3. *In Hemorrhage Due to Cancer.*—The effect was negative in each instance.

4. *Hemorrhage from Peri- and Parametritis after Abortion.*—Rosa Z., aged twenty-three years, married three years, was infected during the beginning of her matrimonial period with gonorrhea. One pregnancy with abortion at the third month. Uterus normal size; physiologic anteflexion, not freely movable; induration on either side and posteriorly; bleeding at intervals of 2½ to 3½ weeks, painful, of 9 to 12 days' duration. Administered ¾ of a grain every 3 hours; six doses without marked effect; Given 1.5 grains subcutaneously twice with marked effect; was, however, subsequently operated upon on account of the intermenstrual pain, and the inflamed adnexa removed. Of the other two patients one was improved, the other cured.

5. *Hemorrhage Due to Pelvic Inflammation after Full-Term Delivery.*—In both cases the condition was promptly ameliorated and hemorrhage ceased on the third and on the fifth day; the patients had been bleeding 10 and 12 days, respectively.

6. *Menorrhagia with Chronic Oophoritis.*—Mary D., aged twenty-three years; had had two children, the last fourteen months previously. Three months after delivery she again began to menstruate, but, whereas formerly the period lasted 3 to 4 days, it now continued 8 to 9 days, and the loss of blood was much larger. Stypticin on the first day diminished the quantity, and on the third day menstruation ceased entirely. In other cases of this class the remedy had a similar effect; in one none at all; and two patients were lost from further observation after improvement had been produced.

7. *Irregular Bleeding after the Puerperium, without Retention of Decidua or Placenta.*—In all of the cases in which, after the diagnosis of retained placental particles or decidua had been made and confirmed by operation, but which still continued to bleed, the remedy had a most astonishing effect.

Katie F., aged twenty-nine years, four days after confinement was still bleeding; examination showed the uterus to be large and soft, the cervix patulous. By curetting considerable detritus was removed; the bleeding, though diminished, still continued. Stypticin, 1.5 grains, was injected into the buttocks and repeated in 8 hours, with marked effect. Subsequently a few doses of ¾ of a grain were given by mouth, when complete cure was effected. In all the remaining cases the result obtained was similar.

8. *Irregular Bleeding Due to Retention of Parts of the Placenta.*—In these two instances, in which the patients declined to be curetted upon being seen in consultation, the drug was given in ½-grain doses at intervals of 12 hours, 4 doses, without producing any marked difference. Both eventually consented to an abrasio uteri, with prompt relief following.

9. *Hemorrhagic Endometritis.*—In this category the results from stypicin were not marked in any case until after an abrasio uteri had been made.

Frances J., aged thirty-one years; married 6 years; 2 children, normal deliveries; an abortion at the fourth month. For three months she had had very profuse menstruation, the flow lasting 9 to 11 days; then it ceased for 2 or 3 days, to begin again in the form of spotting for an additional period of 3 to 5 days. The uterus was of normal size and consistency and was (physiologically) anteflexed. No change in the bleeding was produced by the internal administration of stypticin. Then curettage was performed, also without more than temporary effect. Stypticin was then resumed with marked beneficial effect on the second day. At the next menstrual period stypticin was commenced two days before the anticipated flow, with the result of a perfectly normal flow of four day's duration. In six other cases of this class five patients were likewise treated with good results, in one of whom there was a marked improvement. In one case no effect at all was achieved, and subsequent control was lost of the patient.

10. *Endometritis Fungosa.*—The effect was absolutely negative—subsequent cure by curetting and local treatment.

11. *Retroflexion with Endometritis.*—These two cases were observed for two months, under stypticin administration, with but slight improvement as to the duration of the flow and quantity of blood lost. The trial was made solely for the purpose of watching the effect of the remedy; and, upon determining that it was without avail, the customary treatment was undertaken, with prompt relief.

12. *Chronic Metritis and Endometritis.*—Fanny F., aged thirty-five years; married 12 years; 3 children and 4 abortions, the last 2 years ago. For 18 months the menstrual period had been prolonged from 3 and 3½ days to 6 and 7 days, and the amount of blood lost during the first 3 days of the flow was very profuse. Examination revealed an enlargement of the uterus, but its consistency was unaltered; slight tenderness upon pressure during examination; the portio vaginalis was voluminous and the cervix lacerated without ectropion. The adnexa were normal. In this patient (as well as in the other six), stypticin alone was used, to observe its effect on the loss of blood, with the result that a moderate improvement resulted in one instance (the one detailed), the bleeding being reduced to five-days' duration, and the amount of blood lost on the respective days being smaller. In one instance there was marked improvement, and in the remainder the effect was *nil.*

13. *Irregular Bleeding at the Menopause.*—Our experience with patients who were in the climacteric age and suffered from irregular losses of blood, was very satisfactory.

Mrs. C., aged forty-seven years, had been losing blood in moderate quantities but at irregular intervals for 5 months, the intervals varying from 10 days to 5 weeks, the flowing lasting from 1 to 2 weeks. The pelvic organs showed no abnormal changes and the interior of the uterus was smooth. The drug was given in doses of ¾ of a grain, and the bleeding was completely checked in 3 days. There were 3 recurrences, but each time an almost immediate good result was obtained. In four additional cases the condition present was similar, and the action of the remedy did not differ materially.

14. *Irregular Bleeding without Apparent Cause.*—The following is an interesting example; and although I have seen similar instances on a few occasions yet they are of infrequent occurrence:

Florence M., aged twenty-nine years, married 3 years, no children, 1 abortion at 2½-months' gestation. Two years ago, about one year prior to her seeking advice, the menstrual period began to lengthen in duration from 2 to 3 days; gradually this time increased until it reached 2 weeks. She had been curetted and had received local treatment at other hands, with but temporary benefit. Another abrasio uteri, undertaken by the writer, showed nothing abnormal. The patient was then put upon stypticin, which had some beneficial effect on the third day. She was kept on the drug for 3½ months, and became entirely cured. Four menstrual periods have since passed normally. Fluid extract of hydrastis had had no effect.

15. *Post-puerperal Bleeding Caused by Subinvolution.*—In this the beneficial action was very marked. As an illustrative example the following case is cited:

Sarah C., aged twenty-eight years, mother of three children, was delivered eleven weeks previously of a medium-sized male child; all periods of the labor and puerperium were normal. She left the bed on the seventh day and one week later at intervals the still existing sanguineous discharge increased somewhat in quantity for a few days, then gradually ceased, the complete cessation continuing two weeks, when the bloody flow was reestablished and was quite profuse for 5 days, and then became less for 5 or 6 days before cessation. The next interval was of 3-weeks' duration and was followed as before. When the patient was seen she had been bleeding 4 days. Within 24 hours, upon the administration of ¾ of a grain of stypticin every 2 hours, the amount of blood began to be diminished, and the flow ceased entirely in 2½ days. In only one instance of the eleven in which the remedy was used was the result unappreciable; with this exception the therapeutic value for such indication was all that could be desired or expected.

16. *Meno- and Metrorrhagia Resulting from Traumatic Peri- and Parametritis.*—We had opportunity to observe three such cases due, in one instance, to dilatation of the cervix, and in two other instances to intra-uterine applications. In these cases successful treatment was effected with stypticin; in all three the flow of blood began to diminish twenty-four to thirty-six hours after the commencement of the drug, and was arrested completely within three and four days.

17. *Slight and Irregular Losses of Blood During Pregnancy.*—In three patients these losses were stopped with stypticin.

My house surgeon, Dr. Buddeke, used one hypodermic injection of stypticin after a delivery of placenta previa, with immediate effect on the bleeding. This would make it appear that the drug does possess some oxytocic properties; but two instances of slight bleeding at the third and at the fourth month of gestation, noted by the same observer, in which the bleeding ceased after stypticin, without abortion being produced or without even producing the slightest pain, would again throw doubt on its effect in this direction.

Conclusions.—In reviewing the action of the drug one must come to the conclusion that in certain forms of uterine hemorrhage it is almost a specific. I have found no unpleasant symptoms produced even if it was given in doses larger than usual, as has been observed in cases in which 4½-grain doses were administered. It cannot be corroborated by

me that the remedy produces a hypnotic effect, such as has been observed by Gottschalk, who attributes such effect to its being a derivative of opium.

The belief prevails, according to the experience in Gottschalk's clinic, that stypticin possesses oxytocic properties, which is held to account for the usually prompt action. This, however, has been carefully looked into by Gaertig, in the Prov. Hebammen-Lehr-Anstalt, in Breslau, under the direction of Dr. Baum. Eleven subjects were utilized to determine its effect in this direction. It was used in cases of weakened uterine contraction and for the induction of premature labor, but the result was negative. In the cases of premature labor, not a single uterine contraction was produced; in the cases of atony only in two instances mild, slightly painful contraction was observed; and the observer quite correctly remarks that it is extremely doubtful if they could be ascribed to the action of the stypticin.

For some time more attention has been devoted to operative interference for the control of bleeding from the uterus, or to some form of local treatment, the latter not infrequently with deleterious result to the patient. This was undoubtedly due to the unsatisfactory results which had been obtained from the internal remedies used in the respective cases. These remedies were few in number. With the introduction of stypticin, however, we have a very valuable new remedy, a hemostatic *par excellence* if the proper indication has been selected for the employment of the drug. In the above I have endeavored to show in which classes of cases such results may be expected. If a quick result is to be achieved, an injection into the glutei of 20 minims of a ten-per-cent solution in sterile water, with the customary antiseptic precautions, may be given without hesitation, and repeated in eight to twelve hours. Only a few days ago I saw a most marvelous result from this procedure. A woman who had been bleeding for three weeks, *post-abortum*, and who was exsanguinated from the loss of blood, was seen by me with the expectation that I should curette her. I requested her physician to use the remedy as described above, because from the examination of the pelvic organs I could not find an absolute indication for the use of the curette. After the first injection the bleeding ceased and did not recur.

I should, perhaps, make a differentiation as to the cases in which hydrastinin, hydrastin, ergot, and ergotin, and those in which stypticin can be used with best effect; but this is too great a scope for this paper, and I close this recital of my personal observations by requesting those who have tried other remedies and found them wanting, to add also stypticin to their therapeutic agents, feeling convinced that in it they will find a most useful addition, and that the curette and local treatment will be less frequently called for.

Therapeutic Review.—For the sake of greater completeness, let us now also briefly review the results of the stypticin treatment by other observers. Joseph v. Braitenberg[1] reports twenty-four cases from Ehrendoerfer's clinic at Innsbruck. A sedative action could not be substantiated, neither were disagreeable accompanying symptoms present in any instance. Doubtful or negative results were obtained in uncomplicated hemorrhagic endometritis, if no abrasio uteri had been previously performed; if, however, the bleeding recurred after curetting, the action of the drug was prompt. In hemorrhage due to displacements of the uterus, perimetritis, parametritis, or inflammatory changes of the adnexa, the results were, so far as the arrest of the bleeding was concerned, usually good. Profuse and protracted menses were shortened in duration. In hemorrhage without discernible anatomical changes the results were favorable. In hemorrhage due to fibromyomata (one case) no benefit was obtained. One case of retroflexio uteri gravidi, in which there was persistent moderate bleeding after correction of the displacement, so that an impending abortion was thought of, the bleeding ceased after the administration of seven tablets, each containing ¾ of a grain; no uterine contractions were produced and abortion did not occur.

Backofen[2] had forty cases under observation in the gynecologic clinic of Czempin at Berlin. In his experiments he excluded cases of hemorrhage due to subinvolution after the puerperium and after abortion; in such ergot was given. In virginal menstrual hemorrhage, stypticin was used five times; three times with success, and twice the result was negative; in the latter instance, hydrastis, hydrastinin, ergot, and curetting were also without avail. In menorrhagia in consequence of parametritis, or inflamed adnexa, or displacements with inflammatory processes, the results were excellent. In nine cases there was an invariably prompt action, and there could be no doubt as to its being due to stypticin. In consecutive metrorrhagia accompanying the above conditions, it also had a similar beneficent effect. In twelve cases the action was prompt eight times; once a fair result was achieved, and three times the result was negative. Consecutive hemorrhage from pedicle exudates following salpingo-oophorectomy, four cases. In two the result

[1] v. Braitenberg, *Wiener Med. Presse*, No. 35. 1898.
[2] Backofen, *Munch. Med. Woch.*, April 5, 1898.

was good, and in the other two it was negative; in the latter other remedies also failed. In two cases of acute gonorrheic infection with severe atypical hemorrhage the result was excellent. In 8 cases of subacute increase of chronic corporal endometritis (endometritis hemorrhagica) in 5 good, in 1 doubtful, and in 2 negative results were obtained. Hemorrhage at the menopause, two cases. In one the result was good, and in the other decided improvement took place with a similar good result upon recurrence of the bleeding. In one case of bleeding during pregnancy between the fourth and fifth month of gestation the result was good, and no uterine contractions were produced. In one case of myoma there was a negative result. Secondary effects were noted in two patients, in whom severe headache occurred after taking the drug; two patients had nausea and diarrhea. A sedative action, which was observed by Gottschalk and Nassauer, could not be substantiated.

H. Gaertig[1] reports on forty-six cases: Ordinary menorrhagia, 7; endometritis with hemorrhage, 11; complicated and simple retroflexion with hemorrhages, 11; subinvolution after delivery or abortion, 7; hemorrhage during the menopause, 3; hemorrhage in consequence of inflamed adnexa with retroflexion, 1 case; hemorrhage in consequence of inflamed adnexa without retroflexion, 2 cases; hemorrhage due to fibromyomata, 4; hemorrhage due to impending abortion, 1 case.

The most favorable results were obtained in the instances of uncomplicated menorrhagia, namely, six positive results out of seven cases; equally good results were obtained in the bleeding during the climacterium. The least benefit was obtained in the hemorrhage from endometritis, especially if other complications existed. In hemorrhage due to retroflexion the result was good, negative, however, if an endometritis complicated the displacement. At no time were unpleasant symptoms observed, even with large doses and long-continued use.

Max Nassauer[2] reports 49 cases as follows: Three climacteric hemorrhages, all immediate good results; hemorrhage due to subinvolution after abortion, 12 cases; in 11 excellent result, and in 1 improvement; post-puerperal subinvolution of the uterus causing hemorrhage, 2 cases; 1 excellent result, and the other a good result; myoma-uteri, 6 cases; 1 excellent result, 2 good; 2 improved, and 1 negative; menstrual hemorrhage in virgins without pathologic lesions, 2 cases, in both excellent results; imminent abortion, 1 case; result excellent; the hemorrhage ceased entirely two days after commencement of stypticin administration; in hemorrhage from adenocarcinoma of the uterus, 1 case, with benefit; reflex uterine (secondary) hemorrhage, 10 cases; in 3 excellent results were obtained, and in the other 7 good results; hemorrhage due to endometritis, 11 cases; 1 very good; 2 good; 2 improved; 1 doubtful, and in the remaining cases the result was negative. The menorrhagia in the instance of 1 scrofulous hysterical person was not bettered. Nassauer finds that stypticin has a decided sedative influence, which makes it a valuable remedy in meno- and metrorrhagia and dysmenorrhea. Unpleasant symptoms were not produced, except in patients with idiosyncrasy to opium, when it caused nausea and headache.

Sigmund Gottschalk, in 1895, reported 47 cases: Climacteric hemorrhage, 5 cases; in only 1 case the result was negative, and in this instance Gottschalk had the suspicion that a mucous polypus was present; the other 4 cases gave very good results. Secondary uterine hemorrhage, 6 cases; 5 with good result; in 1 with tubo-ovarian swelling the action of the stypticin was negative; hydrastis had the desired effect. Menstrual hemorrhage in virgins without anatomical lesion, 4 cases; 2 with good results, 1 improvement, and 1 negative. One purpura hemorrhagica, improvement. Fungous endometritis causing uterine hemorrhage, 7 cases; in 5 cases, improvement; in the other 2, negative; then curetting was done, but the hemorrhage continued, when stypticin was again used, this time with good results. Hemorrhage due to fibromyomata, 4 cases; in all a decided improvement. Hemorrhage from endometrial polypi, 3 cases; 1 improved, the other two negative; they were cured after removal of polypus. Impending abortion hemorrhage, 6 cases; in 5 abortion resulted, and in the sixth the bleeding was arrested without abortion being produced. Hemorrhage due to influenza, 2 cases; in 1 immediate cure, and in the other improvement. Puerperal subinvolution, 5 cases, all with excellent result. Hemorrhage due to subinvolution from a blood coagulum at the site of the placenta, improvement, then a slight recurrence, when an intra-uterine douche was used and the coagulum was evacuated. After this the hemorrhage ceased. Hemorrhage with superinvolution of the puerperal uterus without lactation, one case, with excellent result. Menorrhagia after curetting, 1 case, with immediate good result.[1]

[1] H. Gaertig, *Therap. Monat.*, p. 419, February, 1896.
[2] Max Naussauer, *Ibid.*, Nos. 32 and 33, 1897.

[1] Since the above writing, my colleague, Dr. A. P. Dudley, reports a case of profuse metrorrhagia due to uterine fibroid controlled promptly by stypticin given subcutaneously as described above. I have also observed the arrest of flooding in a case of interstitial fibromyoma from the administration of the drug in 2½-grain doses every two hours; also the arrest of dysmenorrhea associated with intense headache during profuse and prolonged menstruation in another case.

THE PRESENT STATUS OF PHARMACY AND ITS POSSIBLE IMPROVEMENT.[1]

By ELI H. LONG, M.D.,
OF BUFFALO;
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE UNIVERSITY OF BUFFALO.

Pharmacy has been called the handmaiden of Medicine. Its normal relation is certainly one of helpfulness and dependence. But we as physicians must remember that the helpfulness is born of a need of that help which many fail to appreciate, and also that the dependence of pharmacy implies an ability on our part to direct, to educate and to fix standards for our dependent. Furthermore, the question of ideals has more than a passing influence upon the character of pharmacy. Particularly at the present time, when it is a question whether pharmacy in the future shall be a trade with business ideals or a profession with humanitarian ideals, should this thought engage our minds. Pharmacy naturally looks to medicine for her ideals. Is she disappointed?

But let us not separate the two too widely. Pharmacy must be regarded as a part, a special branch, of medical science; and this relation is emphasized by the present tendency in medical schools, where a course in practical pharmacy is coming to be regarded as essential to the medical education.

The ability also that pharmacy has shown in meeting our needs in the way of more precise medication and pleasanter preparations, in the isolation of active principles of drugs, and in processes of assay which guarantee a certain quality of preparation should be appreciated. But in order that our respect for our helpers may not rest solely upon these achievements it is asserted that the best thought in pharmacy today is fully abreast of progress in all practical lines. If any are inclined to doubt the assertion, convincing support of the same may be found in the history of the United States Pharmacopœia during the past sixty years. In the successive revisions of this admirable book pharmacal aid has been on the increase since 1840, when it was invited to the work of revising this our standard of materia medica. In the edition of 1840 the value of pharmacal assistance was evidenced by the introduction of the process of percolation as a means of exhausting drugs. Since that time representative pharmacists have regularly participated in the work, and their interest in the book even led to their delegates outnumbering those from medical bodies at the last Pharmacopœial convention in 1890.

Corresponding with this enlarged pharmacal influence we note very great improvements in the book, among which is that of the adoption of the metric system in its formulæ.

I admit that this is taking pharmacy at its best and that some minds will at once draw a comparison with the average drug-store, which may be very disparaging to the latter; but I maintain that, in spite of the commercial atmosphere of the ordinary store, pharmacy is making a steady improvement, largely unaided by us, and that its best men are anxious to keep pace with the rapid progress of medicine in the sphere of their relation to it.

Now what are some of the evidences of improvement? *First*, in the line of literature. We find that while during the fifty years from 1829 to 1879 there were established in the United States *four* pharmacal journals, or an average of one in twelve and one-half years, during the sixteen years from 1880 to 1895 inclusive there were established *twenty*, or an average of one every ten months. *Second*, in the line of restrictive legislation. Previous to 1880 the practice of pharmacy in this country was practically unrestricted except in five States and three cities. Since 1880 there have been enacted thirty-nine State laws which originated in pharmacal bodies. These laws in the main require four-years' experience and an examination in order to license. *Third*, still greater evidence of progress is seen in the increase of Colleges of Pharmacy from *three* in 1840 to *fifty* in 1895, and this without the existence of any legal necessity of a college training on the part of pharmacists. This advance cannot be born of any commercial spirit but must be expressive of an ambition to prepare well to meet the recognized need of trained men. And the writer is convinced that the college training of pharmacists should be as broad as is possible within reasonable limits. The maxim, "A little knowledge is a dangerous thing" is probably nowhere better or more generally exemplified than in our drug-stores. The average dispenser without college training possesses some knowledge of medicine above that needed in his work and he frequently uses that knowledge improperly. But the college man, if properly trained, though possessing a larger knowledge of facts pertaining to medicine, has learned when *not* to use them. In other words our college-trained men are not as a rule engaged in illuminating the fences, in counter-prescribing, and in substituting. The commercial spirit so prominent in the pharmacy of to-day, with deficient training, must be held largely responsible for such abuses, while the progress in education, as shown in the increase of colleges, gives hope of a better state of affairs in the future.

Let us now consider another feature of our subject—one of some importance—the individual phar-

[1] Read before the Buffalo Academy of Medicine, February 14, 1899.

macist. We have drawn outlines of the picture of what he may be and we are very sure we know what he ought to be, but he is not it. Our average pharmacist of to-day is a commercial man and not the professional man we should want him to be. Why is this? The reason is not far away if we follow the path of the drug-clerk. And truly his path is not an inviting one. From the beginning of his apprenticeship as bottle-washer and errand-boy he sees the motto of the store plainly visible everywhere and that motto is—*business*. He sees how things are done behind the counter. His employer is not a professional man, may even ridicule the college graduate. In his school of experience he has learned to place highest value upon the business qualities in a clerk, and, therefore, the professional aspirations of the college man are all moonshine to him. Do not blame him too severely for he was trained in a business environment.

But it is evident that the whole atmosphere of the store is such as to favor a perpetuation of his kind unless our clerk has professional instincts and is able to rise above the level of his surroundings. Even then his advisers are likely to take the business view and remind him that he need not go to college, he can study up and pass the State or county board and get his license, and what more does he want? Now just reflect upon the situation of our clerk and imagine what will be the bent of his mind by the time he comes to be manager of a store. Add the business necessities that attach to the modern pharmacy and the question why our average pharmacist is a commercial man is largely answered.

Most colleges have abolished the requirements of a number of years of drug-store experience as a prerequisite for graduation. This must be regarded as an advance for we will probably agree that, after a certain amount of experience, the earlier the college training is had the higher will be the ideals and more ethical will be the practice of the pharmacist. A long experience of the ordinary drug-store kind, taken alone, is certainly inimical to a professional development.

But there are still other influences which help to make the pharmacist what he is. The rush of trade —soda-water, cigars, candies, and the like, the appeals to turn his windows to account through well-paying advertisements, living or otherwise, the resurrection of celebrities of the past to preside over the cigar department, etc. In such a whirl of interests how can he be expected to give scientific pharmacy his first attention. He knows that inferior fruit syrups will be criticised more than inferior drugs. He knows that the cigar customer will not wait while the prescription is being compounded, so the latter has to. In short, the average pharmacist has to subordinate the scientific to the commercial. He is not wholly to blame. The conditions and usages which he has to face require it to a great degree. But we are led to say that, from our viewpoint, while the training of the pharmacist may be said to be simply deficient in character, the prominent features of the average drug-store are an abomination.

Our pharmacist further has to undergo a certain discipline. He has not only to consult the needs of the doctor but to humor his whims. He has to bear his criticisms, not always consistent or seasoned with charity, but does not usually trust to his own tact to retaliate profitably. He is affected more than he sees fit to complain of by the changing fashions and fads in medical practice. The doctor often does the experimenting at his expense. When he is asked to stock up with a high-priced new article he cannot refuse; but when at the end of the year he finds the stock lessened by the filling of *one* prescription he murmurs not, but the balance in that transaction is on the wrong side of the page. His thoughts we will not reveal. But I do think that the educated and ethical pharmacist might be expected to regard with some contempt the physician who passes by the potent official preparations on his shelf because of ignorance of their action or inability to properly prescribe them, but calls for one after another semiproprietary mixture whose chief recommendation is its extensive advertisement. What a short step to the sale of fully patented preparations.

These thoughts come so naturally in a discussion of this topic that I will presume upon your indulgence a little farther. Legitimate pharmacy now for a number of years has had to endure serious competition from the tablet manufacturer and his ubiquitous agent. It is not proposed to discuss the comparative value of drugs in the form of their liquid extracts or in the pleasanter tablet forms; but it is evident that with certain drugs the use of tablets is to continue, and must be accepted as a normal departure. But the use of tablets, as well as of other ready-made combinations, encourages an unwholesome tendency to depend upon others for our formulæ.

And were I a pharmacist my bitterest reflection would be upon the decline of independent combining and prescribing on the part of physicians. Prescribing is destined to become a lost art unless our medical schools take warning and educate better along these lines. There are many who allow the wholesale manufacturer to do their combining, their prescribing, and I would almost say their thinking for them. The wonder is that physi-

cians will tolerate the effrontery of some manufacturers in their efforts to dictate the use of their proprietary products. But so long as they do we will find one branch of pharmacy developed to perfection, namely, the large commercial manufactory where capital employs both medical and pharmacal talent at a good figure to prepare formulæ for physicians' use, while the would-be professional and deserving retail pharmacist struggles with the question of selling patent medicines to make ends meet.

This last allusion bears upon the question of income, which will not be discussed except in relation to the drug-clerk's prospects. The decision against taking a college course is very often compelled by the meagerness of the ordinary clerk's salary. Indeed, small is the financial inducement to take a course of training which is optional, when after time and money is expended the probable income for years will not exceed $12 or $15 per week. It is said that all pharmacists save money. But that is due less to any large income or virtue on their part than to the providential conditions which compel them to stick so closely to business that they have not time to spend it.

Now as to improvement in pharmacy. Every thinking physician owes it to medical science as a whole to give serious thought to this subject. We cannot get along without pharmacy much as we may condemn the practice of the commercial pharmacist. You have doubtless seen in the foregoing remarks indications of a conviction that the medical profession is to some degree responsible for the present state of pharmacy. The writer is further convinced that no great improvement can occur without our thoughtful aid, and that the future usefulness of pharmacy requires a constant and considerate cooperation of physician and pharmacist.

Our thought must extend in five directions: To the college, to legislation, to the pharmacist, to the store, and to ourselves. In the first two our aid must be less direct, but a brief allusion will indicate what should be our attitude. The colleges of pharmacy are probably as good as they are likely to be under present conditions. They have to provide an optional course of training for students who attend voluntarily, many of whom are obliged, for financial reasons, to work in a drug-store while attending. And let me state that there are many more ambitious young men who would gladly take a college course if there were sufficient opportunities for them to aid themselves in such way, but who are obliged to content themselves with a license granted by a board of pharmacy, and they aid to swell the ranks of the less ethical because less educated pharmacists.

Pharmacy has reached that stage of educational progress when a college training should be required by law. Medicine passed that stage many years ago, and should now encourage and aid pharmacy to secure the benefits of such legislation. The results of such a law would be fewer pharmacists and better, better colleges, the development of the professional and lessening of the commercial spirit; and this is what physicians should always foster. I believe no step could result in as great improvement in a short time as the enactment of laws making a college training obligatory upon the student of pharmacy.

The objection will be here raised that the colleges will teach too much of the uses of medicines and make counter prescribers of their graduates. I do not fear this for one moment. And I repeat, for the sake of emphasis, what appears earlier in the paper, that the little knowlege of medicine possessed by the commercial pharmacist is a dangerous thing, but that the greater knowledge possessed by the professional man is a safeguard against the improper use of his knowledge. This must be just as true here as in medicine, where the better training in a special line leads to a practise restricted to that line. The college training should, therefore, be as broad as is possible within proper limits. One thing, in addition to the essentials, seems especially important. That is the study of hygiene. A knowledge of the infections and of proper sanitation would render him a valuable coadjutor to the physician in his community, where an intelligent public sentiment is so often wanting.

Our thoughts for the improvement of the pharmacist are partly involved in our previous considerations. Further than that, he should be regarded as the ally and equal of the physician, and as possessing in some directions knowledge and skill superior to the physician. Throughout this paper free use is made of the terms "commercial" and "professional" as applied to pharmacy and pharmacist. Are they not good terms to employ? They will tend to preserve in our minds the distinction between what pharmacy largely is to-day and what it should be. They will aid in discriminating between what should be aided and what should be discouraged. And we must remember that there are professional pharmacists. There is great need of more.

The same distinction will apply to stores. And we must remember that there are also professional pharmacies. In some cities there are strictly legitimate prescription pharmacies, and there might be in every city or town with the aid of the medical profession. With a knowledge of present conditions it is entirely proper, if not indeed a duty, for

physicians to discriminate between stores for the compounding and dispensing of their prescriptions. Whatever the future has in store for pharmacy, a thoughtful regard and cooperation on the part of physicians would probably lead to two kinds of stores: the professional, where chief attention would be given to compounding prescriptions, and commercial stores, where soda water, cigars, and proprietaries might be sold, scissors sharpened, bicycles mended, or anything you please.

In introducing our final direction of thought—toward ourselves—permit me to repeat that pharmacy naturally looks to medicine for her ideals. Is she disappointed? Our influence upon pharmacy, by our personal attitude toward the pharmacist, is inevitable. Our own ethical standard tends to determine his. Due courtesy toward him, therefore, will command a more careful attention to our needs, not upon the ground of policy, but because his standard of action is raised. On the other hand, an inconsiderate behavior on our part will tend to make his assistance in our practice only perfunctory, and will degrade the standard of his service. Our conception of professional ethics should be such as to lead us to treat with the utmost fairness and courtesy any one who is engaged in applying to any branch of medical science a skill supposedly equal to our own in any direction.

We should likewise exhibit a high standard in the line of education. Our attainments in those branches which are most intimately related to his practice should approach his. I feel that a plea should be made for greater efficiency in prescribing and for a more thorough acquaintance with the resources of our United States Pharmacopœia. For, beside the great benefit thereby to ourselves, we should better appreciate the work of the pharmacist, and he would not behold so monstrous and degrading a spectacle as that now presented of physicians gulled and deluded into aiding by use and by testimonial the proprietary manufacturer in the sale of his high-priced but inferior products.

SOME OBSERVATIONS UPON ERYSIPELAS AND ITS TREATMENT.

BASED UPON A NEW SERIES OF 100 CASES.[1]

By CHARLES W. ALLEN, M.D.,
OF NEW YORK;
CONSULTING DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITAL; CONSULTING SURGEON TO THE CITY HOSPITAL, ETC.

The clinical study of erysipelas has interested me for a number of years, and I have upon two previous occasions presented the results of clinical experience. In July, 1891, I published in the *American Journal of the Medical Sciences* a personal experience in fifty cases, in which paper I also reviewed and analyzed 419 cases in the City Hospital during the preceding two and one-half years. As a result of my observations at that time, I concluded that the treatment of erysipelas would be best carried out by conforming to bacteriologic findings, and that since the streptococcus had been found to grow more rapidly and luxuriantly under conditions of abundant oxygen supply, it seemed rational to attempt to shut off this supply in treating the disease. To do this, I employed collodion medicated in various ways. Of the numerous remedies tried none was found to work so well as ichthyol. Permit me to state here that so far as the remedy to employ is concerned, my paper might terminate with the statement that during the past eight years nothing has been found to take its place. There are, however, some things to be said about the manner of using the remedy, and also about a combination method for suitable cases.

Up to the time of reading my first paper at a meeting of the American Dermatological Association, in September, 1890, I had employed the method of mechanical pressure by means of an adhesive band as recommended by Wölfler in but a single instance. Its action was so manifestly efficacious that before the paper was printed I had tried it in three others, with good results in two. In a paper on "Erysipelas in Its Etiological Relation to Preceding Skin Lesion and Its Local Treatment," published in the *Medical Record* for November 23, 1895, I reported the results in fifty additional cases.

Before reverting to therapy, I would call attention to the fact that in these two series of cases a cutaneous defect of some kind was found to serve as a *porte d'entrée* for the infecting micro-organisms in no less than fifty per cent. Of the other half the throat was accused in 9 instances, nasal catarrh in 3, and lacrimal fistula in 2.

In treating and observing this last group of 100 cases, most of which have been seen since the spring of 1897, I have been struck with the frequency of coexisting or preceding nasal affections in the facial cases. In former times these were almost always put down as "idiopathic" in contradistinction to the traumatic forms or those in which some solution of continuity of tissue could be discovered. It has become my conviction that in the absence of cutaneous lesion or throat affection to account for it, the nose is the part through which ingress is effected by the cocci. In every instance of facial erysipelas observed (and the great majority have been of this variety) I have inspected the nares and

[1] Read before the Lenox Medical Society of New York, December, 1898.

made enquiry regarding nasal disease. The result has been that at least two-thirds of the patients gave evidence or history of disease.

Believing as firmly as I do in the efficacy of ichthyol, I have naturally turned to this remedy as well in combatting the process at its seat of origin, and have applied in all cases a fifty-per-cent. watery solution of ichthyol, so as to bathe the whole anterior and posterior nares as far as possible, covering over all fissures and excoriations at or near the introitus. Upon the skin surface I employed a twenty-five-per-cent. solution in collodion. The results have been surprisingly good, and I have repeatedly been able to demonstrate to my assistants and to students a complete cessation of the process, so far as symptoms, temperature, and objective signs go, within twenty-four hours of the first visit. Many other patients were discharged cured upon the second or third day. Almost all the cases were seen early, *i. e.*, in from twelve to twenty hours of the chill or earliest evidence of local inflammation.

Aside from an occasional prescription of ichthyol in pill form to correct some gastro-intestinal disturbance or something to relieve headache, no internal medication whatever has been made use of during the attack. During several years I have not given a single dose of tincture of iron in erysipelas. The adhesive band has been applied in a number of instances, usually in erysipelas of an extremity, in combination with the ichthyol paint, and always with the most gratifying results.

There have been no deaths to record in this last 100 cases so far as I have been able to follow them, or to learn from the district visiting-physician who might have seen some of the patients subsequently, although extremes of age are represented. In view of the fact that many subjects gave a history of one or more previous attacks, and the well-known tendency of facial erysipelas to recurrence, I would strongly recommend attention to the nose and throat as a prophylactic measure, and I have no doubt ichthyol will be found a useful drug in ozenas and chronic conditions requiring antiseptic and deoxidizing or reducing agents. The advantage of rubber adhesive-plaster bands over the application of several layers of contractile collodion is that the latter is apt to break at some point, and it is through this open door that the erysipelatous process is seen to advance into new territory just as water rushes through a break in a dam and overflows the plain.

I have recently treated a number of children for erysipelas of the extremities, and have had the most prompt results from what I call my "combined method." I now have about fifty cases in which the adhesive constriction has been combined with collodion painting. I feel confident that if this plan be resorted to early and be properly carried out no necessity will arise for scarification to produce a barrier, nor for resort being had to antistreptococcic serum, which, so far as I can learn, is of doubtful efficacy in severe cases in infancy and childhood.

CLINICAL MEMORANDUM.

AN OBSTINATE CASE OF PURPURA HEMORRHAGICA.

By J. H. BURCH, M.D.,
of Baldwinsville, N. Y.

The patient, Susie C., aged fourteen, a blonde, of Irish parentage, weighed at the commencement of her illness 125 pounds. Her mother and father had always been healthy, but the latter's brother had died from the effects of excessive loss of blood from a very slight scalp wound, the hemorrhage, it was said, having been uncontrollable.

The patient had been apparently strong and well-nourished up to the age of seven years, when she was suddenly attacked by epistaxis, the hemorrhage, I am told, being excessive and demanding repeated post-nasal plugging for several days. The physician in charge, Dr. Barton of Clyde, N. Y., informs me that the attack began with a pronounced chill, and that at the end of the third day purpuric spots appeared on the child's leg and abdomen. She recovered from this attack and remained in good health until September 7, 1886, when, without premonitory symptoms another attack was ushered in by a severe chill, followed by high fever, her temperature at 9 A.M. being 105° F. and her pulse 150, very weak and feeble.

On September 8th her temperature was 100° F. and her pulse 120. The following day her temperature was normal and she felt fairly well and seemed to be in a fair way toward a rapid recovery, but on September 11th she again had a very severe chill which was followed by high fever, her temperature reaching 105° F. This was followed by sweating and a reduction of temperature. During the sweating stage an oozing of blood from the mucous membrane of the gums and mouth occurred, which was controlled with considerable difficulty by strong, astringent mouth-washes. The next morning, September 12th, she was unable to retain nourishment, the ejections from the stomach being mixed with blood. Nausea and vomiting then became a constant symptom, each ejection containing blood. During the evening of the same day hematuria developed, the urine being scanty, smoky, and containing one-half of one per cent. of albumin and granular and epithelial casts and blood. The next day her condition remained about the same, her maximum temperature being 103° F. and pulse 160, the latter very weak but steady.

On the 13th her condition was much better; the vomiting had ceased but the urine was still bloody and contained albumin and epithelial and granular casts. Her maximum temperature was 100° F. and pulse 100 and

stronger. During the night she was bathed in a cold, clammy perspiration, and a marked jaundice manifested itself. The sclerotics were yellow, as were also the face and neck. I also noticed for the first time purpuric spots on the left arm and ankle.

On September 14th her general condition was better, the icterus and hematuria being less pronounced, but the purpuric spots were beginning to appear on her abdomen. At three o'clock in the afternoon I was called in great haste and found her nearly exsanguinated, there being a profuse hemorrhage from the left nostril. The nostril was immediately plugged with iodoform gauze, which controlled the bleeding. The next day she was much better. The hematuria was disappearing, albumin was present to the amount of ¼ of 1 per cent., but there were no more casts. On September 16th I removed the tampon from the nostril but as this was followed by excessive hemorrhage another was introduced. On September 18th I again removed the tampon from the nostril but the hemorrhage was again excessive, demanding replugging. On September 19th the purpuric eruption disappeared and her general condition was much better, her temperature being normal and her pulse 90 and stronger. On the following day I again removed the tampon from the nostril, but the hemorrhage was so profuse that I at once replugged it, using strips of sterilized gauze saturated with a 20-per-cent. solution of antipyrin. On September 22d I once more removed the tampon and no hemorrhage followed. She made a good recovery and remained apparently well until February 5, 1898, when, without premonitory symptoms she had a severe chill which was followed by well pronounced fever and sweating.

On February 6th she felt fairly well, but on the following morning she was again stricken with a severe chill, followed by a profuse hemorrhage from the left nostril. I was hastily called and found her in a state of collapse. Her pulse was scarcely perceptible and was weak and thready. The extremities were cold and bathed in a clammy perspiration. I immediately plugged the nostril, both anteriorly and posteriorly, with gauze, but the blood continued to ooze drop by drop. I then removed the tampons and replaced them very carefully with tampons of absorbent cotton, saturated with 1 to 1000 bichlorid-of-mercury solution. The plugs were carried far back into the posterior nares and the whole nostril was very firmly packed. This controlled the hemorrhage, and it was indeed time, as the patient was rapidly sinking. By the aid of heat and stimulants, hypodermically administered, she gradually revived and when I left her temperature was 99° F. and her pulse 160, very weak and compressible.

During the profuse hemorrhage I collected about ten cubic centimeters of blood as it flowed from the nostrils, and fully verified the observations of Hayem, which were afterward confirmed in sixteen cases reported by Beusaude[1] of Montpelier, in regard to the non-retractibility of the clot and the formation of serum. The blood in this case, as in the greater number of the graver cases reported by Beusaude, showed no tendency whatever to clot but remained entirely fluid.

[1] *Semaine Medicale*, June 20, 1897.

At 3.30 in the afternoon I was again hastily called and found the patient bleeding profusely from the right nostril, which I was also obliged to plug in order to control the hemorrhage. On February 8th, she had a pronounced chill, her feet, legs, and hands being icy cold. The chill continued twenty minutes, her temperature then rising to 105° F. During the night she slept somewhat and was bathed in perspiration. She vomited a little blood, which was thick and of a dark color. The area of hepatic dulness had not increased, nor had that of the spleen. The urine was of a dark color, the specific gravity being 1028. The reaction was distinctly acid. Carefully centrifugalized sediment revealed only a few crystals of uric acid and squamous epithelium. I pierced a lobe of the ear to obtain a drop of blood for examination, and a small stream issued forth from the puncture, which was so difficult to control that I was obliged to apply a compress of styptic cotton for more than half an hour. A microscopic examination of several specimens of fresh blood for the plasmodium malariæ revealed nothing suspicious. A blood-count (Toma-Zeisse) showed the number of red blood-corpuscles to be 3,800,000 per cubic millimeter, and the leucocytes, 10,000 per cubic millimeter, the increase being manifested mostly in regard to the polymorphonuclear cells; hemoglobin was thirty-five per cent. A dried specimen, stained after the method of Ehrlich, revealed simple anemia, both red and white cells being fairly normal in appearance. During the afternoon of that day her temperature was 104° F., and her pulse about 180, but so weak and rapid that it was very difficult to count it accurately. The heart sounds were distinct. The bowels moved five times during the day, the ejections being of a thin, brownish character. There was some ileocecal gurgling. Nothing could be retained in the stomach except Valentine's beef-juice, only a few drops of which could be given at a time. The drugs employed at this time were strychnin sulphate, $\frac{1}{30}$ of a grain every four hours, and 10 minims of aromatic sulphuric acid every three hours.

On February 9th her temperature was 101° F., and the pulse 150, the latter weak but regular. The coating of the tongue was dry and brownish. The bowels had moved but twice during the night, and she had vomited but twice. Some sleep had been obtained, and her general appearance was improved. The area of splenic dulness was increased, and the urine was clear and dark-brown in color, and contained a trace of albumin and epithelium. The blood-count showed the red cells to be 3,500,000 per cubic millimeter; white cells 12,000 per cubic millimeter; hemoglobin 35 per cent. The stained specimens began to show slight poikilocytosis and the Maragliano reaction. The nuclei of the white cells showed evidence of fragmentation. The Widal Johnson reaction was negative. The bowels moved twice that day, and she vomited but once, and retained beef-juice in larger quantities. The tampons were removed from the nostrils, which resulted in excessive hemorrhage, demanding immediate replugging.

On the morning of the 10th her temperature was 101° F. and pulse 120. She had slept fairly well. The menses

appeared that morning but were not at all profuse. The urine was of a dark-brown color, the specific gravity being 1028. It contained one-half of one per cent. of albumin, and a small amount of epithelium. The blood-count was: red cells, 3,400,000 per cubic millimeter, and white cells, 12,000 per cubic millimeter. Stained specimens showed distinct poikilocytosis; there were also distinct degenerated changes within the nuclei of the polymorphonuclear cells. At 5 o'clock in the afternoon her temperature was 103.5° F., and pulse 160, the latter being weak and compressible. The bowels had moved twice, the ejections consisting of thin, brownish liquid, and there was ileocecal gurgling. The Widal-Johnson test was negative. She had vomited three times, and her general appearance was bad.

On February 11th her temperature was 101° F. and pulse 120, very weak but regular. The heart-sounds were normal. The spleen was distinctly palpable. There were no bowel movements during the night and she appeared better. The urine was dark and smoky, the specific gravity being 1025. There was a strongly acid reaction. The urine contained one-half of one per cent. of albumin; the chlorids were normal, but there was an increase in the phosphates. The Ehrlich diazo-reaction was marked, the foam being distinctly red. Centrifugalized sediment showed an increased number of blood-cells, granular and epithelial casts, and very peculiar bacilli about as long as a colon bacillus, but thicker and non-motile. The blood-count showed the red cells to be 3,300,000 and the white cells 13,000 per cubic millimeter, the increase being both in regard to the small mononuclear and the polymorphonuclear variety of leucocytes. There was a marked poikilocytosis, the red cells being deformed and with distinct polychromatophilic changes. The appearance of the white cell was very peculiar and the polymorphonuclear cells appeared distorted in shape. The cell-wall was broken in places and the protoplasm was apparently filled with granules which seemed to be exuding from the broken cell-wall. The nuclei were fragmented, taking the stain badly, and in close proximity to the cells were clusters of fine granular bodies which were very indistinct. Within the red cells were bodies not having the appearance of nucleated cells or of the plasmodium malariæ. Several cover-glass preparations were then stained after the method of Romonoviski.[1] This brought out these bodies more distinctly, and also revealed groups of bacilli similar in appearance to those found in the urine. The bodies were about one-quarter the size of a red blood-cell, and were stained a deep blue and were round in shape. The staining qualities differed from the hematozoon of malaria from the fact that each body was deeply and regularly stained, and also from the fact that they were outside the red cells in exactly the same regular form, being found in groups of from two to three in the immediate proximity of a polymorphonuclear leucocyte. These bodies were similar, I should judge, to those described by Dr. Deney[2] in the case of a woman who had suffered from obscure gastric symptoms and in whom a few days before her death, hemorrhagic spots appeared on the mucous membrane of her fauces, vagina, and on the skin. A careful examination of several fresh specimens of blood failed to reveal the plasmodium malariæ or the motile granules described by Müller. The blood was carefully examined for blood plaques, with negative results, none being found during the entire course of her illness. During the afternoon of that day the patient had a very slight chill. I again removed the tampon but the profuse hemorrhage demanded immediate plugging of both nostrils.

On February 12th her temperature was 105.5° F. and pulse 120, weak and compressible. The bowels had moved once during the night, the ejection being thin, watery, and offensive. Nausea and vomiting had ceased. Through the night there was considerable hemorrhage, the blood oozing from the mucous membrane of the gums and posterior nares, and also from the nose, the plugs not entirely controlling the hemorrhage. I again removed the tampons from the nostrils and the hemorrhage was very profuse. I repacked both nostrils with absorbent cotton saturated with a solution of acito-tartrate of aluminium. This controlled the nasal hemorrhage but a slight oozing of blood continued from the mucous membrane of the gums. Menstruation had ceased and the urine remained the same except that it contained more blood. For the purpose of isolating the bacilli several large test-tubes were carefully sterilized. A catheter was then employed under strict aseptic precautions and about fifty cubic centimeters of urine were thus obtained. The urine was very clear in color, decidedly acid in reaction, and contained one-half of one per cent. of albumin; the specific gravity was 1028. It was then centrifugalized in sterile tubes, the sediment revealing hyalin and granular casts, also an immense number of red blood-cells, and the peculiar bacillus above mentioned. Immediately after obtaining the urine I inoculated a tube of nutrient gelatin, one of agar-agar, one of potato, and also one of bouillon, all of which were transferred to an incubator, except the gelatin which was transferred to a Petri dish and allowed to develop at room temperature. At the time I also thoroughly sterilized the flexor-bend of the elbow, using the most rigid aseptic precautions, and drew from a distended vein about two cubic centimeters of blood with which I inoculated a second series of the above-mentioned tubes. The blood-count was as follows: Red cells, 3,200,000 per cubic millimeter; white cells, 14,000 per cubic millimeter; hemoglobin, 35 per cent. The morphological appearances were unchanged. After my experience in piercing the lobe of the ear to obtain blood for examination I employed the finger-tip which gave me no trouble. During the day blood continued to ooze from the mucous membrane of the gums and from the cavity from which a bicuspid tooth had been removed.

On February 13th her temperature was 101.5° F., and pulse 120. She had a slight chill at 7.30 in the morning. The bleeding had continued all night from the mucous membrane of the gums, the roof of the mouth,

[1] A saturated solution of methylen-blue and a one-per-cent. solution of aqueous eosin.

[2] *Indiana Medical Gazette.*

and posterior nares. The blood-count per cubic millimeter was 3,100,000 red cells; 12,500 white cells; hemoglobin, thirty per cent.

After remaining in the incubator twenty-four hours the bouillon remained clear, but a cover-glass preparation revealed the same bacilli, and a hanging drop proved them to be non-motile. Upon the agar-agar there was a thin layer with smooth edges. There was nothing upon the potato or gelatin. The bacilli stained readily with Loeffler's methylen-blue and carbo-fuchsin, but were very poorly stained by Gram's method. The bacilli appeared in pairs, and were non-motile. At the end of forty-eight hours a thin hyalin growth appeared upon the gelatin, and a thin strip upon the potato. The results were exactly the same from the tubes inoculated with both blood and urine. I injected 1 cubic centimeter into the abdominal tissue of a rabbit. At the end of twenty-four hours the animal appeared sick and would not eat, and at the end of seventy-eight hours it died. An autopsy revealed hemorrhagic extravasation in the subcutaneous tissue, also in the peritoneum and pleura, and extravasation was also found in the ear muscles. The blood showed no tendency to coagulate, and cultures from the spleen, blood, and liver revealed the same organism. The appearance, behavior, and pathogenic characteristics closely resembled the bacillus of purpura hemorrhagica described by Kolb in 1891.

On February 14th the patient's temperature was 102.5 F., and pulse 140, the latter being very weak and compressible. The heart sounds were clear and distinct, and the spleen was distinctly palpable. The hemorrhage continued from the mouth, and there was considerable oozing from the nose. I repacked the nostrils, which operation greatly fatigued the patient, as the nose was very much inflamed from constant pressure. Upon removing the tampons the hemorrhage was as profuse as ever. The blood-count per cubic millimeter was: Red cells 2,300,000, and white cells 10,300. The poikilocytosis was, perhaps, more marked. There was an occasional nucleated red cell, and the same round, deeply stained bodies as before.

On the following day, the 15th, she vomited some blood. The examination of the blood showed the red cells to be 2,100,000 per cubic millimeter; white cells, 14,000 per cubic millimeter; hemoglobin, thirty per cent. The diazo reaction was still marked, as it had been each day from its first appearance. For the first time purpuric spots made their appearance on the legs and back. The patient was very weak and in a semicomatose condition. The left side of the nose and left eyelid were badly swollen and very painful. The bowels had not moved during two days, and she had a chill at 12.30 o'clock. On February 16th her temperature was 99.5° F., and pulse 130 and much stronger. The heart sounds were distinct, and the purpuric spots were increasing. The left eyelid and side of the nose were badly swollen and discolored. I repacked the nostrils, profuse hemorrhage following the removal of the tampons. On the 17th her temperature had risen to 102.2° F., and the pulse was 140, very weak but regular. The patient was able to retain beef-juice, milk, and small doses of brandy. The nose was still badly swollen and ecchymosed. The urine did not contain albumin, but still contained granular and hyalin casts. The blood-count was: Red cells, 2,300,000 per cubic millimeter; white cells, 12,200 per cubic millimeter; hemoglobin, thirty-five per cent. The poikilocytosis was still marked. The nucleated red cells were not present, but the small, round bodies were still observed, and also the same degenerated condition of the leucocytes.

On February 18th her temperature was 101° F., and pulse 120, and stronger. There was less hemorrhage from the mouth and nose, but the removal of the tampons resulted as before. There was a disagreeable odor from the nose, notwithstanding the fact that strict antiseptic precautions were observed. The swelling of the eyelids and side of the nose was increasing. A free incision disclosed the presence of thin, ichorous pus and necrosis of the nasal bones and of the nasal process of the superior maxillary bones. The necrosed portions of bone were removed, and the wound packed with iodoform gauze. The blood-count per cubic millimeter was: Red cells, 2,400,000; white cells, 12,000; hemoglobin, thirty-seven per cent.

On the following day her temperature fell to 99.5° F., her pulse being 140, and very weak. The spleen was still distinctly palpable. The urine was of a clear straw-color, and did not contain albumin; the specific gravity was 1020. The diazo reaction was absent for the first time. Indican was also absent, this having been present part of the time during her illness, but not as a constant constituent. The blood-count revealed red cells, 2,100,000 per cubic millimeter; white cells, 14,000 per cubic millimeter; hemoglobin, thirty-two per cent. There was still present a marked poikilocytosis, the cells varying both in size and shape. The peculiar round bodies were still seen, but were not so numerous; the small mononuclear leucocytes greatly predominated over the polymorphonuclear variety. The character of the latter was very different, they being much smaller in size, with cell-wall and nuclei of normal appearance. I removed the tampons from the nose again, with less resultant hemorrhage, and examination revealed necrosis of the lower turbinate body of the left side, which was readily detached and removed. Both nostrils were irrigated with a 1 to 2000 bichlorid-of-mercury solution, and the tampons replaced.

On February 20th her temperature was 102.6° F. Purpuric spots appeared upon the chest, abdomen, and leg, and also behind one ear. I removed the tampons for the first time without hemorrhage. The wound on the side of the nose was doing nicely. The blood-count was: Red cells, 1,000,000 per cubic millimeter, and white cells, 13,000 per cubic millimeter. An examination of stained specimens showed profound anemia. There were several nucleated red cells, and the Maragliano reaction was marked. There were also many of the small, round bodies before mentioned. The appearance of the leucocytes was fairly normal. The urine was normal, there being neither albumin nor casts present, and the diazo reaction was absent.

On the 21st her temperature had risen to 104° F., and the pulse to 150. The heart sounds were weak but distinct. The skin was bathed in cold perspiration, and the general appearance was very bad. The urine contained a slight trace of albumin, and the bacilli, which had been absent for several days, again manifested themselves. Indican was also present, and the diazo reaction was again marked. The blood count was as follows: Red cells, 2,000,000 per cubic millimeter; white cells, 12,500 per cubic miilimeter; hemoglobin, thirty per cent. The condition of the blood remained about the same, except that the bacilli had again made their appearance, being grouped together in pairs. At 12.30 o'clock she had a slight chill. On February 22d her temperature was reduced to 99.5° F., and pulse was 140. She had rested fairly well through the night, and her general appearance was better. The swelling of the side of the nose and of the eyelid had disappeared, and there was no more hemorrhage from the nose. The urine was again normal, containing neither bacilli, casts, nor albumin. The diazo reaction and indican were still absent. The following was the blood-count per cubic millimeter: Red cells, 3,800,000; white cells, 13,500.

From that time on the condition of the patient very gradually improved. The blood-count revealed an increase in number of red cells from day to day, and the character and appearance of the cells changed for the better. The leucocytosis diminished also, the small mononuclears greatly predominating. The purpuric spots gradually disappeared, and on the 26th of March I saw her for the last time, she being at that time convalescent. She is now a well and healthy girl.

The treatment in this case consisted of the administration of strychnin sulphate, which I used as soon as asthenia became manifest. I began with $\frac{1}{60}$ of a grain, and increased to $\frac{1}{30}$ of a grain, every three hours. For the hemorrhagic condition I employed aromatic sulphuric acid, 10 minims every three hours, and ergotin, ¼ of a grain every three hours. For the impoverished blood state I used arsenic in the form of Fowler's solution, 2 minims every three hours, and after the degenerated condition of leucocytes became so marked I prescribed nuclein (Auld's), one tablet every two hours. This, with small doses of brandy at times, as indications for its use arose, comprised the treatment throughout the case. I will here mention that after prescribing nuclein for thirty-six hours I detected a difference in the appearance of the polymorphonuclear cells. They increased in number, were of smaller size, and the degenerated condition, which had before been present, gradually disappeared. Still, it is difficult to assure one's self that this result was brought about by the nuclein, and I mention it only for the reason that the drug was prescribed, and the change became manifest after its exhibition.

MEDICAL PROGRESS.

Cerebrasthenia.—Hirschkron (*Wien. Med. Blat.*, March 2, 1899) describes a special form of neurasthenia which he calls cerebrasthenia. It develops gradually with irritation and exhaustion of the nervous system which at first disappears after rest and sleep but later becomes permanent. There is at first a condition of psychic weariness. If there is a hereditary taint, or the circumstances are unfavorable, the need for sleep increases and the depression is greater until every mental act becomes an effort and the patient is in no condition to make a decision of any sort. Nevertheless the memory is unclouded, the judgment is unimpaired. By making an effort the patient can rouse himself for a time. Since the cause of the trouble lies in overwork of the brain the condition is usually found in brain-workers who overestimate invariably their power of endurance.

The treatment must be principally one of toning up the general nervous system. The patient should above all things avoid all irritating conditions, such as anger, cares, excessive work, disturbed sleep, excitement, excesses, and alcohol. Treatment is naturally best carried on away from home, in a health-resort, preferably in high mountains. Hydrotherapy, electricity, and among drugs, the syrup of hypophosphites are mentioned by the writer with approval. To secure sleep the bromids are first to be tried and if they fail the stronger hypnotics, such as sulfonal or trianol. To secure sleep for such a patient is of prime importance.

An Interesting Bit of Nose Surgery.—Abbot-Anderson (*Lancet*, March 11, 1899) was called upon to treat the nose of a cook who had cut off its tip while sharpening a knife. The patient appeared at his office without the fragment, and a boy was sent to the kitchen to look for it. His search was successful and the piece, which was a thin strip an inch long and half an inch broad at its lower end, was thoroughly washed in warm boric-acid solution and stitched in place with fine black-silk sutures. It had been severed for about thirty-five minutes. For four hours the nose was kept covered with compresses wrung out of hot boric-acid solution and was then protected from temperature changes by a thick dressing. The wound healed by first intention and the part was kept warm for some days afterward.

THERAPEUTIC NOTES.

Iodothyrin in Thyroid Chlorosis.—Jeulain in a monograph upon thyroid chlorosis, quotes the investigations of Hayem to prove that the thyroid gland is abnormal in most chlorotic persons. The affection is usually one of hypertrophy. He endorses this view not only because the symptoms of many chlorotic patients resemble those of exophthalmic goiter, but also because these patients were much benefited by the administration of thyroid extracts. His conclusions are these:

1. Among the chloroses due to auto-intoxication, is one which clinic and therapeutic observation explains as a thyroid auto-intoxication.

2. Clinically it is characterized by the usual symptoms of chlorosis, to which are added edema similar to that of myxedema, hypertrophy of the thyroid gland, and the signs of a commencing exophthalmic goiter.

3. Therapeutically this chlorosis disappears under treatment by iodothyrin.

The iodothyrin was administered in tablets of 4 grains.

each, of which from three to five were taken per day, the amount being gradually increased for a considerable period, and then decreased.

Treatment of Crural Ulcers.—FREUDENTHAL (*Monats. für prak. Dermat.*, February 1, 1899) after a long series of experiments with different remedies, comes to the conclusion that in the treatment of ulcer of the leg the particular remedy used is of far less consequence than the frequency with which the dressing is changed. No dressing ought to be left on more than three days, and it is better to change it every day or two. If the ulcer is sloughing or indurated it should be scraped out with a sharp spoon after thorough disinfection, or burned with the actual cautery, or nascent sublimate, obtained by mixing salt and bichlorid of mercury together. The patient should remain in bed for a week or two. After an ulcer has healed it should be watched for a time in order to protect the new tender skin from injury. A two-per-cent. solution of resorcin is valuable. Flannel and rubber bandages and rubber stockings are absolutely to be rejected on account of their irritating and sweating properties. A bandage of tricot woven in a long tube, five inches wide, is the most serviceable. After several weeks, from use and washing, such a bandage loses its elasticity and should be cast aside.

Morphin Combined with Cocain for Local Anesthesia.—CECI (*La Semaine Med.*, February 8, 1899) has used with complete success in more than a thousand operations a combination of morphin and cocain. The morphin is injected some minutes before the cocain so that its general effect may be felt before the injection of the latter. The dose of the morphin for an old person is from ⅓ to ½ of a grain and only one-half as much for a young person. The cocain is dissolved in a three-per-cent. boric-acid solution so that it shall contain one-half per cent. of cocain. Proceeding in this manner it is not necessary to obtain complete insensibility and the amount of cocain required is very slight. Ceci has, therefore, never had a case of intoxication and has not found it necessary to resort to the method of Schleich as his own procedure offers all of the advantages of the Schleich method. He has operated upon 362 hernias by this method, performing the radical cure, and prefers it in most cases to a general anesthetic.

Headache from Nasal Causes.—THOMPSON (*Jour. Amer. Med. Assoc.*, January 14, 1899) calls attention to the frequency with which headache is found to be due to nasal causes. Hypertrophic rhinitis, spurs pressing on the turbinate bones, deflected septum, or new growths, especially fibromata, or ulcers, or polypi, or purulent inflammation of the nasal or adjoining cavities are some of the common causes of nasal headaches. The disease in the nose which causes the headache is usually complicated by catarrh of the nasopharynx, pharyngitis, laryngitis, and bronchitis. The mucopurulent expectoration, cough, and dry throat in the morning are valuable symptoms. If understood they direct the physician's attention to the nose as the site of the primary disease. The coated tongue of obstructive disease in the nose is apt to be misleading. Mistake in diagnosis and mortifying failure in treatment can be avoided by remembering that a coated tongue means mouth-breathing more often than it indicates dyspepsia. The diagnosis of headache from nasal causes will be suggested by the history of catarrhal symptoms and long-continued pain. Direct examination of the nose will show evidence of one of the causal diseases already described. If cocainization of the nasal mucosa gives temporary relief of the headache there is greater probability that the cause is some disease in the nose. Touching the affected area in the nose with a probe often increases the pain if the headache comes from this cause. These tests, though, are not always diagnostic. One must sometimes depend on the results of treatment for a positive diagnosis.

Brewers' Yeast for Boils.—BROCQ (*La Presse Med.*, January 28, 1899) has experimented with an old remedy much used by the people in the North of France and in England, namely, the ingestion of brewers' yeast for the cure of boils. He was able to cure himself of pustules to which he was subject by taking at the beginning of each meal a teaspoonful of the yeast in a glass of wine and water, or mineral-water. In the summer it is necessary to obtain it fresh every day. In the winter, according to the temperature, it will keep one or two days. If brewers' yeast cannot be obtained bakers' yeast may be taken in its place, but it is not so well borne by the stomach and the good results are not so promptly obtained. He tried this remedy upon ten other sufferers, nine of whom received a prompt benefit from it.

Wherein Lies the Success in Treatment of Ulcer of the Leg? FREUDENTHAL (*Monats. f. prakt. Dermat.*, No. 3, 1899) believes in the most exact cleansing of a varicose ulcer as well as the area about it with cotton soaked in formalin solution, or peroxid of hydrogen, etc. If there is a phlegmonous inflammation he applies compresses wet with a solution of acetate of aluminum, 4 per cent. If the ulcer is sluggish it should be curetted or touched with a Paquelin cautery; but as patients usually object to such measures it is necessary to resort to topical applications. As an ulcer in a short time grows used to the particular application which is made upon its surface it is necessary to change frequently, not only the medication employed, but the method of its use, varying from a powder to a compress, or to a salve, or a plaster as the necessity arises. When the epidermis has once grown over the ulcerative area it is necessary to harden it by a resorcin salve (2 to 4 per cent.). A bandage of tricot should extend from the toes to the knee. Elastic stockings, rubber or flannel bandages, all exercise an unfavorable influence upon the skin and should be rejected.

Use of Apomorphin after Antitoxin Injections. — A Polish physician, ARNSTEIN by name, has employed apomorphin when, after injection of antitoxin for laryngeal diphtheria, the swelling and softening of the false membrane cause signs of suffocation. A hypodermic dose of $\frac{1}{12}$ of a grain induces vomiting and clears the larynx.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, APRIL 8, 1899.

TRANSFORMATIVE POWERS OF EPITHELIAL CELLS.

We called attention recently in an editorial on "Epithelial Regeneration, Epithelial Overgrowth, and Cancer" (Medical News, March 25th) to Dr. Leo Loeb's work on this important subject, and to the interest it involved because of the light it might serve to throw upon the etiology of malignant neoplasms. We have since had occasion to comment on Dr. Roswell Park's excellent article (Medical News, April 1st) on the nature of cancer. While there are a great many workers in pathology and pathogeny who have adopted the conclusion that the cause of cancer is a parasite there are many good authorities who think that the cause of neoplasms in general will yet be found to be bound up with the essential vitality of certain cellular elements awakened into unusual activity by persistent or unaccustomed irritation.

Our special correspondent in this week's account of "Medical Matters in Chicago" gives an abstract of a paper read by Dr. Loeb before the Chicago Academy of Medicine at its last meeting. In the observations we quoted two weeks ago from "Progressive Medicine" Dr. Loeb brought out especially the power which regenerating epithelial cells have of bringing about the absorption of other cellular elements. Even cartilage was observed to disappear before it. The present observations seem to show that epithelial cells may transform themselves into connective-tissue cells. After all, there is in the present state of our knowledge of original germinal conditions no embryologic impossibility involved in this. Dr. Loeb's microscopic specimens seem to have exhibited various stages of this metamorphosis from epithelium into connective tissue.

Of course observations differing, as these do, so radically from views that have been accepted up to the present time require further substantiation. The work has been very carefully done, however, and is not the result of some sudden inspiration or unexpected discovery but is rather the climax of a series of painstaking studies.

How suggestive for pathogeny the new ideas may be is clearly apparent. The abnormal sympathetic growth of connective tissue in the midst of epithelial neoplasms has been one of the special mysteries of this obscure subject. The new light thrown on the essential vitality of epithelial cells is of the greatest interest. We can only hope that Dr. Loeb's plan of cultivating epithelial elements upon some such artificial culture-medium as agar or blood-serum will meet with the success he seems to anticipate. Such serious workers as now have the subject in hand, both in histology as well as in parasitology, cannot fail ere long to solve the mystery of the etiology of that dread disease, cancer.

THE NEW YORK HEALTH DEPARTMENT AND THE SALE OF SERUM.

The bill before the New York Legislature, known as the "Collier Bill," restraining the New York City Board of Health from selling its surplus serum, has been defeated in the Assembly by a decisive vote, and the Board is, therefore, at liberty to dispose of its surplus serum as may seem to it wise. The private, financial, and personal interests involved in securing the passage of this bill have stimulated the expenditure of a great deal of money and produced much acrimonious talk and many unseemly insinuations in regard to personal motives, not only in the discussion before the committee, but also in the lay

and medical press, especially in the *Philadelphia Medical Journal*. In a series of editorial articles beginning in the issue of February 4, 1899, this periodical makes a series of statements which, if even partially true, would require the most serious attention of the physicians and citizens of New York. It is alleged that the mortality from diphtheria in New York City is double that in any other large city, and that this is due to the poor quality of its antitoxin; that furthermore, the people are taxed for this antitoxin some $80,000, — an amount of money many times that for which the same quantity of antitoxin of good quality could be obtained from private sources. A careful perusal of the articles show that they are founded on such a false interpretation of the official records that the attitude assumed could only emanate from a wilful misunderstanding. This remark applies not only to the number of cases of diphtheria occurring in New York, but also to the alleged great waste of money by the city laboratories.

To those who know the facts it is hardly necessary to allude to the personal attack upon those in charge of the laboratories as being interested financially in the sale of the serum. The motive for this attack upon the New York Board of Health is to be found, undoubtedly, in the effort to aid in the passage of the Collier Bill. The large distribution of a recent issue of the *Philadelphia Medical Journal* throughout New York State, for which it was undoubtedly handsomely paid, may also account for the ardor apparent in these editorials. We publish this week a candid statement over the signatures of Drs. Biggs and Park, which, while properly ignoring the insinuations as to personal financial interests, which are unworthy of the source from which they emanated, answers, to the satisfaction of any unprejudiced mind, the charges that have been made.

The question of selling the surplus serum, so far as legal enactment is concerned, seems to be settled for the present. The Board did wisely, considering the charges that were preferred, to exonerate itself by carrying on the contest to a successful issue. The throwing of mud will now probably cease. The economic question, however, of a subsidized institution entering into competition with private enterprise, still remains. Except under extraordinary circumstances it is pretty well agreed that this is wrong. The extraordinary circumstances which have justified this procedure on the part of the Board of Health up to this time no longer obtain, and we suggest the propriety of the Board of Health now accepting this economic principle, and by official action discontinuing the sale of all serum.

The great work that has been done by the Board of Health in helping to establish diphtheria antitoxin as a specific in diphtheria, its influence as an educational center for the dissemination of knowledge upon the subject, and its advanced work in bringing antitoxic serum to a high grade of perfection, is recognized by the community, and there need be no apprehension lest New York City should fail to supply whatever financial support may be necessary to maintain and continue the work. Let both the rich and the poor of New York be supplied with antitoxin free of charge, if class legislation to the contrary be unconstitutional, but let the Health Board clear its skirts of any charges detrimental to the interests of private enterprise.

THE NEWER(?) PATHOLOGY AND TREATMENT OF LOCOMOTOR ATAXIA.

It is difficult to comprehend the motives that prompt some writers on medical matters to the publication of their views, especially when their remarks teach no lesson and convey no moral. Of course it is impossible for every writer, who essays to illumine or to be illumined by writing on a subject, to say something new, or even to say it in a new way, but this does not license him to present it in a light which he must know, provided he possesses the faculty of comprehension, is not founded in fact. In a not remote number of a sincerely esteemed and high-class medical journal there is an article, entitled "The Newer Pathology of Locomotor Ataxia, and Its Bearing upon Treatment," which would lead us to expect, in the first place, that there is a new pathology of tabes, and in the second place that it has some bearing upon treatment.

It is the consensus of opinion of neurologists whose opinions are worth having that the conception of an anatomical unit of the nervous system, the neuron, has aided very little in pathology and absolutely none in therapeutics. Yet in the article referred to above we are told that "It has wrought a

revolution in the management of diseases of the nervous system," a statement that is absolutely and unqualifiedly without any foundation in fact. Furthermore, the writer would have us believe that "an early diagnosis and a lively appreciation of the nutritional character of the primary degeneration enable us now to hold out a much more hopeful prognosis than was possible with the older conceptions of tabes," a statement which we contend is subversive of the truth. An early diagnosis, even though it be accompanied by the most vivacious appreciation of the "nutritonal" character of the disease, does not warrant a prognosis fraught with one more atom of hope than did such a diagnosis a decade ago before the neuron was heard of. To support us in this opinion, we have the written testimony of the leading neurological authorities of the world, of Erb, of Ferrier, of Raymond, of Dana, and others to the end of the list, who have delivered themselves upon this matter in recent times.

"All measures which conduce to a restoration of the normal metabolic function of the nerve-cells are to be instituted." Was it ever otherwise, we would ask? Did not Duchenne, Meyer, Wunderlich, Remak, Charcot, Ross, Seguin, and Hammond maintain the same necessity, though with less pretension? If we recall the fact that Erb contends that more than ninety per cent. of these cases are syphilitic, that Fournier teaches that ninety-five per cent. have a syphilitic history, and that Mobius and Marie aver that all cases of tabes are syphilitic, how, we ask, can any man have the effrontery to speak of the marvelous treatment and improvement of locomotor-ataxia subjects under antisyphilitic medication? If there is one question that more than another is considered debatable among neurologists to-day, it is: Should antisyphilitic treatment ever be instituted in tabic patients who have no manifestations of syphilis other than tabes? It is not improbable that if this question were put to vote a negative reply would be obtained.

ADVANCES IN INORGANIC CHEMISTRY.

The past few years have seen most remarkable advances in inorganic chemistry. Previous to this scientists generally had about adopted the notion that until newer methods of investigation should be invented, discoveries in inorganic chemistry would be limited to the description of new and unusual combinations of elements.

Some three years ago the scientific world was startled from its lethargy in this respect by the announcement that Lord Rayleigh and Professor Ramsay had discovered a new element in the air. Ramsay, the codiscoverer of argon, has described during the past year three other hitherto undescribed elements that exist in the atmosphere. These he has called krypton, the hidden, because so long concealed; neon, the new, and metargon, an element having certain analogies to argon. To these new atmospheric elements an American, Mr. Charles Brush, has added a fifth, etherion, so-called because of certain points of resemblance to the ether that pervades all space. This substance has not yet substantiated its right to a place in the list of elements, for while certain very interesting evidence of its existence is at hand, as yet it has been impossible to obtain its spectrum.

Two other elements, it is claimed, have been discovered during the past year. One of them, polonium, has been studied in its sulphate, which occurs in pitchblende, a substance found in Poland, hence its name. It resembles uranium in its chemical properties and its compounds have been observed to emit like those of uranium an invisible radiation analogous to the Röntgen-rays. The other new element, coronium, was observed in the sun's atmosphere, and it is believed to be very much lighter than hydrogen.

We welcome sincerely this reawakening of the ardor of discovery in inorganic chemistry at the end of the century whose beginning saw such rapid strides in the just awakening science. The discoveries, and especially the newer methods brought into play, are of special interest to medical men because they open up a prospect of new applications of inorganic substances in therapy, and a better understanding of the therapeutic effects of old ones. The new discoveries in the air are particularly interesting because it had been thought that the ultimate elements of this substance at least were long known. They throw an interesting light on certain therapeutic opinions. There are those, and men of prominence, too, who have insisted that the ultimate constituents of such natural medicinal agents as the extracts of plants or

of the mineral waters were not known. What were known, they said, were merely the gross constituents; some of the finer components were missed entirely, and the method of their combination was a complete mystery. Hence the better results to be obtained very often from the crude drug, or its extract than from any of the chemical substances obtained from it. Hence, too, the better effect of the natural mineral water than of any artificial imitation of it. Whether the new era of discovery that seems to be opening up in inorganic chemistry will bring any nearer a definite solution of these important questions is for the future to decide, but any advance along the line toward the ultimate solution of them is encouraging and gives promise of great things for the new century.

ECHOES AND NEWS.

Tubercle Bacilli in Butter. — Dr. Petri of the Imperial Health Office in Berlin has found tubercle bacilli in 32.2 per cent. of 102 samples of butter examined.

Combined Business and Pleasure.—The patient may now take his cod-liver oil in the form of *pate de foie de morue*, which, according to a French paper, is both effective and agreeable.

Antitoxin Bill Defeated.—The "Collier" bill to prevent the sale of antitoxin and other serums by the New York City Board of Health was defeated in the Assembly at Albany on March 30th.

For the Care of Sick Soldiers.—The Jersey City Hospital has received from the United States Government $891 for the board and care of soldiers who were taken sick while passing through Jersey City.

Helmholtz's Brain.—Professor Hansemann of Vienna has examined the brain of the late Professor Helmholtz. Its weight was 1440 grams (about 45 oz.), and the convolutions were extraordinarily complex.

Rates for the Columbus Meeting.—It is announced that the Central Passenger Association has made a rate of one fare for the round trip for the Columbus Meeting of the American Medical Association in June.

Cerebrospinal Meningitis in Washington and St. Louis.—During the three weeks ending with March 27th there have been thirty deaths from this disease in Washington. A number of deaths due to the same cause are reported from St. Louis.

A Hospital Automobile.—An automobile ambulance has been presented to a Chicago Hospital. The vehicle weighs 1600 pounds, and is capable of a speed of sixteen miles per hour. This is probably the first electric ambulance ever constructed.

The German Red-Cross Medal.—This decoration has been created by the German Emperor at the suggestion of the Empress. The medal will be given to men and women belonging to the Red-Cross Association who distinguish themselves by their zeal.

Pensioner Regrets His Cure.—A Minnesota veteran, having given a public testimonial to a patent-medicine firm that its medicine has restored him to perfect health, is now trying to set himself right with the Pension Office, which proposes to take him at his word and cut him off the pension rolls.

A Summer Course in Medicine. — Cornell University Medical College announces that it will conduct a summer course for students of all grades during the summer of 1899. The course will cover the period from May 15th to August 1st, and the instruction will be chiefly clinical, with laboratory work and quizzes.

Typhoid Fever in Newark.—From March 1st to March 24th there were 260 typhoid cases in Newark, N. J. During the whole of the year 1898 there were but 179 cases. The source of infection for the present epidemic is the use of the water of the Passaic River during the water-famine resulting from the blizzard.

Tuberculosis in Tenement-houses. — On March 21st President Murphy of the New York City Board of Health ordered an inspection of tenement-houses with a view to ascertaining the number of cases of consumption among the inmates. The inspectors will distribute slips to the tenants, on which are printed directions as to prophylaxis, etc.

An Accidental Improvement —The table of contents in a recent number of a well-known and much-liked contemporary begins as follows: Original Communications: Fractures Improving the Elbow-Joint. By turning to the page indicated, it appears that the "improvement" was "original" with the printer, and did not "involve" the writer of the article.

German Soldiers Gain in Weight.—Mueller of Berlin is authority for the statement that the German soldier gains on the average nine pounds' weight during the first three months of his service. A portion of this is lost during the summer maneuvers, but at the close of the twelve months he weighs on the average 4.5 pounds more than upon his entrance into the service.

Chicago Dental Charity.—The Chicago Bureau of Associated Charities has arranged to open a dental dispensary in each of its ten districts, the object being to furnish dental service to the poor at the smallest possible cost. Teeth will be extracted for ten cents. Filling will cost from fifteen to twenty-five cents. The dentists volunteer their services and the material used is furnished at cost.

Photographing the Stomach. — Drs. Lang and Meltzing of Berlin have presented an apparatus which they have invented for photographing the interior of the stomach. The tube, the end of which contains a microscopic camera

and an electric light, is inserted into the stomach. The negative is about the size of a cherrystone, but it can be enlarged. When the stomach is emptied and filled with air the photograph is made.

A Bipartisan Charities Board.—On March 30th a bill was introduced in the Assembly at Albany which practically makes the Charities Department of New York City bipartisan. The number of charities commissioners is increased to six, of whom two shall be from Manhattan and the Bronx, two from Brooklyn and Queens, and two from Richmond. In none of these instances shall more than one of the commissioners be of one political party.

Contagious Diseases on Trains.—The Jersey City Board of Health has appointed a committee to confer with the officers of all the railroads centering in Jersey City to the end that some means may be devised by which the Board of Health can be notified at once of the arrival of any person who is suffering from an infectious disease. Cars which may have come from places where infectious diseases are prevalent will be fumigated on their arrival at Jersey City.

Professional Secrecy in English Law. — A memorandum of the law of England relating to the obligation of medical practitioners with regard to professional secrecy has been prepared by Mr. Muir Mackenzie, at the request of the General Medical Council. It is declared that "a medical man not only may, but must, if necessary, violate professional confidences when answering questions material to an issue in a court of law." The law of New York is directly contrary to the English law in this respect.

Information as to Dr. Hjalmar Stromberg Wanted. — A letter has reached us asking for information as to the present whereabouts of Dr. Hjalmar Stromberg formerly of Ystad, Sweden. He came to this country, as we gather from a letter to us from his mother, in July, 1891, and was in a hospital in Memphis, Tennessee, during August and September of that year. Afterward he studied medicine for three years and graduated as a physician. Since 1895 nothing has been heard from him and relatives in Sweden are anxious for information.

Increased Pay for Army Nurses. — All contracts made with the nurses in the employ of the United States Government which were renewed on April 1st are at a salary of $40 per month instead of $30 for the nurses serving in the United States, and $50 per month for those serving abroad. No one under twenty-five years of age will be received. All nurses, except those who are to nurse yellow-fever patients, must be graduates of a training-school, and must furnish a physician's certificate as to physical ability to undertake the work. Dr. Anita Newcomb McGee, Acting-Assistant Surgeon, has charge of the trained nurse department of the Surgeon-General's Office at Washington, D. C.

Aguinaldo as a Medical Student.—Our London contemporary, the *British Medical Journal*, is authority for the statement that for a time at least, Aguinaldo, the leader of the Filipino rebels (or patriots?) was a medical student. His European cast of features has given rise to the story that he is a half-breed, though it is not known who his parents were. The honor of his paternity is attributed to a Spanish general. At fifteen years of age he entered the Pontifical University of Manila, where he worked under Professors Naldo and Buitrago. He afterward studied at the Victoria College (British) at Hong Kong. He was remarkable for his ability as a student but further than this nothing seems definitely known of his college career. It is not known for instance whether he pursued his medical studies up to graduation or not, so that we cannot say that he is more than a professional half-brother at most.

Another Strike among the Italian Medical Students —The year has not been allowed to pass without the usual row between the students and faculty of at least one of the Italian Universities. There has been for a number of years a strained feeling between faculties and students over the question of an Easter examination. This has always kept things in a state of tension that made lapses into insubordination easy whenever anything occurred to set up a little vibration in the mutual relations of students and professors. This year it is at the University of Turin, and the cause is a revolt against Professor Fusari, the teacher of anatomy. Every effort has been made without success to induce the students to give up their opposition. It has been pointed out that Professor Fusari owes his place to a successful competitive examination, and that his work eminently fits him for the place, but to no purpose. Professor Bacelli, the Minister of Public Instruction, endeavored to call them to their senses in the matter by an admonitory *avviso* in his public capacity. This was no more successful in bringing about better feelings than previous efforts at reconciliation so the Government has decided to close the medical school for the rest of the session. This will cause the loss of a year to all the students in the medical department, and not alone to those in the school of anatomy who seem to be the real offenders.

CORRESPONDENCE.

THE NEW YORK BOARD OF HEALTH AND DIPHTHERIA ANTITOXIN—AN OFFICIAL STATEMENT.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Replying to your inquiries regarding certain statements which have been made in the *Philadelphia Medical Journal* and in the lay press as to the work of the New York City Health Department we gladly submit the information that you desire.

1. All of the experimental work upon diphtheria antitoxin as well as the work connected with its routine production for curative purposes has been entirely done by the bacteriologists of the Department of Health and has always been directly under our own personal supervision. The city authorities declined to make the appropriation necessary to provide special stables for the Department of Health for this purpose, and, therefore, the horses have

always been kept at the stables of the New York College of Veterinary Surgeons. They are, however, and have always been wholly under the supervision of the officials of the Department of Health.

2. The Department of Health in order to carry on its work has been compelled to produce its own vaccine virus and diphtheria antitoxin, for only in this way can it be always certain to have at command a sufficient quantity of active vaccine virus and high-grade diphtheria antitoxin. On several occasions the Department of Health has supplied large quantities of diphtheria antitoxin to private producers who have not had sufficient to supply a sudden large and urgent demand. The Department of Health can also produce diphtheria antitoxin much cheaper than it could buy this agent because of the large and constant demands upon it for use among the poor in Greater New York.

3. The Department administers antitoxin without charge in any case of diphtheria among the poor upon the request of the attending physician. It also gives diphtheria antitoxin free to any physician who states that it is to be used in the case of a patient to whom payment for it would be a hardship, and it further not only supplies its own hospitals but furnishes diphtheria antitoxin and all its other laboratory products free to all public institutions in Greater New York. The amount of antitoxin administered by its own inspectors constitutes a very small portion of that given free. In 1898 more than $40,000 worth of diphtheria antitoxin and other antitoxins was given free while the sales for the year amounted to only $13.963. No attempts have ever been made to increase the sales by advertisement or in any other way.

4. The reports from the Division of Bacteriology as to the number of cultures examined are entirely distinct from those made from the Division of Contagious Diseases as to the number of cases of diphtheria reported as occurring in the city. In the period alluded to in an editorial in the *Philadelphia Medical Journal* (*i.e*, the first half of 1898) there were 7051 cases of diphtheria and croup reported to the Division of Contagious Diseases. All of these cases were regarded by the attending physicians as diphtheria, a portion only were examined bacteriologically (no regulation of the Health Board requires bacteriological examination) and many of these were only reported as diphtheria after the examination by culture. Many cases, however, were so clearly diphtheria from a clinical standpoint that no cultures were made (for example, only very rarely are the fatal cases of croup examined bacteriologically). Others were doubtful from a clinical standpoint and were only considered by the physician to be diphtheria after the results of bacteriological examination were known. Many other doubtful cases occurred, but as the cultures showed no diphtheria bacilli they were not regarded by the attending physicians as diphtheria and were, therefore, never reported as such to the Division of Contagious Diseases and do not appear among the 7051 cases reported for the half year. Therefore, only a portion of the cases examined bacteriologically appear in the 7051 cases of diphtheria reported to the Division of Contagious Diseases.

5. As to the advisability of the Department of Health being allowed to sell its surplus product of vaccine virus, diphtheria antitoxin, and other antitoxins it should be kept in mind that these substances are solely employed for the preservation of life and the prevention of disease. They are so necessary for the public health and so difficult of preparation and preservation that they are almost universally considered to be in a different category from ordinary drugs and in Europe are largely made either under the direct supervision of the health authorities or in some semi-official scientific laboratories, such as the Pasteur Institute in Paris and the British Institute of Preventive Medicine in London. So far as this city is concerned, where most of the sales of department antitoxin are made, it may be said that it would be necessary to give antitoxin free to all persons desiring to use it, both rich and poor, if the Department did not have the right of sale. To give it free would merely cut off a revenue amounting to some thousands of dollars which is now used for purely experimental work in the laboratories and which, up to the present time at least, the city authorities have declined to appropriate for this purpose.

6. Those who are familiar with the work of the laboratory know how small a part of the expense is due to the simple production of diphtheria antitoxin. Even those engaged chiefly in its production give much of their time to the experimental work relating to the separation of the serum and its better chemical understanding. Others are working upon infections due to the streptococcus, pneumococcus, typhoid bacillus, tubercle bacillus, and other pathogenic organisms.

The work of the laboratories has always been open to inspection, and any information as to its methods has always been, and so long as we are in charge of it, always will be freely and gladly given to any who rightly apply for it.

Very sincerely yours,

HERMANN M. BIGGS,
Director of the Bacteriological Laboratory.
WILLIAM H. PARK,
Asst. Director of the Research Laboratory.

NEW YORK, March 29, 1899.

AUTOPSIES AND THE ANTIVIVISECTIONISTS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your recent editorial headed "Autopsies, the Antivivisectionists, etc.," you say: "One of the serious objections on the score of inhumanity, we suppose, that was urged against the management of the General Hospital at Vienna, by the zealous antivivisectionists at their recent meeting in Philadelphia, was that an autopsy is performed in the case of every patient that dies in the hospital. Like many statements made by the antivivisectionists, this is not entirely true."

I beg to assure you that there is not the slightest foundation for one word of this paragraph nor of another soon after, which is as follows: "The truly senseless phase of this discussion, so conspicuous at the recent

Philadelphia meeting, reveals the true inwardness of the antivivisectionist movement and its fanatical opposition, for certain merely sentimental reasons, to scientific advance."

At that meeting not only was there not a single word, that I can remember, spoken upon the subject of autopsies, but never in the whole history of the antivivisection movement, has there been the slightest objection made to them or to anything else which came strictly within the province of the medical profession and had no connection with our work. The only thing to which we do object, is the torture of helpless, unoffending animals, the infliction of which we consider is a grievous sin in the sight of a merciful God. Yours truly

Caroline Earle White,
Cor. Secretary of Amer. Antivivisection Soc.
2024 Chestnut Street, Philadelphia.

[We are sorry that the newspaper accounts of the meeting of the antivivisectionists should have led us into the error that Mrs. White points out and we are glad to be assured that the antivivisection movement does not oppose autopsies.

We have to apologize for a misstatement of what Mrs. White said at the same meeting of the Antivivisectionists with regard to experiments upon patients at the Vienna General Hospital. In this, too, the daily papers exaggerated what was said at the meeting, and quite changed its purport. That and the interviews on the subject at the time led us to suppose that bitter criticism had been indulged in at that meeting, while we learn that only certain extracts from foreign journals were read.

We cannot refrain from pointing out the mischief that is done by repeating unauthoritive newspaper stories containing the most vague and general accusations against the great hospital that has done so much for modern medicine. They can only arouse bitter feelings, and can never lead to reforms, supposing there should be need of them. Many a physician interested in the prevention of cruelty to animals is deterred from expressing his feelings in the matter because it would seem to associate him publicly with those who are too ready to give credence and publicity to unsubstantiated statements about the medical profession and its relations to animals and patients.—Ed.]

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

ANNUAL MEETING OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA—FORTY-THIRD ANNUAL COMMENCEMENT OF THE PENNSYLVANIA COLLEGE OF DENTAL SURGERY—ELECTION OF THE PHILADELPHIA COLLEGE OF PHARMACY—THE WATER QUESTION AGAIN—HOSPITAL BEQUESTS—CHARITY-BALL PROCEEDS—STATE MEDICAL LAWS UPHELD—PERSONAL NOTES—HEALTH STATISTICS.

Philadelphia, April 4, 1899.

Johnstown is to be the meeting-place of the forty-ninth annual meeting of the State Medical Society which will be held on Tuesday, Wednesday, and Thursday, May 16th, 17th, and 18th. The following addresses will be given: President's address, Dr. W. B. Lohman, Johnstown; address in medicine, Dr. J. C. Lange, Pittsburgh; address in surgery, Dr. G. W. Guthrie, Wilkesbarre; address in obstetrics, Dr. F. P. Ball, Lock Haven; address in hygiene, Dr. W. M. L. Coplin, Philadelphia; address in mental diseases, Dr. H. L. Orth, Harrisburg; address in laryngology, Dr. D. Braden Kyle, Philadelphia. Dr. George W. Wagoner, Johnstown, is Chairman of the Committee on Arrangements and Credentials and Dr. S. S. Towler, Marionville, Chairman of the Committee on Scientific Business.

The forty-third annual commencement of the Pennsylvania College of Dental Surgery was held last week, 113 graduates receiving diplomas.

The Philadelphia College of Pharmacy has elected for the ensuing year the following officers: President, Chas. Bullock; secretary, William N. Stern.

Acting Chief of the Bureau of Health Colonel Lewis J. Good believes he has discovered the source of pollution in the Schuylkill river, which is responsible in great part, at least, for the epidemic of typhoid which so far shows no signs of abating. The Manayunk canal from Glen Willow, where it starts, to the Schuylkill, at Manayunk, where it ends, was thoroughly inspected by Colonel Good and Dr. L. C. Wessels, the Bureau's inspector for that district, and it is believed that the trouble arises in this vicinity.

The movement or agitation in favor of pure water continues and well it may, with a total since January 1st of 4855 cases and 493 deaths from typhoid. The Board of Education has taken steps to utilize the $23,000 appropriated by councils for water-filters to be placed in the schools. Dr. Morton and Dr. Williams, members of the Committee on Hygiene. are to make a special report to their fellow board members this week advising that not only should filters be purchased but means for boiling the water should be provided. To add to the general trouble of the pollution of the water it now appears that owing to broken-down and inadequate pumps the city is in danger of a water-famine which may occur at any time. If the facilities for pumping were improved enough water could be held in reserve to allow sedimentation to take place and thus the water would be less impure; with this fact in view it is proposed to patch up the pumps, prevent all waste of water and struggle along in this way until Providence sees fit to bring about the millennium and provide us with councilmen honest enough to give us pure water.

The will of George W. Lukens, which was probated last week, provides nearly $50,000 to the Grand Lodge of Masons to endow a hospital for the Masons of Pennsylvania. The old Lukens homestead in Frankford is left for this purpose and should the Masons refuse the bequest, all is to be turned over to St. Mark's Episcopal Church for the same purpose. S. C. Blake of Santa Barbara, California, who died recently, bequeathed $10,000 to the Orthopedic Hospital of this city. Still another bequest of last week is that of Jane McAnally who died in St. Agnes' Hospital two weeks ago. St. Joseph's Hospital is left $1000, St. Agnes' $1000 and St. Vincent's Home Maternity Hospital $2500.

The Hebrew Charity Ball Association has distributed $16,368.50, the proceeds of the February ball, among the following institutions: Jewish Hospital Association, $5237.92; United Hebrew Charities, $5074.23; the Jewish Foster Home, $4910.55 and the Orphans' Guardians $1145.80.

The Philopatrian Ball was given for the benefit of the Free Hospital for Consumptives but owing to the blizzard the receipts barely met the expenses. For this reason a progressive euchre is to be given for the hospital on Monday evening, when it is hoped a sufficient amount of money will be raised to carry on the work as there is a great need for funds.

Owing to the energetic work of the Erie County Medical Society the Pennsylvania Medical Law has been declared constitutional and too much gratitude cannot be shown the society for its sterling work in pushing this case. Part of an abstract of the opinion given by Judge Walling of Erie, taken from the *Pennsylvania Medical Journal*, follows: "In the case of Commonwealth *vs.* Robert Lee Finn, the Medical Society of Erie County, acting as complainant, the jury found that Mr. Finn was practising medicine without conforming to the law. His attorneys thereupon contended that the law was unconstitutional, in that it did not provide for other schools of medicine than the regular, homeopathic and eclectic. The number of Boards of Medical Examiners which should be provided for, is a question for the legislature, and not for the courts. The act would have been valid had it only provided for one Board of Medical Examiners, and because the legislature had seen fit to broaden the field, and thus render it less difficult for the applicants to comply with its terms, cannot be a valid objection to the act. It is a mistake to assume that the act limits the practice of medicine in Pennsylvania to three schools. True, there are only three Boards of Examiners, but after the applicant has successfully passed one of these boards, there is no limit to the school of medicine in which he can practice."

Dr. Edward Schellinger has been appointed assistant surgeon on the visiting staff of the Cooper Hospital of Camden and Dr. F. Otis Bryant on the medical staff of of the Chester Hospital to succeed Dr. D. W. Jeffries, mayor-elect of Chester.

Dr. D. W. Bland of Pottsville, died suddenly last week of heart disease. He was surgeon of the Ninety-sixth Pennsylvania Infantry during the Civil War and for nearly forty years had practised in Pottsville.

The total number of deaths occurring in Philadelphia for the week ending April 1st, as reported at the Health office was 504 of which number 128 occurred in children under five years of age. The total number of new cases of contagious diseases was 497 reported as follows: diphtheria, 59 cases with 11 deaths; scarlet fever, 33 cases with 3 deaths; typhoid fever, 404 *cases with* 43 *deaths.*

Mortality in New York State —There were 10,763 deaths in New York State during February, 1899. This number exceeds the mortality during February, 1898, by 1500. Grip is considered responsible for the increase.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

ORIGIN OF CONNECTIVE TISSUE FROM EPITHELIAL CELLS—IMPLANTATION OF URETERS IN RECTUM —DONATION BY MRS. OWSLEY—ANTITOXIN TREATMENT OF DIPHTHERIA IN CHICAGO.

CHICAGO, April 1, 1899.

AT the March meeting of the Chicago Academy of Medicine Dr. Leo Loeb read an interesting paper in which he discussed the possibility of the origin of connective tissue from epithelial cells.

He reported some observations of transitional stages between epithelium and connective tissue. These observations were made in connection with experiments on the transplantation of skin. In one series of experiments the skin was transplanted on superficial wounds; in another it was transplated in the deeper layers of the ear of the guinea-pig. The transplanted skin was examined in many stages of its healing process.

In many places one gets the impression that the nuclei of the deeper epithelial cells were transformed into the nuclei of the connective tissue. The nuclei of the deepest epithelial cells may sometimes have a different morphological character. In such cases the nuclei of the underlying connective tissue have frequently forms corresponding to those of the nuclei of the epithelial cells. Not infrequently the nuclei of the deepest epithelial cells have no longer their usual vesicular structure, but have a structure more like that of the connective tissue, being more or less rod like in character. Secondly, at certain places beneath the epithelium one notices the fading away of the epithelial cells so that only their dim outlines may be visible. The regenerating epithelial cells are often closely connected by protoplasmic bridges with the underlying tissue. Especially in the hair-follicles beneath transplanted tissue there appears a gradual transition of the character of epithelial cells to the character of connective-tissue cells. Under certain conditions the regenerated epithelium presents the appearance of the "upper protoplasmic layer." The latter is characterized by its homogeneous transparent protoplasm and its lack of visible-cell limits. It possesses nuclei which do not have the ordinary vesicular appearance of epithelial nuclei.

Microscopic sections obtained from three experiments were described more in detail. They showed at different places appearances of gradual transition of epithelial cells to connective-tissue cells.

The nearer the cells were to the epithelium the more closely did they have the character of epithelial cells. Farther away they showed the typic character of connective-tissue cells. In a former paper the author had reported an observation of the epithelial tissue breaking through cartilage. Here the epithelial cells take a spindle form, being much drawn out, so that they could be easily taken for connective-tissue cells.

To these cases of transition the epithelial cells and connective-tissue cells have the same direction. It must be stated that at many places there is a sharp line of demarkation between the epithelium and the underlying

tissue, but frequently there is a direct connection no, such line of demarcation being present.

The papillæ in the regenerating or in the transplanted skins do not have the regular form as seen in the normal skin, but have the most irregular and grotesque forms. They may form an overhanging protuberance, the basal portion of which is separated from the epithelium by a straight line. This curious formation can be explained on the supposition that the papillæ are formed by the gradual breaking down of the epithelium.

Along the margin of the papillæ one sometimes observes the dim outlines of the original epithelial cells and nuclei which have the character of connective tissue, yet nuclei resembling the nuclei of the epithelial cells are situated in the direction of the nuclei of the epithelial cells. In a former paper the author had described how in certain cases the epithelium penetrated into the blood, but in such cases no connective tissue could be detected. Further experiments are in progress to study the action of different tissues on substances like agar, and blood-serum, in order to observe the regeneration under these conditions, and if possible to get means to isolate different tissues in this way.

Beneath the regenerating epithelium one very often finds a layer of fibrous tissue so closely attached to it that it appears to have been derived from the epithelium. This layer has the character of a connective-tissue lamella, and branches out beneath into the connective tissue. These are the main facts. The theory that epithelium can change to connective tissue would explain them. The pictures described above are not brought about by the epithelium being dragged into the connective tissue by the microtome knife. These microscopical appearances cannot be explained by the hypothesis that connective tissue changes to epithelium, because epithelium regenerates only in connection with epithelium. They might be partially explained by the supposition that connective tissue from beneath grows upward and forms a connection with the overlying epithelium. But in a number of cases we observe that the cells near the epithelium are much more like epithelial cells than the cells far away. This fact must be explained. And, in addition, the peculiar forms of the papillæ cannot be produced by the destruction of the epithelium through connective-tissue cells. If that were the case we should expect to see much more frequently that cells of one character, namely, connective-tissue cells, penetrate into and mingle with cells of another character, namely, epithelial cells.

Embryological facts do not exclude the possibility of the above-given interpretation. A closer analysis of the term germ layer, as has been given in a paper of Braem, shows us that the term has by no means such a fixed meaning as was formerly thought.

At the meeting of the Chicago Gynecological Society, held March 17th, Dr. Franklin H. Martin exhibited specimens and made a further report of implantation of ureters into the rectum. The new operation has for its object the making of subsequent infection of the ureters and kidneys impossible after double implantation of the ureters into the rectum. The post-mortem findings in experimental operations for uretero-rectal anastomosis where no effort was made to provide for valve formation show unmistakable signs of infection of the kidneys due to ascending infection through the ureters. He has operated upon nine dogs by his new operation, two of which recovered. The paper deals with the report of the first dog in the second series which lived, that is, the one operated upon after the improved method. The dog was operated upon December 22, 1898, and was anesthetized and killed March 11, 1899, having lived nearly three months.

The principles of the operation are: (1) The ureters empty into the bowel in the direction of its long diameter, and from above downward, so that the urine is discharged in the direction taken by the fecal current. (2) The ureters are buried in the walls of the rectum for a distance of an inch or more longitudinally, so that in the act of defecation the fecal mass will squeeze the ureters and close them by its pressure on the mucous membrane. Moreover that pressure is exerted from above downward in the direction of the onward flow of the urine, thereby emptying the ureter by a milking process. (3) The ureters are further protected by the muscular coat of the intestines, this is accomplished by surrounding them in their longitudinal course through the intestine to the extent of two centimeters by the circular coat of the bowel. This muscular coat of the bowel in acting from above downward, milks the urine downward and holds the ureters closed when the rectum is aiding in defecation. When the contraction and closure due to the defecation are over the urine will spurt forth with considerable force acting as its own cleanser. (4) The ureters are implanted in the lower bowel which is normally empty except at defecation.

A preliminary report of bacteriological findings during life and post-mortem in the case of implantation of both ureters into the rectum was given by Dr. F. Robert Zeit.

In the discussion of Dr. Martin's paper, Dr. Reuben Peterson stated that some four of five months ago he had under his care a case of malignant disease of the bladder. Thinking that possibly the extirpation of the bladder would be necessitated he perfected himself in the technic of implantation of the ureters in the rectum. He performed the operation on a dog who promptly died. A second examination of the case convinced him that the disease was too far advanced to warrant total extirpation of the bladder. But his interest was aroused in the subject and he has been experimenting upon ureteral implantation ever since. He is not prepared to report definitely regarding either the technic of his operations or their results. He confesses, however, that he cannot take as favorable a view of it as Dr. Martin does, if by favorable is meant that there is hope that the operation may be applicable to the human subject. From his experience of this operation on the lower animals, he does not feel justified in implanting the ureters into the human rectum. Final judgment should be reserved until an opportunity is had of examining many specimens of the kid-

neys and ureters of dogs who have lived months after the operation; then and only then will surgeons be in a position to decide upon the merits of the operation.

Mrs. Heaton Owsley, representing the heirs of the Carter H. Harrison estate, has presented $8700 to the Mary Thompson Hospital for Women and Children. The money will be held in trust, and the interest applied to the maintenance of a room to be known as the Carter H. Harrison room.

The record of the antitoxin treatment of diphtheria of the Chicago Health Department for the past four months —November and December, 1898, and January and February, 1899—is even better than that heretofore published, showing a reduction of mortality to only 4.78 per cent. in 418 cases. There was no deaths in 129 cases treated with antitoxin in the first or second days of the disease, and there are only three among 114 on the third day, a percentage of 1.23 in a total of 243 cases treated in the first three days from the onset. These records deal exclusively with the gratis treatment of diphtheria among the poor and under the most unfavorable conditions, and do not include the cases removed to hospitals. Thirty-eight or 9 per cent. of the cases required intubation, with 30 recoveries and 8 deaths, a mortality percentage of 21, or less than ⅔ of the average deaths-rate of all cases before the introduction of the antitoxin treatment. The constantly decreasing mortality statistics also indicate that the use of the antitoxin treatment is increasing in private practice, and that Chicago physicians are employing this method more generally and successfully than any similar number of their profession in any part of the world.

OUR LONDON LETTER.

[From Our Special Correspondent.]

AMAZING ADVICE FROM THE LAY PRESS ON INFLUENZA—THE PRESIDENCY OF THE ROYAL COLLEGE OF PHYSICIANS—AGAIN THE NEW "ORDER OF MERCY"—THE CHAIR OF PHYSIOLOGY IN THE UNIVERSITY OF EDINBURGH—EMOLUMENTS OF UNIVERSITY CHAIRS—VARIOUS NEWS ITEMS OF INTEREST.

London, March 24, 1899.

The influenza still subtends a large arc of the public visual angle both lay and professional, although it is fortunately now diminishing both in extent and intensity. An amusing feature has been the oracular advice of the daily press in regard to the prevention and mitigation of the disease. The *Daily Chronicle* one day editorially Solomonizes to the effect that "people do not get serious attacks of influenza who keep their blood well alkalinized with potash" whatever that may mean. Two days later it semi-editorially "hedges" by quoting from "one who speaks with authority" the awful warning that there is danger in the use of potash salts of any kind "as the smallest amount of free potash formed by the interaction of the potash salt with other mineral salts in the blood—is the cause of heart failure!"

This "Daniel come to judgment" must be either a freshman medical student or an amateur dabbler in physiology who has been reading of Claude Bernard's classic experiment of stopping the frog's heart in systole by a potash solution, a result which we need hardly say has never yet been paralleled in the human body even under the most heroic "tertiary" doses of the iodid.

Truly a little knowledge is a dangerous thing. This solemn warning proves, however, to be simply Daniel's introduction to a remedy of his own, repeated doses of a one-per-cent. solution of common salt which he avers to be "the natural and normal remedy for preventing and curing the disorder." It is to be taken in "frequent potations until a reduced watery state of the organism" is attained. A cheerful and convivial remedy but one which is even more dangerous than the potash according to Daniel's own logic, for, have not thousands of deaths in the human family been attributed to breath-failure, due to salt-water in sufficient excess to produce precisely a "a reduced watery state of the organism"?

The annual election of a president for the Royal College of Physicians is at hand and as the present incumbent, Sir Samuel Wilks, has announced that this being his third term he will not allow his name to be again presented as a candidate, the college is looking about for his successor. Some four or five names are mentioned of Fellows whose seniority entitles them to consideration. Sir William Broadbent, Dr. W. H. Dickenson (of albuminuria fame), Dr. W. S. Church, and Dr. S. J. Gee, of whom Sir William Broadbent appears the favorite and most probable candidate. The presidency is the blue ribbon of the medical side of the English profession and it has come to be practically expected that its holder will be knighted at the close of his term, if that honor has not already been conferred upon him.

The *British Medical Journal* has a long editorial comment upon the Prince of Wales' new Order of Mercy which criticises it very much along the same lines as that of our last letter. It regrets both the necessity of such a movement, the manner of practically enforcing small contributions, the "snowball scheme" of charity and the granting of an order for what ought to be the spontaneous kindly impulses of humanity. Still it wishes the plan success as the need it has undertaken to fill is a crying one.

The lists have been formally opened for candidates to the Chair of Physiology in the University of Edinburgh left vacant by the death of Professor Rutherford. A number of quite distinguished names have already been presented, among which are those of Professor Schäfer of University College, London, well known for his superb histological work in the new "Quain"; Professor W. D. Stirling of Owens College, Manchester, and Dr. E. Paton of Edinburgh.

The emoluments of the chair are officially announced at $7000 per annum. Not a few of the Scotch chairs are surprisingly well paid. The chair of anatomy in Edinburgh by dint of various "hereditary" grants and dues which have been accumulated is reported to be worth $20,000 per annum. Several chairs in both Edinburgh and Glasgow draw from $8000 to $12,000 and

even in Aberdeen, far North as it is, a number of the chairs both scientific and medical run about $5000.

In spite of our huge donations and legacies to universities and colleges, we are really falling behind in America in the matter of salaries, for much to my surprise, I find that the class of teachers who with us are getting $2500 to $4000 (and there are few enough of any class at the latter figure) here receive from $4000 to $6000. Even the German universities are becoming more liberal, for when in Berlin this summer several *privat docents* inquired as to the supposed large salaries in America and were greatly disappointed when they learned their real figure. The leading chairs in the University of Berlin are worth from $10,000 to $15,000 a year, chiefly from a share in students' fees.

The Scotch salaries come chiefly from old, long-established government grants or municipal funds, proof of the splendid public spirit which has always prevailed in poor but plucky Old Scotia in respect to education. The body which will elect Professor Rutherford's successor, known as the "Curators of Patronage," are seven scientists, four chosen by the Town Council of Edinburgh and three by the Court of the University. If England instead of endowing fat priests and progress-hating bishops had "established" education three centuries sooner, she might not have been compelled to draw so many of her best workers and thinkers from north of the Tweed.

The Medical Society of London has just celebrated its 126th anniversary by that most solemn and sacred rite known to the Englishman, a dinner. At the close of the speech-making, which was of a comparatively cheerful character, the President, Mr. Edmund Owen, presented the Fothergillian gold medal to Dr. Monkton Copeman for his work upon glycerinated lymph in vaccination.

Professor Burden Sanderson of Elsford delivered last week the Croonian lecture before the Royal Society upon "The Electric Concomitants of Motion in Animals and Plants."

Owing to the death of Professor Kanthack it is announced that no summer medical session can be held at Cambridge this year.

Lord Lister has been elected as an Associate of the Academie de Medecine of Paris. It is an amusing comment upon the force of "patriotism" even in the most sublimely scientific circles that Koch was also elected at the same meeting and that while Lord Lister's vote was unanimous and by acclamation upon Koch's several of the members abstained from voting.

The public is greatly concerned over the fact that nearly 35 per cent. of the recruits for the army during the past year were rejected on physical grounds, but as nearly half of these rejections were on account of defective teeth the matter hardly seems serious enough to talk of "racial degeneration." It will be remembered that our own army medical examiners rejected almost as many and for the same most frequent cause.

Mr. Frederick Treves, who resigned his surgeonship at the London Hospital on account of the pressure of his private practice—and because certain ancient and hidebound rules and traditions would not allow him to delegate the drudgery of his hospital work to assistants—has been appointed Emeritus Professor of Surgery, which honorary position involves the delivery of four lectures a year.

Mr. Justice Darling voiced the sentiments of the community at the late Chester Assizes when he protested against "sham death-sentences" and advised a grand jury in considering an abortion case not to bring in a bill of murder unless they thought the offense was committed with intent to kill.

Two cases of the use of preservatives in milk have recently been before the courts, one in Liverpool and the other in London. Formalin was used in one case and borax in the other and the addition admitted in both cases by the vendors. As usual the profession stultified itself by testifying "expertly" upon *both* sides of the question as to whether the said adulterants were harmful. One set of experts declared the drugs to be poisonous and capable of producing "diarrhea, indigestion and eczema," while the other averred them to be in the quantities used as harmless as common salt and of direct value in preventing decomposition. So the puzzled magistrates dismissed the cases. When are we going to have the sense to recognize that *no* non-dietetic addition of any foreign substance whatever to milk, cream or other perishable foods ought to be tolerated on the ground that it not only permits and covers up but puts a premium upon careless and dirty handling at every stage of its production and shipment?

Dr. Monkton Copeman's Nulvey Lectures on the "Natural History and Pathology of Vaccination" have just appeared in book form and are attracting wide attention. It will, we think, be news even to most medical men to learn that Jenner's original thesis that cowpox was smallpox modified by the tissues of the cow, has been experimentally verified by no less than fourteen different observers since 1801 including Dr. Copeman himself. Nearly all the lymph at present in use is the "descendent" of one or another of these inoculations, spontaneous cowpox being a very rare disease of late years, though apparently much commoner in Jenner's time.

From a study of the results of these inoculations Dr. Copeman finds that repeated inoculations of the first "cow-smallpox" from heifer to heifer are necessary before the disease becomes thoroughly transformed and the lymph safe for vaccination purposes. It was ignorance of this fact that led to the unfortunate reproduction of smallpox by vaccination by Chanveau in 1865 and our own Martin of Boston in 1860, hugely to the joy of the "antis." It also accounts for the fact, stated by Mr. Jonathan Hutchinson in discussion a few days ago, that in his early years of practice he had seen several cases of vaccinia which were in no respect to be distinguished from smallpox except that they did not prove infectious to others. He related a most disquieting experience of his own in which a former student of his reported to him the death of a child from an alleged "vaccination-disease" and offered to have the body sent up to his clinic for demonstration.

He accepted the offer but when the cloth was lifted

from the body in the presence of a theater full of medical men and students he found to his dismay that the case was in every detail one of malignant smallpox. He went home extremely unhappy and for a week after kept dreading to hear of an outbreak but to his great relief not a single case developed either among the audience present or in the family of the child. Dr. Copeman used monkeys extensively in his experiments and found that they were susceptible to both variola and vaccinia although the former was never fatal to them. He also gave his lymph the "variolation" test which its critics regret cannot be used for effective testing and standardizing, by inoculating monkeys which had recovered from vaccination with virulent smallpox virus, in every case with negative results.

NON-PULSATION IN ANEURISMS AND THE TREATMENT OF ANEURISMS—AUTO-INTOXICATION AND ITS RELATION TO THE TREATMENT OF DISEASE—"PSEUDO-TUBERCULOSIS"—VARIETIES OF ECZEMA AND THEIR TREATMENT—VANISHING TUMORS—THE COMMUNICABILITY OF TYPHOID FEVER.

AT the Royal Medical and Chirurgical Society, February 28th, WALSHAM made some remarks on non-pulsating aneurisms, and on the extirpation of aneurisms in general. He described a case of slowly growing aneurism in the neck of a patient aged forty-eight years. No pulsation could be felt in the tumor, nor any bruit heard over it. A needle was thrust into it, but no fluid could be withdrawn. The swelling was considered glandular, and probably malignant, and was cut down upon for the purpose of removal. It was then found to be an aneurism of the common carotid. This vessel was ligated and divided, and the whole aneurismal sac dissected out and removed, the efferent vessels being ligated as they were exposed. The patient recovered. Non-pulsation in an aneurism is a rare symptom, and in this case did not seem to be easily explained since there was no leaking of the sac nor blocking of its mouth with clots. The operation described may be looked upon as the ideal method of treatment, and its risk is very slight. It is indicated (1) when there is insufficient room to apply a ligature to the artery on the proximal side, or when a proximal ligature is attended by great risk, as ligature of the innominate for subclavian aneurism; (2) when a number of large vessels communicate with the sac; (3) when other measures have failed to cure the aneurism; (4) when the aneurism, as in the popliteal artery, has become diffused, or rupture of the sac or gangrene of the limb is threatened; (5) when the setting free of the emboli, as in carotid aneurisms, would be attended by risk of cerebral softening. In these conditions this method of treatment is probably the best; but for an ordinary popliteal aneurism without complications, enucleation can hardly be compared with such a simple and usually successful procedure as ligation of the popliteal artery or even of the femoral at the apex of Scarpa's triangle.

GODLEE excised a popliteal aneurism, and the patient had an annoying edema of the leg, more than is usually seen after ligation of the femoral.

GOULD had a patient with an aneurism of each popliteal artery. He ligated the vessel on one side and performed excision of the sac on the other. There was more interference with the circulation on the side where the femoral artery was ligatured at a distance from the aneurism than on the side where the aneurism was excised; for six months after the first operation the right leg felt numb, and no pulse could be detected in the tibial arteries, while pulsation returned in the tibial arteries on the left side three weeks after excision of the aneurism. He considered that it is not necessary to excise the whole of the sac, in cases in which it is adherent to a vein for example. In a nervous patient he had once tied the femoral, thinking thereby to cause less shock than by excision. Gangrene of the leg followed, rendering amputation necessary, which he was inclined to think might have been avoided had the sac been excised.

BOWLBY said that an examination of many museum specimens had convinced him that the artery, contrary to the general opinion, is more healthy near the aneurism than it is at some distance nearer the heart. This is especially true of popliteal aneurisms, which should therefore be ligated near the sac and not in Scarpa's triangle.

WALSHAM thought it better to remove the whole of the sac if possible as it facilitated the healing of the wound, and also because branches which open into the part of the arterial wall which is left might be overlooked and so give rise to secondary hemorrhage.

At the Medical Society, February 27th, MARTIN read a paper on auto-intoxication and its relation to the treatment of disease. The term is used to designate three different conditions: poisoning from the gastro-intestinal tract, the poisoning of chronic disease, and the poisoning from the glands of the body, thyroid, etc. With reference to the first form of auto-intoxication, it may be said that most of the intestinal bacteria are non-pathogenic as long as they remain in the intestine. If the products of putrefaction are absorbed the body is poisoned, but this process frequently passes from one of intoxication to one of infection of the intestinal wall or of the peritoneum by the germs themselves. Again in the normal processes of digestion bodies are formed which possess poisonous properties, and if they are absorbed without further change they may give symptoms of poisoning. In uremia it has been shown that the toxic properities of the urine are diminished and it may fairly be inferred, therefore, that poisons are retained in the blood which would normally be eliminated.

At the sessions of the Pathological Society, held February 21st, and March 7th, there was a discussion on "Pseudo-tuberculosis," a term which was used by the different speakers to cover a variety of lesions mostly occurring in animals. These lesions suggested tuberculosis either in their gross appearances, or in the fact that they contained bacilli which acted toward stains in a manner similar to that of tubercle bacilli.

FOULERTON said that it was a fallacy to suppose that there was anything truly characteristic about a tubercle,

since a similar lesion may result from the action of many different bacilli, just as an abscess may be produced by the action of several different organisms. But no one thinks of speaking of all the abscesses which are not produced by one particular germ as pseudo-abscesses.

HUTCHINSON admitted that the word "pseudo-tuberculosis" is unscientific, but he thought that it at least had the advantage of not committing the profession to a particular theory in the case of an obscure lesion. Names thus hastily given may later be found to be erroneous, as has frequently happened, for example with the word uremia.

At the Harveian Society, February 16th, WHITFIELD read a paper on varieties of eczema and their treatment, in the course of which he said that the evidence that eczema is of a parasitic origin is almost wholly clinical, and that while certain experiments tend to show that certain seborrheic forms of eczema are parasitic in their origin, that until the different microbes of the different varieties have been isolated, as has been done with the ringworm, it is better to group them all together as a seborrheic eczema. There are two main opinions as to the nature of simple eczema. One regards it as the outward manifestation of a constitutional disorder, and the other ascribes it to the action of some local irritant. The parasitic theory of simple eczema is as yet entirely unproved. In the treatment of supposed parasitic forms, antiparasitic remedies may be used much more freely than in simple eczema. In acute weeping eczema it is better to treat the skin with soothing lotions which have just enough antiseptic power to prevent the growth of any accidental contamination with cocci. When the discharge has ceased ointments can be used, and they should be firm enough not to run into the covering, and leave the surface dry. Later stimulating applications may be made to resistant patches, and it has even been recommended to scarify very old and thickened parts.

THORNE said that he attached more importance to toxic conditions of the blood in relation to eczema than Whitfield was disposed to accord to them, and he could not regard as valid the argument that if the kidneys were sound they must be innocent of mischief, because they might, by habit and regimen, be inhibited from performance of their normal function. He instanced the case of a woman who for seven years had suffered from a severe form of eczema palmaris with inflammation of the matrices and deformity of the nails. The total daily ingestion of fluids including tea, coffee, and claret was barely seven-eighths of a pint. In three weeks the disease was arrested by the use of an ointment containing ammoniated mercury, of a mixture containing grain doses of potassium iodid, and by the ingestion of two pints of water daily. The result had been maintained mainly, as the speaker believed by the continued use of the water, which gave the kidneys an opportunity to promote the purity of the blood.

At the meeting held March 2d, POWER read a paper on vanishing tumors. He mentioned in illustration three cases, one that of a cystic lymphangiomata of the neck which had been noticed soon after birth, and which had been tapped 150 times with a trocar and cannula. The tumor had disappeared after the removal of a portion of it. The disappearance of the remainder was preceded by three attacks of lymphangitis. In a second case the abdomen was opened to relieve the cause, if possible, of a marked increase in size of the liver of a child, associated with jaundice and fever. On the supposition that there was an abscess, a trocar was thrust into the liver in several directions, but no pus was obtained. The wound was closed and the patient recovered; all the symptoms, including the increased size of the liver, disappeared. Other cases were mentioned; one of a vascular growth in the pelvis, and another in the lumbar region, which were exposed by operation and thought to be sarcomatous, too extensive for removal. They disappeared completely in three or four months. Six or eight tumors developed in a man's scalp after a blow from a part of a fly-wheel. One was removed, and shown by microscopical examination to be a fibrosarcoma. Some of the others disappeared spontaneously. The speaker also pointed out the diminution of a hypertrophied prostate after removal of the testicle, and the atrophy or disappearance of adenomata of the breast as the result of pregnancy and lactation as illustrations of the spontaneous disappearance of tumors.

JULER mentioned a case of tumors of both orbits in which the microscopical diagnosis was sarcoma. They disappeared after the administration of mercury and iodid of potash.

DORAN mentioned the disappearance of fibromata of the abdominal wall in two cases which had come under his notice.

EASTES referred to the large number of vanishing tumors which are associated with some part of the genital tract, including the female breast. A striking instance was furnished by the uterine fibromyomata of middle life. Most of the disappearing tumors of the abdomen were fecal accumulations.

GUTHRIE thought the spontaneous disappearance of tumors might be due in some manner to the cutting off of the blood-supply, not in a manner which can be accomplished by surgery, but through the vasomotor system. This might explain the success which was said to follow the application of toads to cancerous breasts in the last century. The skin of a toad excretes phrynin, which is a powerful vascular astringent. It should not be forgotten that strong mental emotions may possibly affect the sympathetic system so as to cause a local constriction of blood-vessels. In this manner may be explained the miraculous cures of cancer at Lourdes and elsewhere.

At the Epidemilogical Society, BOOBBYER read a paper on ten-years' experience with typhoid in a midland town. Emphasis was laid on the personal communicability of typhoid. His conclusions were that (1) a sustained mean temperature of over 55° F. was followed by a higher autumnal rise in the prevalence of typhoid, and a cooler summer by a lower than the average; (2) that the disease was endemic in poor, crowded districts irrespective of elevation and geological formation, provided soil pol-

lution and like favorable conditions were present; (3) that even on foul made-soil and where pail closets were in use the better class of houses suffered less than the poorer; (4) that the incidence was far less in houses with water-closets than with dry conservancy, and heavier in those with middens than in those where pails were used, the differences being more marked in the poorer class of houses; and (5) that it was directly communicable by personal intercourse even in well-regulated hospitals, and more so in the confined dwellings of the poor.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, March 9, 1899.

THE President, DR. WILLIAM H. THOMSON, in the Chair.

DISCUSSION ON SYPHILIS.

(Concluded from page 414.)

The third paper of the evening on

VISCERAL SYPHILIS IN CHILDREN,

was read by DR. A. JACOBI.

Children suffer not infrequently from syphilitic lesions of the lungs. The most frequent forms of the pulmonary affection are gummata and interstitial change. Not rarely it is complicated by pulmonary tuberculosis, the tendency to which at least is inherited from the mother, the syphilis coming from the father.

The heart is not often affected though cardiac gummata do develop at times and there is a syphilitic fibrous myocarditis. As regards the blood itself we are coming to realize more and more that profound essential changes may take place in this fluid tissue as the consequence of syphilis. Escherich pointed out the connection there may be between syphilis and pernicious anemia. Others have shown the etiological relation of the disease to pemphigus, symmetrical gangrene, etc.

The jaundice of syphilis in children occurs after 2 or 3 weeks, never on the second or third day, so that it is not hard to distinguish it from the icterus neonatorum which occurs within a few days after birth. Heubner's absolutely unfavorable prognosis in these cases seems scarcely justified by clinical facts, at least not by observations made here in America. Professor Jacobi himself has had two patients completely recover and they are still alive. The liver during the course of syphilis may be the seat of very various lesions so that the symptoms are most variable. The spleen is often affected by syphilis, enlargement and induration sometimes with tenderness having been observed, but it is to be remembered that the spleen may be palpable yet not be enlarged, the possibility of its palpation being due to ptosis or prolapse of the organ.

A very interesting and extremely important and practical phase of syphilis in children is the development of retarded syphilis. This is rather a metasyphilitic or parasyphilitic form of the disease than a frank manifestation of congenital syphilis. It is a metamorphosis of the familiar affection that gives no symptoms until the children are five or six, or even seven or eight years of age. Then it is noticed that the children do not thrive, that they are underweight, puny, and delicate, pale and sickly, without the appetite and energy that normal children of their age should have. There is very little subcutaneous fat and its absence is easily noted in the pale thin skin through which the blue veins may be clearly seen. Such children are sometimes precocious mentally though they may, on the contrary, give evidence of intellectual hebetude.

It would seem from observation of such children that a true metasyphilitic condition exists. It is, however, almost without exception ameliorated by specific treatment; such cases are often very puzzling. They fail to improve on iron and arsenic or the improvement is but slight and not persistent. A course of mercury and the iodids, however, continued for three to four months brings improvement, and then this improvement may be continued by the judicious administration of arsenic and iron, by exercise, air, tonics, and other measures calculated to better the general health.

The last paper, entitled

SYPHILIS IN RELATION TO OBSTETRICS

was read by DR. EGBERT H. GRANDIN. He insists on thorough inspection of the genitals before gynecological or obstetric examination is made. It seems almost providential that more doctors are not infected from a neglect of this rule. Examinations are sometimes almost completed, in cases where inspection does not precede, before the doctor finds to his utter disgust and subsequent mental discomfort that his patient is undoubtedly syphilitic, and that great risk of infection has been run needlessly. As it is many a doctor in the city and in the country is suffering from syphilis acquired in this way. The necessity for the greatest precautions and of frequent reminders, for a certain familiarity with the danger begets forgetfulness, is evident.

Syphilis is the great cause of sterility whether relative or absolute, *i.e.*, sterility either with conception occurring but inevitably followed by abortion each time, or positive absence of conception. It would seem at times when the menstruation appears to recur regularly, that what really takes place at each or at least at certain menstrual periods is an abortion. The uterine mucosa, owing to syphilitic alterations in it, not having sufficient vitality to retain the ovum during the recurring monthly nervous impulse, proliferation, and fatty degeneration asserts itself. Habitual abortion is a misnomer if really considered to be a faulty habit of the organism as it is always syphilitic in origin.

Specific treatment in all cases of pregnancy where syphilis is known to exist in either parent is of the utmost importance. Active antisyphilitic treatment may even save an affected fetus, especially if the infection has come after the sixth month. No wet-nurse can justifiably be allowed to nurse a child no matter how clean seemingly its personal bill of health if either parent has had syphilis. The mother should be encouraged to nurse her own child especially in these cases of lowered vitality.

Syphilis constitutes the great menace to households, and while the speaker was not Utopian in his hopes for improvement in present conditions from legal enactment he is sincerely of the opinion that legal regulation will yet have to be appealed to to prevent the spread of specific disease. Legislation is much more needed in this matter than for tuberculosis which is at present attracting so much attention. Certain States, as Texas and Massachusetts, already have laws against syphilis. A notable attempt was made recently in a Western State to secure proper certification of the health of people before marriage. This may yet be considered as Quixotism, but some such legal regulation will surely come in the not distant future.

It is absurd to quarantine as we do against other and much less dangerous diseases and allow syphilis to spread absolutely without let or hindrance. It is a strange inconsistency due to certain mistaken notions of modesty and so-called propriety that whenever sexual questions assert themselves they are simply ignored. But this state of affairs cannot and will not be allowed to continue much longer without a serious attempt to solve the serious questions involved.

In the discussion, Dr. H. H. Smith said that the iodids do good in the treatment of syphilis in two ways: by their stimulation of absorptive powers and by their effect upon the circulation. They dilate the peripheral vessels and so lessen the strain upon the already fibrous heart. The iodid of potash as used in the Tufnel treatment for aneurism lessens the general blood pressure and so diminishes the tension on the arterial walls and upon the aneurismal sac.

Dr. Jacobi said that iodid of potash has a wide field of therapeutic application outside of syphilis. The iodids are favorite drugs of his. After peritonitis and other inflammation of serous membranes they are of the greatest assistance in helping to carry off the inflammatory material that has been deposited. Non-specific glandular swellings may also be successfully treated by the same drug, though it will have to be administered for months. patients suffering from these obscure ailments may be greatly relieved by a course of the iodids to which mercury in small amounts is sometimes added with great benefit. Potassium iodid often does good even in non-specific cirrhosis of the liver, and tabes dorsalis, though not always due to syphilis, may often be distinctly benefited by this same remedy.

Dr. Bielapowski said that mercury, as well as the iodids, does good, not by acting directly against the virus of the disease, but by its action on the tissues. Hence it is that other chronic pathological processes in the tissues not unlike those produced by syphilis are benefited. Psoriasis lepra and tuberculosis might be mentioned.

Stated Meeting, Held March 16, 1899.

(Discussion on Syphilis Concluded.)

The first paper of the evening, entitled

SOME SURGICAL ASPECTS OF SYPHILIS

by Dr. Frank Hartley, was read, because of his unavoidable absence, by the Assistant-Secretary, Dr. Huddleston. It will appear in a future issue of the Medical News.

The second paper, on

SYPHILITIC DEMENTIA AND PARETIC DEMENTIA AND TREATMENT OF SYPHILIS OF THE NERVOUS SYSTEM,

was read by Dr. Charles K. Mills of Philadelphia. He said that a better title for his paper would be "Syphilitic Insanities and Pseudo-insanities; Their Prognosis and Treatment, with Some Remarks on the Treatment of Syphilis of the Nervous System." In the consideration of syphilitic affections of the nervous system affections due indirectly as well as directly to the disease must be considered, *i.e.*, the parasyphilitic and metasyphilitic affections that have occupied so much attention of late must be considered under this head though they are not truly specific.

The forms under which insanities as a consequence of syphilis occur are, first, as toxic syphilitic insanities; second, as dementia paralytica which is really a parasyphilitic condition, and finally as an accompaniment of syphilitic pseudoparalysis. Syphilitic toxemias, with mental symptoms, may take the form of melancholia, of mania, or of stuporous dementia. The melancholic state of depression is really a consequence of the action of the toxins of the disease, and is not due to drugs nor to apprehension. It may often be complicated by other symptoms than those of typical melancholia. Especially is it often accompanied by neurasthenia. Not infrequently a suicidal impulse develops during the depression and patients may need careful surveillance.

The mania due to syphilitic toxemia does not differ materially from the ordinary mania of acute mental disease. The apathy that occurs in dement states is of other stuporous variety. It is to be remembered that any of these mental conditions may develop as the result of syphilitic toxins without the occurrence of a single symptom pointing to organic involvement. The eyes may be absolutely unaffected, the knee-jerks, and other reflexes absolutely normal.

That general paralysis is usually a result of syphilis seems clear to Dr. Mills, and he holds tabes and general paralysis to be varying and variously localized manifestations of an identical pathological process. Analogously, syphilitic pseudo-tabes and syphilitic pseudo general paralysis are comparable. Degenerative or true tabes and general paralysis are usually and remotely though not always post-syphilitic in origin.

The prognosis of general paralysis is absolutely fatal. The treatment can only be symptomatic and palliative, but the physician owes it as a duty to his patient to keep him out of the hands of quacks who but exploit his helpless mental condition and impose upon the sympathies of his friends.

Syphilitic pseudo-paresis, due directly to multiple syphilitic lesions, in the membranes of the brain, in its blood-vessels, in the nervous substance itself, and especially in the cortex has not so unfavorable a prognosis if treated early. The treatment, however, is just as hopeless if it is

undertaken too late for degeneration takes the place of inflammatory exudation and will not yield to remedies. It is to be borne in mind that such syphilitic pseudo-paralyses may occur at any time after infection. It may be that only a year or two will have elapsed, but they may supervene long years after infection.

The conclusions as to the treatment and its effects may be briefly stated thus: Meta- and parasyphilitic conditions are not helped but hurt by specific medication. Recent direct syphilitic processes in the nervous system, especially when they do not involve nervous elements primarily disappear as a rule under properly directed syphilitic treatment.

Those that run a subacute course are the most hopeful. Very acute processes may kill before specific medication has its effect so that there is need for vigorous treatment. Often a rapid reaction can be obtained that will save life even when things look hopeless.

Chronic syphilitic processes in the nervous system as, for instance, Erbs' syphilitic spastic spinal palsy never get entirely well. They react to specific medication but only to a certain degree, and all traces of the process are never entirely removed. True syphilitic pseudo-tabes is rare, but does undoubtedly occur. When recognized as such and properly and persistently treated its prognosis is not very unfavorable though time is an important element, and none must be lost.

With regard to the syphilitic insanities this may be said: when due to a pure toxemia they are, as a rule, perfectly curable, and react well to specific treatment. General paralysis and its mental manifestations are, of course, incurable. In general, it may be said here as in the case of the neurological conditions that if the mental conditions are directly specific and recent, they can be cured; if they are chronic and degenerative they cannot. In even favorable cases their persistence for any length of time makes the prognosis proportionately worse.

The next paper, on

SYPHILITIC AFFECTIONS OF THE SPINAL CORD,

was read by DR. BERNARD SACHS. He said that our knowledge of syphilis of the nervous system has advanced very much from the time when we used to make the diagnosis of the affection by the exclusion of all other causes. Syphilis of the nervous system is undoubtedly on the increase. The latest statistics seem to show that, excluding tabes and general paralysis, 15 to 25 of every 1000 patients suffering from syphilis have nervous affections from the disease. The increase in syphilis of the nervous system is undoubtedly due to the fact that the struggle for life has became more intense of late years, especially in large centers of population, and that the consequent exhaustion of the nervous system has left it less resistive to the invasion of disease processes. It has been argued that the increase is only apparent and due to better diagnosis, but this, while it is a factor in the larger statistics, does not account entirely for the larger number of cases reported in recent years.

It has been said that syphilitic nervous symptoms develop oftener among those whose original syphilitic symptoms were milder than usual, and Dr. Sachs' experence seems to agree with this. Whether early treatment really influences the development of later nervous manifestations or not is something we do not know. They develop in those who have been carefully treated and do not seem to pick out especially those who have been carelessly treated.

We have learned to realize that the distinction between secondary and tertiary lesions does not hold in the nervous system. We may have cerebral symptoms during the first six months of the disease, and spinal symptoms may develop while the cutaneous lesions are still running their course. Certain undoubted cases have been reported where symptoms in the central nervous system developed before the primary lesion had disappeared.

The most frequent lesion in the central nervous system is the occlusion of blood-vessels by a syphilitic endarteritis. Vessels may not, however, be entirely occluded at once so that transitory symptoms may develop as a warning of the process that is at work.

The multiplicity of lesions and their fleeting, variable character are often the best diagnostic points of beginning syphilis of the nervous system. The multiplicity of lesions is at least as important in the diagnosis of syphilitic central nervous lesions as Dr. Fox showed it at a previous meeting to be for syphilitic cutaneous lesions. Suspicious symptoms are headaches, eye troubles, passing hemiplegias, apoplexy, especially in comparatively young patients without heart or kidney trouble. Dr. Sachs pointed out some years ago how valuable for the diagnosis of syphilis in puzzling conditions of the nervous system is the pupil. Further experience and observation has only served to confirm this opinion. It is in his opinion much more important and valuable as a diagnostic sign than the bony lesions or epitrochlear and other glandular enlargements that are usually looked for. The important pupillary diagnostic points are: (1) inequality of the pupils; (2) unequal response to light; (3) failure to respond to light (this, others have dwelt on, especially Jonathan Hutchinson); (4) a circularity of the pupil, especially on contraction, and occurring when there are no iritic adhesions.

Silex of Berlin especially pointed out these as diagnostic points in obscure syphilis of the central nervous system: (1) choroiditis; (2) scars at the angle of the mouth; (3) irregular and early carious teeth. Vertigo is sometimes an urgent early symptom. In a Canadian physician who consulted Dr. Sachs some time ago after having been under treatment for all manner of supposed causes of the symptom at the hands of various specialists, his vertigo proved to be the only symptom of nervous syphilis that had as yet manifested itself. Syphilitic apoplexy, if thrombotic, affects especially the base at the interpeduncular space commonly, and ocular palsies and double or anomalous optic neuritides develop. This syphilitic double optic neuritis must be borne in mind because a double optic neuritis is sometimes considered pathognomonic of tumor.

For spinal lesions spastic palsy invading first one side then the other is very significant, and usually indicates a syphilitic basis for it.

Syphilitic pseudo-tabes may be diagnosed from true tabes by this tendency to affect one side more than the other. One leg will be more ataxic than the other, one knee-jerk or other reflex will be more affected than the other, one eye will be more affected than the other. In true syphiiitic pseudo-tabes the pupils are often immobile—a very important sign which is not a mere clinical fancy but an important symptom often observed.

The fourth paper of the evening, on

OPHTHALMOLOGICAL ASPECTS OF SYPHILIS,

was read by DR. CHARLES STEDMAN BULL. It will appear in a subsequent issue of the MEDICAL NEWS.

THE MEDICAL NEWS.

THE DIFFERENTIAL DIAGNOSIS OF PELVIC AND ABDOMINAL DISEASES IN THE FEMALE.

BY PAUL F. MUNDÉ, M.D.,

OF NEW YORK;

GYNECOLOGIST TO MT. SINAI HOSPITAL.

IN no other part of the human frame is the recognition of the more complex forms of disease more difficult and confusing than in the female pelvis and abdomen, with, perhaps, the sole exception of the brain. At least so it appears to the gynecologist if he frankly admits the truth, and reviews with a dispassionate and humble spirit the many occasions where his experience and skill have failed him and the correct diagnosis has been revealed at the exploratory laparotomy, at the autopsy, or, if made during life, too late to benefit the patient.

I have admitted one of the two other great cavities of the body, that containing the brain, to be subject to the same difficulties of exploration and diagnosis as the abdominal and pelvic cavities, but I do not extend the same concession to the remaining cavity, that of the thorax, for the reason that it contains but two organs, the heart and the lungs, the diseased conditions of which are usually easily recognizable. In the pelvic and abdominal cavities, however, we have in the female not only the generative organs which in disease may invade the general abdominal cavity, but also the liver, gall-bladder, intestines, stomach, pancreas, spleen, and general peritoneum, to which should be added the kidneys and ureters which, though retroperitoneal, are subject to diseases simulating intraperitoneal conditions.

All these abdominal organs are in health so covered and protected as to be difficult of palpation; besides a not uncommon excessive adipose development and rigid or over-sensitive abdominal walls form additional obstacles, and the natural aversion of a modest woman to exposure of her person contributes a decided objection to an examination, which at the best can extend only to her external genital organs, vagina and cervix. Beyond that the same drawbacks apply which I have mentioned in the case of the abdominal viscera.

If, now, the gynecologist with his specially trained touch often finds himself unable to arrive at a satisfactory conclusion in regard to a doubtful case, the general practitioner, and still less the specialist in some other branch, cannot be blamed if he fails to make the correct diagnosis, provided, of course, that he faithfully employs such knowledge and experience as he happens to possess and omits none of the usual methods of examination.

Before speaking of special instances of difficult differential diagnosis it may be well for me to say that an examination of other organs than those constituting the female sexual apparatus, especially the urinary and digestive tracts and their secretions should never be omitted when advice is sought for some supposed "female trouble." The bladder should be examined by bimanual palpation in regard to unusual sensitiveness which, if present, is generally found at the trigonum, between the mouths of the ureters; the ureters should be sought by the intravaginal finger, and can frequently be detected in health, and always if swollen or tender, as is commonly the case in pyelonephritis. I have even felt a stone impacted in the ureter, and by removing it through a vaginal incision have relieved a pyelonephrosis of the kidney which would otherwise have escaped discovery. The urine should be chemically and microscopically examined whenever there is the least suspicion of disturbance of the urinary organs, and if inspection or a superficial chemical examination in the office suggests possible organic vesical or renal disease, a specimen should be procured with the catheter and be sent to a competent urinologist for careful examination. Many a case of doubtful pelvic and abdominal pain for which the sexual organs proper offered no solution has thus been found to be due to pyelonephritis, renal calculi, cystitis, stone, or tumor in the bladder.

By a digital eversion of the rectum, easily performed with two fingers in the vagina, fissure of the anus, catarrh, and ulceration of that organ, internal hemorrhoids, polypus, or even pinworms, may be readily exposed, and recognized as the cause of the pain in the sacral, coccygeal, and perineal regions, which was supposed to be due to some so-called "womb disease." If this digital eversion leads to a suspicion of disease higher up, a small cylindrical speculum, or two small Sims' specula inserted, if necessary, after the introduction of a tampon soaked in a four-per-cent. solution of cocain, will permit inspection of the rectum nearly up to the sigmoid flexure.

The condition of the coccyx should also be investigated, and its mobility, direction, and tenderness tested. Mere pain in the coccyx, when unconnected with dislocation, fracture, or disease of its periosteum, is no evidence of pelvic disease, but usually a sign of general neurasthenia, and almost invariably associated with pain or ache in the favorite locations of that distressing affection, *viz.:* base of the sacrum, intrascapular, cervical, occipital, left parietal and supra-orbital, and left submammary regions. Pains complained of at all, or the majority of these points, may unhesitatingly be ascribed to neurasthenia, and need not by any means necessarily depend upon or even be associated with any pelvic disease whatever.

Further, it is well to bear in mind the peculiar mental and nervous organization of female patients in properly estimating the acuteness and gravity of their complaints. Some women, especially of the lower classes, systematically exaggerate their ailments and magnify every symptom; others, of the hysterical, hyperesthetic, neurotic temperament, really feel, or imagine they feel, pain here, there, and everywhere, for which a careful examination can find no cause.

Cutaneous hyperesthesia of certain parts of the abdomen, thorax, back, or limbs may simulate inflammatory conditions of deep-seated organs. If the painful or tender points are on the abdomen, peritonitis, appendicitis, salpingo oophoritis, metritis, or cystitis may be suspected, and their absence discovered only on examination under anesthesia. A hyperesthetic uterus, peritoneum, vagina, vulva, or excessively tender ovaries and tubes may likewise be mere nervous disturbances found frequently in neurotic, hysterical women.

Again, the explanation of the etiology of many pelvic, abdominal, and dorsal pains must be sought in the constipation to which the majority of women are subject, to colic, chronic colitis, fecal impaction, intestinal indigestion and fermentation, and worms. A curious instance recently came under my observation of a young lady who consulted me for pain in the rectum attended by mucous discharges. I found the sexual organs healthy, but the rectal mucous membrane intensely congested. On seeking for the cause of this congestion, I learned that the lady had for some months been taking daily enemata of very hot water to relieve constipation, they having been ordered by her physician. Before taking these hot enemata there had been no mucous discharge and I suspected the hot water to be the cause of the trouble. I ordered a discontinuance of the hot enemata, a daily enema at night of 4 ounces of olive oil and lime water, equal parts (which I have found an excellent soothing remedy in catarrhal proctitis) to be retained, and a mild laxative, and requested her to report again in two weeks, when the discharges had ceased and the rectum was found normal. The lesson from this case is that the delicate mucous membrane of the rectum does not bear the unlimited hot douches which the comparatively tough cutaneo-mucous lining of the vagina not only endures with impunity, but even with complacency and benefit.

In proceeding to the consideration of our subject in detail, I know of no better way than to take up *seriatim* the most prominent diseased conditions of the female genital, pelvic, and abdominal organs, in which difficulty or error in diagnosis are most likely to occur. I shall not, of course, touch on all abnormal features, for that would carry me too far and prove unnecessary and wearisome.

Of diseases of the vulva I shall mention prominently that first described as *kraurosis* by the late Professor Breisky of Prague. This peculiar and rather rare affection may be mistaken most readily for eczema, indeed it has been so called by several eminent dermatologists. But it is essentially different. In eczema the skin is diffusely red, inflamed, scaly, dry or later moist; the eruption extends not only over the whole cutaneous portion of the vulva, but also may spread to the thighs, groins and abdomen. The inner surface of the labia is not affected. The pain is a burning, itching, scalding sensation.

In kraurosis, the disease attacks chiefly the mucocutaneous surfaces, the clitoris, labia minora, vestibule, hymen, vaginal introitus, perineum and the anal border. The true skin itself I have never seen attacked elsewhere about the vulva. The diseased surface is not uniformly red, quite the reverse; it is covered with dry, white patches of different size, interspersed with irregular red spots; the surface cracks and bleeds easily; the whole tissue seems infiltrated with a white, cheesy matter which can be scraped away with the finger-nail until the red, underlying cutis vera is reached; the pain is sharp, darting, intense. Finally, eczema is usually easily cured by local applications, whereas kraurosis seldom yields to any remedy short of the excision of the diseased parts and the approximation of the healthy edges by sutures.

Deformities of the external genital organs, if congenital, are usually of the variety known as *androgyny* or man-woman, that is, the individual is of the masculine gender, possessing a short, hypospadiac penis, thick labia, each containing a testicle and epididymis; or one testicle may be in the groin and the other still in the pelvic cavity or abdomen; a vagina of greater or lesser depth, but of course no uterus or ovaries.

Far less common is the variety called *gynandry*, or woman-man, which is characterized solely by a hypertrophied clitoris, the rest of the external and internal sexual organs being distinctly feminine. There is no difficulty in distinguishing between these two forms of spurious hermaphrodism. More puzzling are the rare cases (there being only six on record) where the individual possesses every characteristic of a perfect woman, locally and generally, but has no uterus or ovaries, and instead in the labia, groins or abdomen on each side a testicle and epididymis. Only a microscopical examination of these, in life, doubtful organs can settle, and has in five of these six cases (mine being the exception) settled the question of their being testicles.

The urethra and bladder present two pathological conditions of diagnostic interest, *urethrocele* and *suburethral* abscess. Both are not very common and may be mistaken for one another and for cystocele, as well as for the natural urethral bulb. Urethrocele is a sacculation of the urethrovaginal septum; suburethral abscess is a collection of pus in the same septum. Both open into the urethra; the former by a large, the latter by a small, opening (see Figs. 1 and 2) which constitutes the difference between them, for both cause painful urination through the purulent decomposed urine which each cavity contains. The diagnosis is easily made by the catheter

Fig. 1.

or sound, which shows the size of the opening, and the existence of the abnormal pocket in the urethral wall, below the neck of the bladder. In cystocele the urethra is not involved in the prolapse, except in the worst cases, when the whole urethra and posterior bladder wall with the anterior vaginal wall protrude between the labia.

A cyst of the anterior vaginal wall may be mistaken for a cystocele. I have seen three such cases, in one of which I excised the cyst; in the second the patient had been treated with a pessary for cystocele by a physician who sent her to me at the Polyclinic where I easily detected the error, and demonstrated it by showing that the sound did not go to the bottom of the supposed cystocele; and the third case is a woman with a large intraligamentous ovarian

Fig. 2.

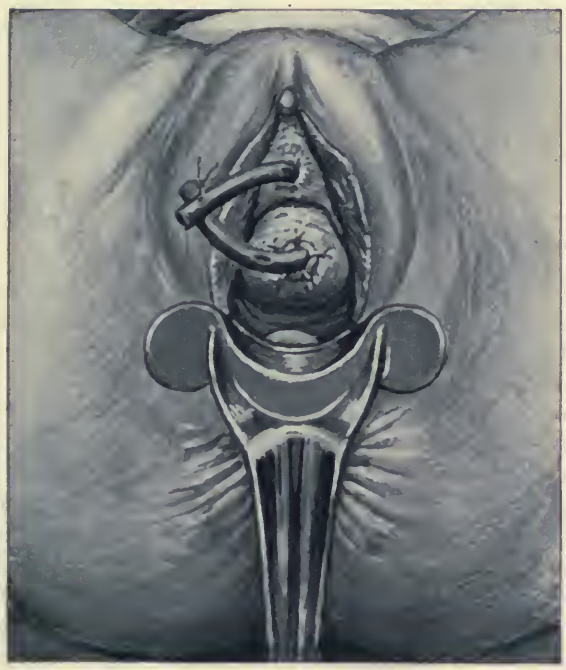
cyst who refuses operation for the vaginal cyst as she says she has had it for thirty years and it does not trouble her.

The diagnosis of a *gonorrhea of the vagina, endometrium or endosalpinx* cannot be made by the eye nor the nose, for there is nothing distinctive about the appearance or odor of the discharge, nor the color of the vagina. The discharge is simply green, thin, irritating and pungent, like the secretion in an aggravated case of non-contagious endometritis and vaginitis. Only the discovery of the gonococcus would settle the diagnosis of gonorrhea, which the habits and associations of the woman might lead us to suspect. To accuse a respectable married woman of gonorrhea simply on the strength of an irritating, pungent, greenish, vaginal discharge, and an inflamed, eroded, "granular" (papillary) vaginitis, would be risky and likely to evolve a suit for defamation of character, against which there would be no satisfactory defense.

The diagnosis of *cancer of the cervix* is usually so easy that any tyro can make it. But in the early stage before the destruction of the diseased tissue has taken place, when there is no offensive putrid discharge, or before the cervix has swollen to the size and outline of a turnip or a cauliflower—when, in fact, the disease is in its infancy and nothing but prolonged menstruation or an intermenstrual oozing attracts the woman's attention, it may not be easy

to decide whether the swollen, ragged, bleeding lips of the cervix are merely due to a puerperal laceration, or to malignant disease. As a rule, in a benign case the tissues are hard and bleed but little on touch, whereas if the ulceration is malignant the finger can easily break down and crush portions of the cervix, and the bleeding is profuse although easily arrested. Besides, any extension of the ulceration to the vagina or enlargement of the supravaginal portion of the cervix indicates probable malignancy. The microscope is often required to settle this question, but I must confess that I have usually been able to make up my mind from the clinical facts, and have found in the microscopic reports only a confirmation of my previously expressed opinion.

FIG. 3.



Suburethal abscess. Showing drainage-tube through meatus urinarius and incision in the vagino-urethral septum.

A putrid, offensive discharge is *never* found with a simple lacerated cervix; it means gangrene, perhaps a decomposed piece of decidua, or a sloughing fibroid, or a malignant growth. Hence, such discharge from the uterine cavity calls for the curette, and possibly the microscopical examination of the scrapings. If feasible, it is always advisable to dilate the uterine canal sufficiently to enable the index-finger to pass through the internal os whenever the uterus is enlarged and it is desired to be sure that its cavity has been entirely cleared of the foreign substances for which the curetting was done. Even the largest curette which can be passed through such a canal does not afford absolute assurance on this point, which can be given only by the finger. Hence, it is the finger upon which we must chiefly rely for the diagnosis of submucous fibroids and intra-uterine polypi; the sound is but a poor substitute.

Displacements of the uterus can generally be easily recognized by a finger experienced in detecting the normal position of that organ.

Bimanual palpation will distinguish an anteflexion or anteversion, or a retroflexion or retroversion from a fibroid in the anterior or posterior uterine wall, or from a tumor in Douglas' pouch. If necessary the sound will indicate the position of the body of the uterus. If there is a suspicion of pregnancy, however, the sound is forbidden, and then the diagnosis of the nature of the uterine enlargement may be difficult, or for a time impossible, and a second examination a month or so later may be required to decide whether the uterus has enlarged in accordance with the natural growth of pregnancy since the first examination.

It is particularly difficult to detect the true condition when a woman states that she has not skipped a recent menstrual period and has been bleeding more or less steadily for a month or two. The uterus is found enlarged, soft, outline perhaps slightly irregular, os not admitting finger; hemorrhage moderate. There is no suspicion of pregnancy. The diagnosis is submucous fibroid; the uterus is sounded, found to be four to five inches deep, the cervical canal is dilated, the uterine cavity explored, and a still unbroken amniotic sac or fragments of attached placenta are found; or the curette, introduced without digital exploration, removes portions of decidua. The diagnosis of incomplete abortion is then plain enough; but the situation is a trifle awkward if a diagnosis of fibroid has been made previously and imparted to the family. I have myself repeatedly been misled in this way, and still both fibroids and impending or progressing abortion, or incomplete abortion may co-exist. I have seen many such cases, in which it is well to remember that the disproportion of the size of the uterus from the admitted or suspected time of pregnancy may be due to intramural fibroids. Hydatidiform degeneration of the chorion should be remembered as another, perhaps somewhat less common, cause of protracted metrorrhagia with unusual size of the uterus which, in that case, is soft and flabby, not solid, as with fibroids.

While fibroids and unsuspected pregnancy may lead to an error of diagnosis, impaction of a retroverted pregnant uterus should never be overlooked if the examiner is ordinarily careful. Aside from the history, the soft, boggy, tender mass behind the cervix with which it is evidently continuous, the

absence of the uterine body above the pubis, the bearing-down or expulsive pains, should at least excite a suspicion as to the true nature of the case and induce the physician to attempt a reposition of the uterine body. Even a mistaken diagnosis, as proved by a failure of all the efforts at reposition, is preferable to a result such as I saw last autumn, when a woman was admitted to Mt. Sinai Hospital with a paralyzed, overflowing bladder full of putrid urine, and an impacted retroflexed uterus containing a decomposed ovum of three-months' growth. She stated that this condition of the bladder had existed for ten days. The woman was of course intensely septic. Emptying and constant irrigation of the bladder and uterus failed to remove the sepsis, and she died about four weeks later of septic pneumonia. She had been under the care of a physician whose name was not ascertained or asked.

I admit that an *impacted or adherent ovarian cyst in Douglas' pouch* might, under conditions of doubtful pregnancy, render a differentiation between it and an impacted gravid uterus difficult, but the ovarian cyst could hardly cause pain or be tender, and would not grow rapidly, and usually the uterus can be felt above the pubis. A retro-uterine hematocele, with the history of pregnancy (the hematocele being the result of a ruptured ectopic tube) might also be confusing, but again the uterine body above the pubis would be useful, and the sound might with due care be employed. Once the question settled that the uterus is in its normal position, the nature of a retro-uterine intraperitoneal tumor rests between a subperitoneal uterine fibroid, an ovarian cyst, an exudate of plastic lymph, a distended Fallopian tube, a blood coagulum, and possibly but rarely an intestinal loop filled with fecal matter, a so-called coprostasis. I do not mean a distended rectum, where the fecal matter can be indented or the scybala separated by the examining finger, but a loop of ileum, or a fold of colon which has dropped into Douglas' pouch.

The diagnosis between pediculated fibroids of the uterus and solid or unusually firm multilocular or dermoid ovarian tumors, and between large ovarian polycysts and uterine fibro-cysts is often absolutely impossible, even to the most expert examiner, and errors are quite excusable. The length of the uterine cavity does not in my experience afford the valuable diagnostic evidence usually ascribed to it in distinguishing between uterine and ovarian tumors. In uterine fibroids the uterine cavity is generally supposed to be elongated; in non-uterine growths the uterus, too, maintains its normal depth of two and one-half inches. But I have repeatedly found the uterine cavity to measure but two and one-half to three inches in fibroids which grew away from the center of the organ, whereas in ovarian tumors with short pedicle or in intraligamentous ovarian or parovarian cysts the uterus was drawn out to double its natural length. Again, however, I have seen the uterus unaffected in the latter cases. There is, therefore, no invariable rule in such cases.

(To be continued.)

THE STATISTICS OF FIFTY AUTOPSIES ON TUBERCULOUS SUBJECTS.

By ALDRED SCOTT WARTHIN, M.D.,
of Ann Arbor, Michigan;
Instructor in Pathology in the University of Michigan.

The statistics of a well-observed group of cases of any pathologic condition must always possess some value, and this is true still of tuberculosis, a disease that probably has received more attention at the hands of statisticians than any other, syphilis alone possibly, being excepted. Though the number of my cases is small the autopsies have been conducted with extreme care, the teaching-ideal being always kept in view. The material obtained from the autopsies has been carefully worked up and it is because of the thoroughness with which the cases have been studied that this report may acquire a certain value.

The fifty cases include forty-one cases of chronic pulmonary tuberculosis, seven cases of acute miliary tuberculosis, one case of tuberculous meningitis, and one case of general tuberculous lymphadenitis. The diagnosis in all of the cases was based upon the presence of the tubercle bacillus. The most important point to be noted in this report is the distribution of the lesions in the cases of chronic pulmonary tuberculosis.

Lungs.—About three-fourths of the cases were in females and one-fourth in males. Two-thirds of the cases were well-advanced, one-third being in early stages, death occurring from other complications. In all of the cases the chief lesions were in the upper lobes, the lower lobes being either normal or showing little disease. In no case were the lesions confined to one side; in two-thirds of the cases the disease was equally advanced on both sides; in one-third there was a greater involvement on the left side. No case was of the fibroid type; all showed extensive caseation and cavities.

Pleura.—In all of the cases there was widespread thickening of the pleura with numerous adhesions. In the majority of cases the pleuræ over the diseased lobes were adherent throughout. Only very rarely was there any fluid exudate found. In one case caseating tubercles were found on the surface of the pleuræ and between the adherent surfaces.

Bronchial Glands.—In all of the forty-one cases there was extensive enlargement and caseation of the peribronchial lymph-glands.

Meninges.—Small scattered tubercles were found in the meninges in ten cases. The dura and pia were thickened and the subarachnoidal fluid was increased. There was no fibrinous exudate in any case.

Brain.—In three cases large solitary tubercles were found; in the cerebral cortex in two cases, in the ventricles and cerebellum in one case. Those in the lateral ventricles were attached by pedicles to the choroid plexus. All of these tubercles found in the brain presented on section a firm homogeneous surface having a distinct greenish color.

Nose.—In one case only were tuberculous lesions found in the nose. There was a widespread ulceration and caseation of the nasal mucosa involving the septum and lower turbinated bones. The base of the ulcer consisted of a tuberculous induration.

Tongue.—Tuberculous ulcers were found on the posterior surface of the dorsum in one case only.

Tonsils.—Caseating tubercles of small size were found in the tonsils in two cases.

Larynx.—In every case careful search revealed tuberculous lesions in the larynx. In many instances these were minute ulcers or erosions having a slightly indurated base, while in other cases there were large irregular ulcerations. Small nodular tubercles were found in some cases. The chief seat of the lesions was upon the arytenoids and the disease usually showed signs of progression upward rather than downward. In a number of cases it extended into the pharynx and in two cases the epiglottis was almost completely destroyed. In one case the process extended through the wall of the larynx and esophagus into the latter. The true vocal cords were affected in ten cases, the lesions consisting of miliary nodules situated on the upper and inner surface of the cords.

Trachea.—Numerous miliary tubercles were found in the mucosa in one case; in three others small tuberculous ulcers were present.

Cervical Glands.—Tuberculous in one case only of the forty-one.

Heart.—One case of tuberculous pericarditis was found, there being complete adhesion of the pericardial layers with multiple tuberculous nodules scattered through the heart-wall. The organ was enormously enlarged, the enlargement being due to hypertrophy of the heart-muscle and to the thickening caused by the growth of tuberculous tissue which surrounded the entire heart in a layer one-eighth to three-quarters of an inch in thickness firmly uniting the pericardial surfaces. The pulmonary disease in this case was overshadowed by that of the heart.

Tuberculous Thrombus of the Heart.—A thrombus the size of a large pea was found on the mitral ring in one case. On microscopic examination it was found to consist of a base of epithelioid tissue containing numerous giant-cells and showing a beginning caseation. Fibrin and red blood-cells were also present in the mass. Tubercle bacilli were demonstrated in it. Thrombi were found on the valves in ten per cent. of all the cases but unfortunately no microscopic examination was made of the others. The frequency of occurrence is striking.

Liver.—In every case of pulmonary tuberculosis tubercles could be found in the liver. In the early stages of the disease they were usually small and scarce; occasionally a large encapsulated one could be found. In all of the chronic cases the liver tubercles were more numerous and in many cases the picture was that of an acute miliary tuberculosis of the liver.

Spleen.—The condition found in the spleen was always similar to that found in the liver of the same subject. In the early stages the tubercles were small and scarce while in the more chronic cases they were more numerous, and in many of the older subjects there was the picture of an acute miliary tuberculosis of the spleen.

Kidney.—The kidneys contained tubercles in all of the forty-one cases, but the tuberculous lesions in this organ were always more scarce than in the liver or spleen. In early stages of the pulmonary disease solitary tubercles were usually found; in the chronic cases they were more numerous, occasionally so abundant as to give an appearance of acute miliary tuberculosis of the kidney. The metastasis in the kidneys, however, was never so marked as in the liver and spleen. In two cases the dilated pelvis contained tuberculous ulcers, and in one of these cases there was also tuberculosis of the ure er.

Adrenals.—In one case the right adrenal was found to contain large caseating tubercles. No signs of Addison's cachexia were present.

Bladder.—In one case where there were extensive lesions in the kidneys the mucosa of the bladder contained numerous miliary tubercles.

Male Genitals.—The testes, seminal vesicles, and prostate were tuberculous in one case only.

Female Genitals.—The Fallopian tubes and uterus showed extensive tuberculous lesions in three cases. There was caseation of the entire endometrium in each case, the cavity of the uterus being filled with a soft, yellowish, cheesy mass. In one of the cases isolated tubercles were also found scattered throughout the uterine wall. In one case the vaginal portion of the cervix and the mucosa of the vagina were covered with tuberculous ulcers.

Stomach.—Tuberculous ulceration was found in the mucosa of the stomach in one case.

Duodenum.—In two cases very large tuberculous ulcers were found in the mucosa of the duodenum.

Small Intestine.—In thirty-nine of the forty-one cases tuberculous ulcers were found in the mucous membrane of the small intestine. In one-third of these cases the lesions were small and situated chiefly in the lower portion of the ileum and around the ileocecal opening. When few ulcers were present they were invariably found at the latter location. In many cases the ulcers occupied the site of Peyer's patches, and were situated at regular intervals. Few ring-shaped ulcers were seen; in the majority of cases the long axis of the ulcer coincided with that of the intestine. No perforation was seen though in many cases the ulcers seemed just on the point of breaking through the serosa. Adhesions or thickenings of the serosa over the ulcers were rarely found.

Large Intestine.—Contained tuberculous ulcers in seven of the cases. In one case a tuberculous fistula was found in the rectum.

Appendix.—Tuberculosis of the appendix was found in two cases. In one large caseating tubercles were found in the extremity of the appendix. They appeared to be about to break through the serosa. Tuberculosis of the peritoneum and genital tract was present in this subject. In the other case the lumen of the appendix was obliterated by a firm tuberculous growth, no caseation being present. Peritoneal tuberculosis was present in this subject also.

Peritoneum.—Tuberculosis of the peritoneum was present in four cases—in two in association with tuberculosis of the Fallopian tubes and uterus, in one with tuberculous appendicitis and tuberculosis of the tubes and uterus, and in one with tuberculous appendicitis alone.

Mesenteric Glands.—These were tuberculous in every case in which there was tuberculosis of the small intestine.

Retroperitoneal Glands.—These were tuberculous in three cases.

Bones.—The vertebræ were tuberculous in two cases; in one the fourth and fifth lumbar, in the other the third and fourth dorsal were diseased. Tuberculosis of the pelvic bones, clavicle, and hip-joint was present in three cases. In the case in which there was tuberculosis of the clavicle several of the ribs were also diseased.

Mamma.—Tuberculosis of the mamma was present in one case, a large "cold abscess" being present in the left breast.

Skin.—In the case of tuberculosis of the mamma there were multiple tuberculous abscesses in the subcutaneous tissue of the abdomen, thorax, and neck.

Summary.—The relative rate per cent. of the distribution of the tuberculous lesions in the different organs would be approximately as follows:

Lung	100 per cent.	Prostate	2 per cent.
Pleura	100 " "	Fallopian tubes	7 " "
Meninges	24 " "	Uterus	7 " "
Brain	7 " "	Vagina	2 " "
Nose	2 " "	Stomach	2 " "
Tongue	2 " "	Duodenum	4 " "
Tonsils	4 " "	Small intestine	95 " "
Larynx	100 " "	Large intestine	17 " "
Cervical glands	2 " "	Rectum	2 " "
Heart	7 " "	Appendix	4 " "
Bronchial glands	100 " "	Peritoneum	9 " "
Liver	100 " "	Mesenteric glands	95 " "
Spleen	100 " "	Retroperitoneal Glands	4 " "
Kidneys	100 " "	Bones	9 " "
Adrenals	2 " "	Mamma	2 " "
Bladder	2 " "	Skin	2 " "
Testis	2 " "		
Seminal vesicles	2 " "		

Other pathologic conditions found in association with chronic pulmonary tuberculosis were:

Fatty infiltration of the liver in	100 per cent.	of the cases.
Fatty infiltration of the heart	90 "	"	"	"
Cloudy swelling of the renal epithelium	80 "	"	"	"
Chronic congestion of the spleen	80 "	"	"	"
Amyloid spleen	20 "	"	"	"
Amyloid kidney	15 "	"	"	"
Amyloid liver	4 "	"	"	"

It will be seen, therefore, that in these forty-one cases of chronic tuberculosis of the lungs, in both the early and late stages, there was in every case extensive disease of the pleura, metastasis in the bronchial glands, liver, spleen, and kidneys, and secondary infection of the larynx, and in thirty-nine of the cases secondary infection of the small intestine and mesenteric glands. Though the number of the autopsies is small, and though it is possible that my cases may constitute a unique set, I cannot avoid believing that metastasis and secondary infection in chronic pulmonary tuberculosis play a much more important part than is usually believed, and that in practice the secondary lesions do not receive the attention which they deserve.

How much attention does the average practitioner give to the larynx in cases of chronic tuberculosis? Very little, I believe. Osler speaks of this neglect of the laryngeal complications and I am of the opinion that much might be added to the comfort of the tuberculous patient if more care were bestowed on the larynx. Means may be attempted to prevent infection of the upper air passages by instructing the patient to expectorate as soon as the sputum rises into the larynx. Many patients, in order to avoid expectoration, allow the sputum to accumulate in the larynx until forced to cough. Some attempt at local cleanliness or antisepsis might be of avail. The danger of secondary infection of the intestinal tract might be lessened if the dangers of swallowing sputum were more strongly emphasized.

The case of tuberculous meningitis and that of tuberculous lymphadenitis presented no unusual

features. Of the seven cases of acute miliary tuberculosis four were in males and three in females. The primary focus in each of the four cases in males was in the left seminal vesicle, the dissemination occurring through the veins in the tissue about the vesicles. Tubercles were found extending through the wall into the lumen of the vein. Two of these subjects showed signs of general infection almost immediately after the removal of the left testis, which was also tuberculous. In these two cases dissemination may have occurred through the spermatic veins also, though no evidence of this could be found. The primary focus in the other three cases was in a caseating mesenteric gland, the dissemination occurring through the thoracic duct.

The chief point of interest in these cases of acute miliary tuberculosis is the frequency with which the primary focus was found in the left seminal vesicle. In the majority of the articles in text-books on acute miliary tuberculosis the occurrence of the primary focus in the seminal vesicles is not mentioned.

EXPERIENCE WITH LITTEN'S DIAPHRAGM-PHENOMENON IN 220 CASES.

By RICHARD C. CABOT, M.D.,

OF BOSTON, MASS.;
PHYSICIAN TO THE OUT-PATIENT DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

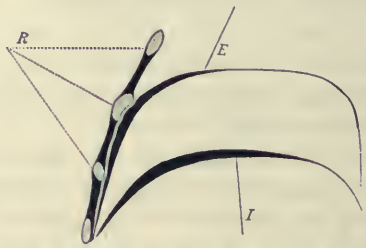
In 1892[1] Litten made this observation: If a person lies with the feet pointing straight toward a window (cross lights being excluded) and the chest exposed, the following phenomenon can be observed during forced respiration: Along both axillæ a sort of shadow is seen to descend during deep inspiration from about the seventh to about the ninth rib, passing up again during expiration. It is best seen in spare, muscular, young persons of either sex. The observer should stand with his back to the light.

There can be no doubt that this phenomenon can be seen in all healthy people except those who are very fat, and those who cannot or will not breathe deeply. The latter condition occurs in hysteria and in some very stupid people who cannot seem to sufficiently understand what is meant by a full breath and to take one. Litten has observed many thousand cases and never failed to see the diaphragm-shadow in healthy subjects except under the conditions just mentioned.

The phenomenon is nearly or entirely absent in the following conditions: (1) Fluid or air in the pleural cavity. (2) Obliteration of the pleural cavity by adhesions. (3) Advanced emphysema of the lungs. (4) Pneumonias of the lower lobe. (5) Intrathoracic tumors low down in the chest. Subdiaphragmatic tumors or fluid accumulations do not impair the phenomenon unless they are of very great bulk. In a case of tumor of the liver weighing thirty-six pounds, and occasionally in very large collections of ascitic fluid, Litten has found the phenomenon absent. Paralysis of a phrenic nerve is also mentioned as a possible cause for absence of the diaphragm-shadow.

The process by which the phenomenon occurs is best understood by imagining a coronal section of the thorax as seen from the front. At the end of expiration a portion of the diaphragm lies flat against the inside of the thorax. During inspiration it "peels off" and allows the lower edge of the lung to come down into the chink between the diaphragm and thorax (see Fig. 1). This peeling off of the

FIG. 1.



Excursion of the diaphragm during forced respiration. *R.* Ribs. *E.* Position of diaphragm at end of expiration. *I.* Position of diaphragm at end of inspiration.

diaphragm from the inside of the thorax is most easily seen in the axillæ but can be made out all round the chest from spine to sternum. It corresponds with the entrance of the "complementary air" during forced inspiration. In quiet breathing it is rarely to be seen. The shadow travels on an average from 2½ to 3 inches, according to Litten, or from about the seventh to about the ninth rib in the axilla. He observes no difference in the distinctness of the shadow on the two sides of the chest though Swenson,[1] Martius,[2] and others have thought it more marked on the right. Similar shadows produced on the abdomen by the descent of the stomach, liver or colon were mentioned by Litten as occasionally visible and attention has recently been called to them anew by Pickler[3]. Martius points out that the shadow begins to move not with the beginning of inspiration but a little later.

The importance of the phenomenon in clinical medicine is due to the following facts: It gives us an easy and accurate measure of the volume or vital capacity of the lungs, enabling us to dispense with the use of the spirometer and of measurements of chest expansion. When the diaphragm-shadow

moves less than 2½ inches during forced breathing, Litten considers the condition abnormal. Such abnormality may be due to general debility, in which case the shadow begins in the normal place (seventh space mid-axillary line) but descends less than 2½ inches. In emphysema the excursion is likewise diminished, but in this disease the shadow begins further down than is normal, owing to the fact that the distended lung prevents the diaphragm from folding back against the chest-wall as much as it usually does. In the later months of pregnancy the excursion is likewise limited by the upward pressure of the pregnant uterus.

So far we have been considing *bilateral* abnormalities in the excursion of the diaphragm. We have mentioned earlier the fact that the presence of abnormal solids, fluids or gases in a pleural cavity abolishes the shadow on that side and this is sometimes of aid in the diagnosis of these conditions. The gradual expansion of a tied-up lung after pleuritic effusions or the contraction of an emphysematous lung as it improves can also be watched by means of the diaphragm-shadow. Litten has also insisted on the importance of the diaphragm-shadow in distinguishing subphrenic abscess from empyema and abdominal from thoracic tumors. Anything *below* the diaphragm except as has been stated, does not abolish the shadow. Bull [1] has not found this distinction to hold good with sufficient constancy to make it of practical diagnostic value. He also dissents from Litten's statement that the shadow can be seen in all healthy people, and states that he has repeatedly found it absent on one or both sides, and frequently restricted to an excursion of one-half an inch or an inch. He finds it less distinct in women and most distinct in children. Rumpf [2] looked for the shadow in seventy cases of phthisis at Davos and found it absent on the affected side in sixty-four of them. The remaining six were incipient cases. The shadow is not visible after the disease has extended down to the second rib in front and to the middle of the scapula behind. He does not consider it of much diagnostic value in phthisis.

Personal Experience.—With the assistance of Mr. Tileston and Mr. Osgood of the Harvard Medical School I made observations on 220 cases at the Out-Patient Department of the Massachusetts General Hospital during the summer of 1898. Our examining-room has but one window and the examining-table was kept always with its foot pointing to the window so that every patient who lay on it was in the best position for examination. The upper and lower limit of the diaphragm excursion was marked in every case with a skin pencil and the intervening distance measured and recorded at once.

These observations confirmed, so far as they went, the results obtained by Litten. In normal cases (102 tested) the excursion was from 5 to 9 centimeters (2 to 3⅜ inches), depending more or less on how hard the patient was made to work over it. It did not seem best to make every patient breathe as deeply as he possibly could as there was some strain and fatigue connected with it. By "normal cases" is here meant those having no evidence of any disease in the chest which could be expected to retard the diaphragmatic movements. Under this heading I include such conditions as syphilis, typhoid, gonorrhea, malaria, leucemia, gastric cancer, adenoids, bronchitis, alcoholism, etc. In these 102 cases the shadow moved practically the same distance on the two sides of the chest, averaging 6 centimeters (2⅓ inches) on the right and 5.9 centimeters on the left. In 50 cases the excursion was slightly greater on the right and in 32 cases greater on the left; in 30 cases it was equal. Slight differences of this kind may be accounted for by fatigue in case the right side is examined first.

Pleuritic Effusion.—In eleven cases of pleural effusion (two of them purulent) the shadow was entirely absent on the affected side and normal on the other.

Pleuritic Adhesions and Dry Pleurisy.—In three cases of acute dry pleurisy with pain and a friction rub and in five cases with a history and signs of old pleurisy with adhesions the shadow was absent or nearly so on the affected side and normal on the healthy side.

Emphysema.—Six cases of chronic bronchitis with emphysema and wheezing were examined. Two of these showed no shadow on either side, two showed none on the left and but slight on the right, and in the remaining two cases the excursion was limited though not altogether wanting on either side.

Phthisis.—Thirty cases of pulmonary tuberculosis with bacilli in the sputum were examined. In only one were the diaphragm's movements normal. The average excursion on the affected side was 2 centimeters (¾ of an inch) in moderately advanced cases and 4.3 centimeters (1⅝ inches) in incipient cases, or an average of 2.1 centimeters ($\frac{7}{10}$ of an inch) in the whole series. Contrary to the results of Rumpf, even in very early cases, in which a few râles at one apex were the only physical signs, we found often distinct limitation of the diaphragmatic movements on the affected side. F. H. Williams has repeatedly called attention to the importance of the evidence given by a restriction of the movements of the diaphragm as seen by the Röntgen-rays. Our results

[1] Bull, *Norsk. Mag. f. Lageviде*, No. x, 1896.
[2] Rumpf, *Berlin Klin. Woch.*, No. vi, 1897.

would seem to confirm this, and I desire especially to insist upon the fact that the diaphragm-shadow gives us a way of observing the diaphragmatic movements much more easily and cheaply than with the X-rays. Not every case of incipient phthisis showed any decrease in the Litten phenomenon, but in a majority of cases it was decreased and served to urge us to more careful study of the case.

In connection with this series of cases it was notable that not infrequently the shadow could only be brought out by making the patient *cough*. Here the attention not being fixed directly on the act of respiration the latter was better performed. The decrease or absence of the shadow in phthisis is probably due to the presence of pleuritic adhesions limiting the movements of the lung.

Cardiac Hypertrophy.—In three cases of valvular disease with marked enlargement of the heart to the left and downward the records show: (1) Mitral stenosis, right 3.5 centimeters (1¼ inches), left 0; apex in seventh space. (2) Mitral stenosis and aortic disease, right 0, left 0; marked ascites and enlarged liver. (3) Mitral regurgitation, left 2.7 centimeters (⅞ of an inch). Whether the cardiac enlargement is really the cause of the limited action of the diaphragm in these cases I do not know. The cases are too few to warrant any conclusions and I record them for what they are worth. The rapid, shallow breathing in cases with ruptured compensation is not suited to bring out the shadow.

Debility and Muscular Weakness.—As the diaphragm phenomenon is due to muscular effort any condition involving muscular weakness or strong disinclination to exertion limits it markedly. This was exemplified in our series in a case of Addison's disease and in cases of debility and neurasthenia.

Obesity.—Our observations simply confirm those of others, that in the very fat, the shadow cannot as a rule be seen.

Subdiaphragmatic Tumors and Ascites.—In a case of cirrhosis of the liver in which the organ was palpable over a space a hand's breadth in width below the ribs and to the fifth rib above the shadow could still be seen to move an inch or more with respiration. Similar appearances were noted in a case of leucemia with great enlargement of the spleen. On the other hand, a very large collection of ascitic fluid in a case of uncompensated valvular disease made it impossible to detect any diaphragm-shadow.

Summary.—1. In 102 normal chests the diaphragm-shadow showed an average excursion of 2⅓ inches on each side of the chest.

2. In 11 cases of pleuritic effusion, 5 cases of adherent pleura and 3 cases of acute dry pleurisy, the shadow was absent on the affected side.

3. In 6 cases of emphysema the shadow was either absent or nearly absent.

4. In 30 cases of phthisis the excursion of the diaphragm was diminished on the affected side (except in one case); even incipient cases may show this change.

5. Muscular weakness may greatly limit the excursion of the shadow. In obesity it is often missed. It may be obtained only during a fit of coughing.

6. Great enlargement of the liver or spleen may exist without abolishing the shadow, but a very large accumulation of ascitic fluid may render it invisible.

7.—The diaphragm-shadow seems to render unnecessary the use of the X-rays in the investigation of diaphragmatic movements.

FOREIGN BODIES IN THE LARYNX.[1]

BY CHARLES H. KNIGHT, M.D.,
OF NEW YORK.

ONE of the most interesting conditions likely to confront us general practitioners, as well as specialists, is that resulting from inspiration of a foreign body. The seriousness of the accident depends upon the shape and size of the object and upon its point of lodgment in the upper air-passages. A very large body, such as a bolus of food or a piece of meat, may fill the cavity of the larynx and cause fatal asphyxia. An irregular or sharp-pointed body like a fish-bone, a pin, or a piece of glass, may be detained in the larynx without interfering very much with the air-current. On the other hand, an object of moderate size with a smooth surface—a glass bead, a bean, a cork—is in danger of slipping through the glottis into a bronchus, where it may be a source of serious mischief. The variety of articles which have gained admission to the upper air-passages at various times is remarkable. Tooth-plates, puff-darts, a toy locomotive, a toy balloon, cockleburrs, coins, and pins of all kinds are found in the catalogue. In fact, almost no object that can be put in the mouth has escaped being inhaled into the air-passages. Children especially have a propensity for stuffing things into their various cavities, and when the mouth has been the situation chosen a deep inspiration preceding the act of laughing or of coughing is apt to carry the foreign body beyond reach.

The first symptoms of a foreign body in the larynx are violent paroxysms of cough, Nature's effort to expel the intruder, and suffocative attacks due to spasm of the larynx and not depending upon the size of the object. The subsequent course of events is very much influenced by the last-mentioned fac-

[1] Read at a meeting of the Northwestern Medical and Surgical Society of New York, February 15, 1899. For discussion, see page 476.

tor. The voice may be abolished, or the object may be so placed as not to interfere with the action of the vocal bands. It is surprising with how little objection the larynx will accommodate even a formidable foreign body. Several years ago I reported a case of tooth-plate in the larynx remarkable for its long retention and for the slight disturbance it caused. The plate fell into the larynx during a puerperal convulsion and was not discovered until a week later, when the patient complained merely of sore throat. A still more extraordinary case was reported a few years ago by Lennox Browne, in which a plate of artificial teeth was impacted in the larynx for twenty-two months without the condition being recognized. Dr. S. W. Langmaid of Boston once removed from the larynx a large pin, such as is used for securing packages of bank-notes, two years after it had been swallowed. Hoarseness was the only subjective symptom after the first disturbance.

One of the most remarkable cases on record as regards duration may be mentioned although beyond the scope of this paper. It is one recently reported by J. L. Bunch and R. Lake. The foreign body, a piece of mutton-bone, passed through the larynx into a bronchus where it rested eight years. It then became shifted to the trachea where it caused more or less dyspnea and certain laryngeal symptoms, and the case was exhibited as one of tracheal stenosis from syphilis. In the course of the succeeding year the bone was discovered and removed through a tracheotomy wound. Recent literature is not very rich in cases of this kind but a few may be referred to briefly. In three of six cases reported by Koch of Luxembourg the foreign body was a meat-bone, in but one instance the bone being arrested in the larynx. In a fourth case the point of a pin had penetrated the larynx from the pharynx. The diagnosis was made by digital exploration and not with the mirror. Two other cases were those of children who inhaled in each instance a bean. In one the foreign body was known to be in a bronchus, where it induced a fatal pleuropneumonia. In the other the bean seems to have passed beyond the larynx, since it was coughed up through a tracheotomy wound, and the child recovered. N. Palazzolo reports having removed with laryngeal forceps a leech which had been fastened in the ventricle of a larynx for ten days. He refers to the frequent occurrence of this accident in the island of Sicily, thirteen similar ones having been observed there. J. Walker Downie reports a case in which a pin was localized in the larynx by means of the Röntgen-ray, its position being accurately defined by a transverse as well as an anteroposterior photograph. An interesting feature of this case is that ten days after the operation pricking and heat over the back of the head and neck were complained of, followed by vesication and sloughing of the skin and loss of hair over a large area.

Kronenberg also reports a case of foreign body discovered with the Röntgen-ray. It proved to be "the hook of a cravat" and was removed by tracheotomy. The symptoms had been attributed to false croup. Lanffs reports a case of eggshell embedded in the larynx and removed with forceps. Delsaux gives the history of case in which he removed a triangular splinter of bone from the subglottic space with forceps. The bone had been *in situ* for six months, one end being just under the anterior commissure and the other beneath the left arytenoid. A case reported by E. Fletcher Ingals in September, 1898, is in several respects a duplicate of one presented by myself at the meeting of the British Medical Association in Montreal in 1897. The foreign body, as in my case, was a metallic shoe-hook or fastener which had been in the larynx five weeks at the time of its removal by laryngotracheotomy. A fruitless attempt was made to examine the larynx with the aid of a vaginal retractor about four inches long. The hook could be felt behind the epiglottis but could not be seen with the laryngoscope on account of the profuse secretion and the intolerance of the patient.

My own case, of which I will give a brief abstract, is a noteworthy tribute to the value of expert use of the laryngoscope. The accident occurred about six weeks before the boy was brought to New York. After a violent fit of coughing and dyspnea there were no special symptoms and it was surmised that the shoe-hook had been swallowed. The voice was lost, however, and after a week spent in efforts to restore it by means of the electric current the laryngeal mirror discovered the foreign body impacted in the right ventricle of the larynx near the anterior commissure. An enlarged tonsil which interfered with manipulations was excised. Many attempts were made to remove the hook both with and without an anesthetic but the patient was so unmanageable that it soon became evident that an external operation would be required. At the time he came under my observation he was completely aphonic and respiration, especially during sleep, was rather stridulous. After several unsuccessful efforts at extraction through the mouth I performed a partial laryngofissure, after a tracheotomy, and met with no difficulty in removing the hook. Recovery was uneventful. At the end of a week, when the trachea tube was withdrawn, a pea-sized mass of granulation tissue was seen at the anterior commissure. No local treatment was permitted except a

sedative spray of menthol in albolene, and attempts to use the voice were positively forbidden. In the course of five or six weeks the patient was allowed to phonate and shortly he regained complete use of his voice.

Before opening the larynx in this case I made an attempt to see and extract the hook with Kirstein's misnamed "autoscope." Its purpose is to substitute direct inspection of the larynx for the ordinary laryngoscopic method. In some subjects a beautiful view of the glottis may be obtained. Others complain bitterly of the discomfort and actual pain produced by pressure of the spatula upon the base of the tongue. The original rather cumbersome apparatus has recently been modified by its promoter and it now consists practically of an elongated angular tongue-depressor. The end of the tongue-piece is slightly curved and is intended to embrace the median glosso-epiglottic ligament and drag forward the base of the tongue. Forced extension of the head so as to bring the long axis of the mouth in line with that of the trachea is essential. The position of the patient and the pressure of the instrument are, to say the least, uncomfortable, and it is not probable that this will supplant the older methods of examination. Max Thorner was more successful in dealing with a case by Kirstein's method. His patient was an adult with a very capacious and a very tolerant larynx who had a chicken-bone embedded in his right ventricle. It was removed with the utmost facility and without cocain. In such a subject the old way of manipulating would certainly have been equally efficacious.

An impacted body which permits respiration may be dealt with somewhat deliberately. A moveable body, or one that may be readily dislodged, is more dangerous because it is liable to shift its position so as to completely cut off the air-current. A sharp-pointed or angular body may lacerate the wall of the passage and cause emphysema of the cellular tissue, or it may penetrate a blood-vessel and induce hemorrhage.

As to diagnosis, the history and the subjective symptoms usually furnish ample testimony, but in every case the laryngeal mirror should be used to determine the situation of the object unless the patient's condition is precarious. Under the latter circumstances a rapid tracheotomy may be demanded for the relief of urgent symptoms.

The extraction of a foreign body from the larynx often calls for the exercise of great ingenuity and dexterity. For example, a pin lying in the larynx with its point directed upward must be seized and pushed down before it can be withdrawn without lacerating the soft parts. Again a rough irregular body must, if possible, be broken and removed piecemeal in order to avoid excessive damage to the tissues. In children the interior of the larynx may be reached with the finger, and our object may be accomplished under general anesthesia. In adults, all endolaryngeal manipulations have of late years been much facilitated by the introduction of cocain. The choice of an instrument to be used must be determined by the character and location of the foreign body. Mackenzie's laryngeal forceps, Cusco's forceps, one of the various tube-forceps, or the cold-wire snare may be selected according to circumstances. Finally, if an external operation becomes necessary I would remind you of the advantage of a *partial* section of the thyroid cartilage with a view to replacement of the vocal bands and preservation of function. When section of the thyroid has been complete it is not easy to secure perfect apposition of the halves of the larynx. The undivided upper margin of the cartilage, however, prevents shifting and in young subjects especially, in whom the parts are pliable and may be readily retracted, it does not interfere with a sufficiently free exposure of the interior of the larynx.

CLINICAL MEMORANDUM.

AN EXTRAORDINARY CASE OF RETAINED CONSCIOUSNESS DURING COMPLETE SURGICAL ANESTHESIA.

BY S. ORMOND GOLDAN, M.D.,
OF NEW YORK.

ON October 24, 1898, Dr. W. requested me to anesthetize a patient whose history was as follows: Age about thirty-four years; general condition good; respiratory and circulatory systems normal; pulse 120; urine analysis negative; had exophthalmic goiter; temperament sanguine; good intellectual development.

The narcosis was induced and maintained easily and with no untoward symptoms; operation consisted of the removal of a dead fetus (six months). The cervix being rigid and tightly closed it required deep anesthesia, which was evidenced by the absence of ciliary and conjunctival reflexes, complete muscular relaxation, slight stertor, and moderate dilatation of the pupils.

The duration of the narcosis was forty minutes, during which time the patient evinced no symptoms of sensation whatever. Her consciousness, however, was complete. She remembered everything which transpired during the operation, as for instance, the surgeon talking to the nurse; an instrument falling on the floor; a call up the speaking-tube and her husband answering; some one knocking at the door, etc. She subsequently said she endeavored by moving her finger to let me know she knew all that was occurring yet felt nothing. There were, however, no muscular movements of any kind. Respiration was deep, regular, and slightly stertorous.

It might be questioned whether the patient was completely anesthetized, but of this there is no doubt. In the first place chloroform was used. This is admittedly the anesthetic which can most easily produce complete narcosis. Secondly, it is well known that the anal reflex is one of the last to be abolished. This is also true of that of the cervix uteri, for if a patient is not completely anesthetized the instant the cervix is dilated the well-known extension of the leg upon the thigh occurs. This patient evinced absolutely no symptoms of sensation during the cervical dilatation or at any time during the narcosis.

The higher the state of intellectual development the longer auditory sensations and consciousness persist. This fact can often be made use of practically when anesthetizing a patient. It is not generally known that the effort of a patient to push the inhaler from the face and to struggle is partly voluntary. They are capable of understanding; if spoken to loudly and told to put down their hands, and assured they are safe they will do as told.

During anesthesia auditory sensations and consciousness keep pace with each other and often persist during the second degree of narcotism. Few patients, however, are subsequently able to remember having been spoken to and having acted in an intelligent manner. All the more extraordinary must it be when a patient retains consciousness and hearing during the third (surgical) degree of anesthesia, a consciousness of not imperfect remembrance of events, during the commencement of anesthesia but details of what transpired after the anesthesia was complete. This patient had been anesthetized previously with chloroform, during which time she remembered what occurred but she also had taken nitrous oxid gas and remembered nothing of what transpired while under the influence of that anesthetic. This is surprising, for if we would expect a patient to retain consciousness to any extent we would suppose this to occur with nitrous oxid and least of all with chloroform. The surgeon also told me the patient has an idiosyncrasy to morphin; she cannot take that drug because of the intense excitement engendered.

MEDICAL PROGRESS.

Increase of Cancer in Prussia.—Heimann (*Arch. f. klin. Chir.*, vol. 57, p. 961, vol. 58, p. 31) says that the number of cases of cancer in Prussia in the year 1877 was 2952, while in 1896 it had risen to 12,548. The latter figures are taken from recently published official statistics. In the order of frequency of their attack, the different organs involved were: uterus, stomach, breast, rectum esophagus, skin, liver, lips, lymph-glands. Between the twenty-fifth and thirtieth year there were no less than 336 cases of carcinoma. In these years the lesion was usually located in the stomach, or in the female genitals, on the face, or the extremities, or in the rectum.

Vesical Calculi Formed around Sequestra of Bone.—Heresco (*Centrabl. f. Chir.*, February 11, 1899) has collected reports of fifteen cases in which, following inflammation of some one of the pelvic bones, an osseous fragment found its way into the bladder, there to be incrusted with lime salts and afterward to be removed. In addition to these rare calculi, he mentions also two formed about silk threads which found their way into the bladder after operations for the removal of the adnexa and for the radical cure of hernia, respectively. In both of these instances a long period of suppuration preceded the deposit of the foreign body within the bladder.

THERAPEUTIC NOTES.

Formalin in the Treatment of Inoperable Cancer.—Mitchell (*Brit. Med. Jour.*, February 11, 1899) employed a solution of formalin containing twenty per cent. of formic aldehyde to stop the almost constant hemorrhage from a sarcoma of the cheek. The healthy skin was protected by painting it with a solution of caoutchouc. The solution of formalin was applied on a bit of absorbent cotton which was covered with gutta-percha tissue to prevent evaporation. The hemorrhage was stopped immediately and the tumor tissue was necrosed for a depth of about a quarter of an inch. The following day the necrosed portion was carefully cut away and the formalin was reapplied. This treatment was repeated daily until the tumor was entirely removed without the loss of a single drop of blood. Injections of the formalin solution with a hypodermic syringe produced an alarming swelling and gave no better result than the external application. There was no suppuration. This method of treatment is simple, produces no shock, and is absolutely bloodless. This formalin has a much more penetrative power than the usual escharotics. As the necrosed tissue is shaved away, an admirable view is presented of the extent of the new growth, and if desired, the excised portions can be examined microscopically, as they are already hardened.

Causes and Treatment of Pernicious Anemia.—Grawitz (*Rev. de Therap.*, February 15, 1899) says that one of the chief difficulties in the way of the successful treatment of pernicious anemia is the improper nourishment of the patient on account of his anorexia. It is necessary to wash out the stomach and bowel and to give saline laxatives to correct this. If the urine contains an increased amount of indican it is a sign that the intestines contain putrefactive material and internal antiseptics, such as calomel and salol, should be given. To correct the hyperacidity of the stomach bitters should be prescribed, or the wine of condurango, wine of pepsin, or porter. It is indispensable that the physician have an oversight of the fluids taken by the patient. Iron is useless. Arsenic is the only drug which has a direct beneficial action. Massage, exercise, and appropriate gymnastics may be of some benefit. Infusion is only indicated in women who have lost a great deal of blood in induced labor.

Treatment and Prophylaxis in Malaria.—THAYER (*Progressive Medicine*, March, vol. i, 1899) quotes Ziemann as highly recommending the intramuscular injection of quinin in malaria. The bimuriate of quinin 0.5 (grs. vii) to 2 grams (m. xxx) of water is the usual dose and is inserted into the glutei. In the proportion of 1 part of quinin to 4 of the fluid the injection is painless, and this method of giving quinin is recommended for its prompt action. During the past year euchinin, the ethyl carbonate of quinin, a new and tasteless product, has received attention. In some cases in which quinin has not stopped the fever euchinin was efficacious in accomplishing this result. The author holds that the favorable reports on the use of this drug in many quarters should justify its more general use. Certainly if intelligent use of the drug proves it to be as efficacious as quinin, the product which is free from unpleasant taste will possess a great advantage in treatment.

In regard to the use of quinin as a prophylactic the author quotes Koch's statement that quinin, 0.5 (gr. vii), taken every other day, was sufficient to ward off attacks of fever.

Treatment of Scarlet Fever and Scarlatinal Nephritis.—BLACKADER (*Progressive Medicine*, March, 1899, vol. i) is opposed to the indiscriminate use of diphtheria antitoxin in the treatment of the anginas of scarlet fever. This should be limited to those cases in which the Klebs-Löffler bacillus can be looked upon as the cause. Much, however, can be accomplished by careful disinfection of the pharynx and nasal passages with suitable solutions. Traube's method of injecting a three-per-cent. solution of carbolic acid into the tissues of the tonsils and soft palate should be practised as soon as enlargement and tenderness of the lymphatic glands of the neck give evidence of septic infection, and should be kept up until the temperature reaches normal. A daily injection of 1 cm. of the three-per-cent. solution is distributed by a number of punctures over the area involved. The pain produced is of short duration, and a marked improvement in the dysphagia is at once experienced, due to the anesthetic effect of the carbolic acid. It is claimed, also, that the fever is favorably influenced. Nephritis is not a contraindication for the employment of this treatment. It is stated that some cases have been benefited and the albuminuria has diminished under the treatment. The urine may show the color of carbolic-acid poisoning, but this rapidly disappears on discontinuing the injections.

In the treatment of scarlatinal nephritis the author endorses Detlefsen's plan which includes: Rest in bed, quick relief to the engorged kidneys by means of mild diaphoretics and purgatives; proper diet, and non-irritating diuretics. The use of baths is warmly recommended, and preference is given to a warm bath of 98° to 100° F. for fifteen to twenty minutes, once to three times daily. Cold compresses should be applied to the head while the patient is in the bath with subsequent warmth to the skin and rubbing. If these measures fail to produce a copious perspiration, hot drinks, or to a child of five years $\frac{1}{20}$ of a grain of pilocarpin or an infusion of 10 grains of jaborandi leaves may be given. When a bath cannot be used the child may be wrapped in sheets wrung out in hot water and packed in hot bottles. Between the baths flaxseed poultices are to be applied over the kidneys. On account of its richness in proteids an absolute milk-diet is not advised. Diluted milk is given and the diet supplemented by gruel, light fruits, and young vegetables. If the urine is deficient in amount diuretics are indicated. Vichy may be given and a lemonade made by dissolving a dram of bitartrate of potassium in a pint of boiling water and adding the juice of one lemon. Acetate of potassium from 3 to 5 grains every three hours is a safe and efficient diuretic. For uremia a free evacuation of the bowels is procured by jalop or senna, or by an enema of equal parts of water and vinegar. An ice-cap should be applied to the head. To maintain the heart's action, hypodermic injections of caffein or of tincture of digitalis or strophanthus should be given, especially in those cases where edema of the lungs is detected.

Effect of Quinin on Asthmatic Attacks.—VAN SWERINGEN (*Ind. Med. Jour.*, March, 1899) tried many remedies for an attack of bronchial asthma lasting two weeks, but at no time succeeded in getting more than two-hours' freedom from distress. Amyl nitrite gave the patient fifteen-minutes' ease; chloroform but little longer, after the inhalations stopped. Belladonna seemed to have lost its effect for good entirely. Morphin did better than anything else, and gave her longest relief, but was followed by so much nausea and vomiting that she refused to have it again. Iodids had been given regularly from the first. Then for the purpose of stimulating the inhibitory reflex center quinin and strychnin were tried. The effect was almost magical. The dose of the quinin was 7 grains, the extract of nux vomica was given in ¾-grain doses, and to this was added ¼ grain of the sulphate of codein. They were taken *pro re nata*. In the intervals the iodids were continued, and the patient had less asthma in the last year than in ten years previous.

Hemalbumin in Chlorosis and Anemia.—DR. GOLINER (*Deut. Med. Zeit.*) recommends hemalbumin for the relief of chlorosis, anemia, and gastric and intestinal catarrhs. An effective iron preparation, provided it contains nutrient material in a predigested condition, especially albuminates, whose absorption and assimilation requires no tax upon the digestive system, is the treatment *par excellence*. Such a preparation of iron is found in hemalbumin. It is a powder, readily soluble in hot water or alcohol, and contains all the salts and albumins present in the blood, *i.e.*, hemoglobin with hematin, serum albumin, and paraglobulin, in the form of albuminates. Therefore hemalbumin closely resembles fresh blood in its composition, the fibrin alone being absent. The iron effects of the hematin, together with the nutritive influence of the albuminates present in this preparation, when administered in appropriate cases, are promptly manifested. The dose of hemalbumin is 15 grains three times a day.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

PSYCHIC PHENOMENA DURING ANESTHESIA.

Many a patient on coming out from the influence of an anesthetic has certain peculiar experiences to relate. It has been the custom in the past to dismiss these phenomena lightly as mere phantasmagoria of intoxication unworthy of serious attention. As psychology has come more and more into prominence during recent years, however, the impression has gained ground that these seemingly unimportant phenomena of ether or chloroform intoxication may be of service in enabling the psychologist to get at the basis of what constitutes the conscious personality. It was the pathologic rather than the physiologic that first added markedly to our knowledge of the anatomy and special functions of the nervous system, and of the functional significance of its various parts, thus enabling the neurologist to raise the science out of the sphere of mere theory. It will not be too much to hope that pathologic psychology will be of corresponding service to the allied branch physiologic psychology which is at present attracting so much attention.

Among our clinical memoranda Dr. S. Ormond Goldan reports this week a case in which complete anesthesia, as far as pain is concerned, was accompanied by perfect consciousness, with knowledge and remembrance of the surroundings, and of the surgical manipulations that were performed. Such phenomena are of great importance in solving that mysterious problem in neurologic psychology, the existence of a dual personality, especially when accompanied by a distinct consciousness for each personalty, or at least a subliminal consciousness not subject to ordinary psychic laws.

These cases of persistent consciousness in the higher or mental sphere during complete anesthesia to pain are not so rare as might be thought from the infrequency with which they are reported. Most anesthetists of wide experience have had such cases. The phenomena are neglected because considered of no scientific value. The psychologic departments of several of our great universities, notably Columbia University here in New York, are interesting themselves in these subconscious phenomena of anesthesia, and medical men should not neglect the opportunity their frequent contact with anesthetized patients affords them to secure material for the interesting cognate science of physiologic psychology.

TREATMENT OF INOPERABLE CANCER.

An article by Mitchell published in the *British Medical Journal* and abstracted in this number of the Medical News calls attention anew to the undying hope in the breast of the surgeon that he may at last find some therapeutic resource which shall destroy a malignant growth, while leaving uninjured the healthy tissues surrounding it. This surgeon used a strong solution of formalin with apparent success upon a sarcoma of the face which had grown far past any attempt at its removal by the knife. The application of formalin was made, not with a view to the cure of the disease, but simply to stop the hemorrhage which was slowly sapping the patient's strength. When the patient returned for a change of dressing the following day, Mitchell was pleased to find that the bleeding points had been thoroughly hardened, and that the characteristic necrosis caused by formalin had extended a quarter-inch into the tissues of the growth. Accepting the suggestion there offered to him, he sliced away most of the tissues so changed, and repeated the application. From day to day he was able to cut the

tumor off bit by bit, without the loss of a drop of blood, until the whole growth had been removed.

It is scarce worth the while to herald this as a discovered cure for inoperable cancer. Too often already have the hopes of the medical fraternity been raised by the reported cures of malignant growths by the latest product of chemistry of the coal-tar products, or by some better known chemical substance, or by some physiological toxin. Chelidoin and erysipelas toxins and protonuclein and carbid of calcium, like the older remedies alcohol and arsenic, have not proved themselves to be the long hoped for cure.

The parasitic theory of the origin of malignant disease is not accepted by the most competent pathologists, and for the present, at least, we must continue to look upon a cancer as "bone of our bone and flesh of our flesh," and while this view prevails, it must be admitted that the hope for a substance which will separate the malignant growth from the rest of the body without injury to what remains, is based on a very slight foundation.

THE THERAPEUSIS OF SUGGESTION IN CHILDREN.

THE modern physician has come to realize very clearly how potent an influence for good suggestion is in the treatment of patients. No matter how material the ailment, no matter how dependent upon gross morbid lesions, mental influence has a wonderful effect upon the course of disease, or at least upon the prominence of symptoms. Whether consciously or unconsciously we are constantly using suggestion in practice. Non-medical minds have come to realize this very fully, and have crystallized their convictions in the matter in such expressions as "there is no use having a doctor unless you have confidence in him," or "the medicine will not do you any good unless you believe in it." The expressions are not without exaggeration, but they have underlying them a certain basis of truth.

Our little patients, the children, have not come to realize yet all the magic influence for health there is in the visit of the doctor. They do not brighten up to tell of their symptoms during the last twenty-four hours, nor wait for the doctor's examination to assure them that the disease is progressing favorably, and so be encouraged to take up courageously once more the battle for health. In many instances children associate the visit of the doctor with unpleasant disturbance of their peace, with discomforting examinations, perhaps with painful investigation of their illness and its causes. They do not welcome his coming; on the contrary, are only too glad to see him go, careless whether he should ever come again, hopeful that he will not.

This is, of course, an unfortunate state of affairs, and one that cannot be entirely ameliorated in every case. Much can be done, however, to remove some of the objectionable features of the doctor's visit. It is more or less necessarily attended with discomfort and inconvenience for the little sufferer, yet it may be so conducted as not to make the child utterly misconceive its purpose. The stories of even wild animals submitting to additional pain when already suffering a good deal, because somehow they had gained the impression that what was being done was for their good, are not entirely without foundation. Certain individuals possess what, for want of a better word, may be called a magnetic influence in such matters that makes their beneficent purpose clear even to the animal.

Very young children also can be made to understand, if properly approached, that the doctor's bothersome visit is for their good. Certain it is that even when scarcely more than a year old they can learn to resent the doctor's meddling, and recognize his presence or even his title by fretfulness.

To win a child's confidence requires above all simple straightforwardness. If an examination is to cause pain the child should not be tempted to submit to it by the assurance that "it will not hurt," for the delusion serves but once and inevitably leads to loss of confidence. Frank explanation that it will hurt but not much, and then sincere efforts to keep this pledge are much better, though for the moment the child may be rendered unfriendly by the pain. If the confidence is gained and retained then the influence of suggestion may be used quite as powerfully as in the case of older people. The child's attention may be directed to its prospective cure, and to the expected good influence of the medicine and other remedial measures. Remedies that are not easy to take and other therapeutic measures that are a source of considerable discom-

fort will be more readily yielded to if the cooperation of the little patient is thus secured.

It takes time, we know, to establish such relations between the strange doctor and his timorous little patient. It cannot be done in the moment or two that is sometimes given for casual examination by the hurrying medical man. The influence for good is in most cases, however, so potent that it seems worth the while. The ability to establish such confidential relations with children is the best earnest of success in the specialty of children's diseases.

As for the direct influence of suggestion in many children's ailments it is not appreciated to a degree corresponding to its true worth. We know of a mother who has by direct suggestion influenced asthmatic attacks in a young child so as to greatly decrease their number and severity. We know of another who has been able several times with a boy of four to influence the course of attacks of laryngospasm, and to practically prevent the feeling of exhaustion that follows them by carefully directed suggestion as to regular breathing. Once the boy's attention was called to the fact that he could breathe easier if he did it quietly, and then the suggestion that he was nervous, not sick, an absolute truth in the matter, made the after-effects much less marked. This whole subject of suggestion as a therap utic agent in children's diseases is too large to handle fully in the limited space of an editorial, but we think we have said enough to show how important and hopeful a feature of pediatric therapeusis it should be.

PET ANIMALS AS CAUSES OF DISEASE.

As the result of the announcement that an Englishman had found that more than ten per cent. of the canaries and other song-birds that die in captivity succumb to tuberculosis, there has been considerable attention given in the daily newspapers to the possibility of human infection from that source. Parrots have come in for a share of condemnation in this connection, and gradually the danger of infection from other pet animals has been drawn into the discussion. A correspondent of the *New York Times* states, what is well known of course, that by far the larger number of monkeys that die in captivity are carried off by tuberculosis, and that the visiting of children to monkey-houses, and especially the keeping of monkeys as house pets (a custom that seems to be spreading) must be sources of serious danger.

We are not of those who like to set up scares of contagion at every possible opportunity, but the fact should be ever kept in mind that the presence of pet animals in a home is always associated with a certain amount of danger. Papers presented last summer at the French Congress for Tuberculosis in Paris demonstrate to our minds, what has been hitherto very doubtful, that aviary and human tuberculosis are essentially the same pathologic process, due to the same germ, modified by cultural environment, but convertible under favorable circumstances, one into the other.

We recall what Nocard, the greatest living authority on tuberculosis in animals, and the man to whom we owe the best culture methods for the tubercle bacillus, found in a series of autopsies on dogs. These animals had previously been considered as very refractory to tuberculosis, so much so that for a time their blood-serum was used as a curative remedy for the disease in human beings. The great student of comparative tuberculosis demonstrated in some 200 successive autopsies on unselected dogs that died at the great veterinary school at Alfort, near Paris, that in more than one-half of the animals there were tubercular lesions, and in many of these the lesions were of such a character as to make them facile and plenteous disseminators of infective tuberculous material.

The recent discussion on rabies at the New York Academy of Medicine, an account of which appeared in a recent issue of the Medical News, shows that whatever may be said as to its rarity that dread disease actually exists in this country. Cases of rabies from various parts of the country that have recently been reported in our columns show that there must be scattered foci of the disease in widely separated districts. As the disease is liable to affect any animal this constitutes not a serious or widespread, but an ever-to-be-remembered danger which is, moreover, practically dependent on pet animals.

Parrots are known to be peculiarly susceptible to a disease so peculiar to themselves that it is called from the Greek word for parrot, ψίτταχος, psittacosis. A number of fatal cases in human beings of

what was at first supposed to be a malignant influenzal pneumonia were in Paris traced to the bacillus at present thought to be causative of the parrot disease. A certain proportion of parrots are known to die from tuberculosis. Cats are known to sometimes have tuberculosis, and that they have in many cases been carriers of diphtheria and other of the ordinary infections directly and indirectly is more than suspected.

These would seem to be the facts in the matter. They are, perhaps, not enough to justify a crusade, on sanitary grounds, against the keeping of pet animals. Pet animals are, however, the fad of the day. They are multiplying more and more, and it does not seem unreasonable nor is it dictated by any desire to produce a sensation that we should demand of their owners great care in the matter of detecting the first signs of disease in them, and then so guarding them as to prevent their being a source of contagion to the human. Especially does this warning seem necessary with regard to children. With them the animals play more freely, and readier opportunities for infection are given. Moreover, growing children are less resistive to disease, and they present excellent cultural opportunities for micro-organismal growth when once implantation has taken place. The older and better-informed people may take foolish risks if they will; there should be no such option in the case of children.

ECHOES AND NEWS.

Sugar from Albumen.—M. Ferdinand Blumenthal has described to the Académie des Sciences de Paris a process of making sugar from albumen which may throw some light on the pathology of diabetes.

A Popular Impression Verified by Science.—A German statistician has discovered that ballet-dancers as a rule attain an age much above the average. The names of a number of celebrated dancers are given whose ages range from fifty to eighty years. Some of these artists are still fulfilling engagements.

Quarantine to Guard against Rabies. — The British Government is making strenuous efforts to stamp out rabies in the British Islands. The State Department at Washington has been informed through the British Ambassador that every dog imported into Great Britain is required to have a license from the Board of Agriculture.

Disinfection at Havana of Ships Clearing for United States Ports.—Dr. Brunner, the chief quarantine officer of the Marine Hospital Service at Havana, has begun the thorough disinfection of out-going ships bound to southern ports of the United States. The health authorities of Louisiana and Alabama have decided to admit such vessels but for the present those of Florida and Georgia will insist upon quarantine.

Appropriation for Professor Koch's South-African Expedition.—The German Imperial Parliament has made a grant of 60,000 marks, about $15,000, to defray the expenses of Professor Koch's scientific investigations of malaria in South Africa. The Government considers very sensibly that anything that will lead to a better knowledge of the disease will redound so much to the benefit of the German colonies and colonists that the expenses involved are regarded as a good investment.

Must Surgeons Wear Masks While Operating?—Gloves for surgical work, in certain lines at least, have come to stay. Now comes the question of making the patient's breath innocuous and preventing particles from the surgeon's face or hair from falling on the field of operation. Dr. Berger of Paris recommends a gauze mask for this purpose. He and his assistants have worn them in sixty-eight cases of radical operation for hernia with union by first intention in every case and no rise of temperature.

Another Medical Martyr to the Plague. — Major Evans, formerly of the British military service in India, and latterly Professor of Pathology in the Calcutta Medical College, died March 13th from plague. He contracted the disease while engaged in making the post-mortem examination of a subject who had died from the disease. This makes at least the fourth victim within the last few years among medical men that the plague has claimed as its own while they were engaged in studying the nature of it.

The Cancer Bacillus.—A cablegram from Paris to the New York *Herald* announces the confirmation of Dr. Bra's statement that he has succeeded in isolating the parasite which is invariably present in cancerous growths. It is a fungoid of the ascomycetes family, and is believed to be the active agent in the production of cancer. Inoculation of animals with a culture produced cancerous tumors, from which the parasite could be again isolated. Experiments are being made looking to immunization and curative treatment.

Sick and Wounded Soldiers Returning from the Philippines.—General Otis has notified the War Department at Washington that he has sufficient transports at hand and will send home at once the sick and wounded of his army. Several of these vessels will leave shortly for San Francisco with the sick, wounded, and convalescent. The transports will be met at San Francisco by paymasters who will pay off the men and send them to their homes at the Government's expense. Those who are unfit for travel will be sent to the Government hospital until they have sufficiently recovered to pursue their journey.

Comparative Mortality of Married and Single.—Dr. Livrier, a French statistician has recently published some very interesting mortality statistics. He announces that

half of all who are born die before 17, that only 1 person in 10,000 lives to be 100 years old and, still more striking, that only 1 person out of every 1000 lives to be 60. The married live longer than the single, but for every 1000 births there are only 95 weddings and as some people indulge themselves in a second and even third matrimonial experience it is evident that only a comparatively small proportion of mankind are willing to make all the sacrifices necessary to secure long life.

Keen's "Surgical Complications of Typhoid" in England.—We had occasion recently to express our high appreciation of Dr. Keen's monograph on this subject, almost at the same time (in the number for March 25th) the *British Medical Journal* comments most favorably in its editorial columns upon the same subject: "The work," the editor says, "deserves the attentive perusal of all practitioners. It is, perhaps, the most important contribution to the literature of the 'borderland' between medicine and surgery that has yet appeared from any American author." This is indeed high praise for an American work, coming from our thoroughly conservative British contemporary.

Yellow Tinge of the Palms and Soles as a Symptom of Typhoid.—A certain yellowish-tinge of the palms and soles is said by the *Medical Press and Circular* to occur at the beginning of typhoid fever and persist until convalescence is well under way. The yellowness is attributed to feeble circulation by which the subcutaneous fat becomes sufficiently apparent through the skin to tinge the cutaneous color. It is said to be more marked in proportion as the integument is thickened by toil, but is visible even when the skin is quite thin. The appearance is called the palmar sign of typhoid. We do not think that any special attention has been given to the sign in this country.

The Fothergill Medal to Dr. Copeman. — The Council of the Medical Society of London has just announced, on the recommendation of a special committee, the award of the Fothergillian Medal for 1899 to Dr. S. Monckton Copeman of London "in recognition of his researches on the preservative effects of glycerin upon vaccine lymph and of the practical benefits that have arisen therefrom." Dr. Copeman delivered the 1898 Milroy Lectures on Vaccination before the Royal College of Physicians of London. They have since appeared in book form and have attracted much attention. They were founded mainly on original investigation into the bacteriology of vaccine material.

"Glimpses of Influenza in the Past."—In the *British Medical Journal* for March 11th there is a very interesting paper with the above title. Among the various epidemics of influenza described are: The "Mure" which prevailed in Italy, Germany, and Great Britain in 1173; the "Coccoluche," a pandemic wave which swept over Europe in 1510; the "New Acquaintance" which was found in Edinburgh in 1562; "Catarrhal Feaver" which Willis described in 1658; the "Epidemic Cough" described by Syndenham in 1675, and a "Most Compleately Epidemic" disease described by Huxham in 1733. From 1693 up to the present time, not counting the series which began in 1889-90, seventeen severe epidemics of influenza have occurred.

A Missing Drainage-tube.—The *Medical Press and Circular* of London gives the result of a recent English trial for malpractice because of the loss of a drainage-tube in an abscess-cavity. Dr. Findlater of Edgware opened an abscess some three years ago and inserted a short drainage-tube. At the next day's dressing it had disappeared and despite careful probing no trace of it could be found. The wound healed but the arm remained more or less useless. A few months ago a fresh abscess formed, which on being opened gave exit to the missing drainage-tube. The patient sued Dr. Findlater for damages on the score of negligence in his professional duties. The verdict was for the Doctor, the telling point in the defence being the fact that the plaintiff herself thought that the missing drainage-tube had been lost in the room and was not in the abscess-cavity.

Drs. Watase and Takamine Honored. — On March 28th the Imperial University of Japan at Tokio conferred the high honor of the doctorate, corresponding to LL.D. of the Occidental Universities, on two of its graduates, Drs. Sho Watase and Jokichi Takamine. The former is Assistant-Professor of Cellular Biology in the Chicago University, and Dr. Takamine has made brilliant researches in some branches of cryptogamous botany which have already yielded valuable economical results in this country as well as in Europe. It will be seen that both these men have won their way in a foreign country, and Dr. Takamine is attached by the most pleasant domestic ties to this country. One of the most important discoveries in his chosen field of research bears his name in a modified form, for to his diastase he has attached half of his name in the syllable "Taka," which means "strong" in Greek, and "high" in Japanese.

Privileges of Doctors on Bicycles.—At Gosport, England, not long ago, the magistrates dismissed a police summons against a doctor who had been brought before them charged with violating the ordinance of the town which forbids riding a bicycle on the foot-paths or sidewalks. The grounds for the dismissal were that a medical man when called to an urgent case has a right to take the shortest, most expeditious way. In certain of the towns of Southern Germany, a doctor mounted on a bicycle has the right of way over other vehicles, the same as an ambulance, by ringing his bell and displaying a colored signal that indicates that he is on a hurry call. Under the same circumstances, too, he may use certain busy streets that are ordinarily closed to bicycles. Are the bicyclists in the profession of America slow to claim the privileges that ought to be theirs, or have we perhaps not the same need here for such privileges?

The O'Dwyer Memorial. — A committee of over forty physicians, representing sixteen different medical societies of the City of New York, and including representatives of both schools of medicine, has been formed for the

purpose of doing honor to the memory of Dr. Joseph O'Dwyer. The memorial will probably take an educational form. By the plan now outlined it is proposed to raise a fund of $30,000, the interest of which shall support two O'Dwyer Fellowships in Pediatrics, open to competition by physicians who graduate in the United States, and to be held by the successful competitors for a period of two years. During this period they must furnish satisfactory proof of their engagement in original research work to a committee of five, one of whom shall be appointed by each of the following: the President of Harvard University, the Dean of the Johns Hopkins Medical School, the Provost of the University of Pennsylvania, the President of the University of Chicago, and the President of the New York Academy of Medicine.

Health and Sanitation at Manila.—Some time ago an ex-officer of the British army wrote to the Secretary of State, John Hay, in regard to the health of the American troops in the Philippines and expressed the fear that the troubles which had overtaken the British in India would likely befall the Americans. The letter was sent to General Otis who returned it with the following endorsement: "The troops here soon become acquainted with and accustomed to the climate. At present, as affairs are somewhat critical, military duty is exacting, but I think, however, that the health of the command will compare favorably with that of the British army in India, there being only eight or nine per cent. on sick report for all causes. The condition of this command is constantly misrepresented in the United States." Considering that the American troops in the Philippines are fighting in a tropical climate where the temperature is constantly so high that the breech-clout is the sole covering of a large proportion of the population, the percentage reported by General Otis should be a matter for felicitation rather than for misrepresentation.—*Army and Navy Journal.*

CORRESPONDENCE.

THE NEW YORK BOARD OF HEALTH AND THE SALE OF ANTITOXIN.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your editorial on the "New York Health Department and the Sale of Serum," published under date of April 8, 1899, you say, "The economic question, however, of a subsidized institution entering into competition with private enterprise, still remains. Except under extraordinary circumstances, it is pretty well agreed that this is wrong."

I cannot refrain from saying that extraordinary circumstances which were assumed to exist when the original law creating the Antitoxin Fund was passed in 1895, were imaginary rather than real. The Antitoxin-Fund law however, became a part of the charter in 1897, and the introduction and advocacy of the Collier Bill was an effort to take the municipality of Greater New York out of trade, in order that the Health Board might be free from all disturbing influences and able to devote its entire attention to the purposes for which it was created. It is also a matter of interest in this connection that it should be assumed to be necessary, for the maintenance of experimentation in other antitoxins, to continue the sale of the surplus antitoxin in order to furnish funds for such investigation. It is a poor principle in political science that a business should be carried on at a loss to obtain, indirectly, an appropriation for an object for which money could be readily obtained directly.

We are most heartily in accord with you when you suggest the propriety of the Board of Health now accepting the economic principle with which this letter opens, and by official action discontinuing the sale of serum. We believe that all fair-minded physicians will agree with you in this position, and this is exactly what the Collier Bill was intended to do. REYNOLD W. WILCOX, M.D.

NEW YORK, April 11, 1899.

CANCER STATISTICS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In Dr. Park's paper on "Cancer," published in your issue of April 1st, he says, "In England and Wales . . . where most careful statistics are kept, the cancer death-rate has risen from 1 in 5646 of the population in 1840 to 1 in every 1306 of population in 1896, that is, in 50 years the proportion has increased nearly five times."

I have not been able to obtain the figures for the years prior to 1864, but the increase in the cancer death-rate since that date, although indicating a steady growth of the disease, does not show anything as extraordinary as Dr. Park's figures. The following statistics, the earliest and the latest at hand, are taken from the reports of the Registrar-General. When this office was created I do not remember; but I hardly think that the statistical methods in vogue prior to 1850 are likely to have been remarkable for their reliability.

Ratio of deaths from cancer to each million of persons living (in England and Wales) in the following years:

1864	385	1884	563
1865	372	1885	572
1866	385	1886	590
1874	461	1894	713
1875	471	1895	755
1876	471		

Startling as these figures are the ratio for 1895 is only double that of 1865. Moreover, taking the total number of deaths and making no allowance for increase of population, the statistics do not demonstrate a three-fold increase in thirty years, although they approach it.

Total number of deaths from cancer in England and Wales: 1865, 7922; 1875, 11,414; 1885, 15,260; 1895, 22,945.

If Dr. Park can vouch for the accuracy of his figures for the year 1840—no doubt fifty years ago the term "cancer" included sarcoma and other tumors—the increase of the death-rate in the twenty-four years from 1840 to 1864 must have been appalling, even as compared with the increase between the latter year and 1895. I confess, however, that I am unable to convince myself that the cancer mortality-rate can have been multiplied five-fold in fifty-six years (1840–1896) when the Regis-

trar-General's reports show that the ratio has only been doubled—an alarming growth—in the past thirty-one years (1864–1895). Should my incredulity upon further investigation prove unfounded I shall hasten to make confession.

A word upon another subject. Any comparison between the cancer death-rate and the phthisis death-rate in New York State is fallacious, because so many sufferers from the latter disease leave the State in the hope of deriving benefit from a change of climate, never to return. As a result the figures usually quoted of the number of deaths from "consumption"—meaning tuberculosis pulmonalis, I suppose—are below what they should be, just as those of the States to which phthisical patients are sent in search of health are higher than the correct facts warrant.

I am not a physician and I know absolutely nothing of pathology. I have ventured to write this letter in consequence of having had some little experience in dealing with statistics.

Yours etc.,

Lawrence Irwell (M.A., B.C.L.).

Buffalo, N. Y., April 10, 1899.

VERATRUM VIRIDE IN THE TREATMENT OF PNEUMONIA.

To the Editor of the Medical News.

Dear Sir:—Among physicians, with few exceptions, blood-letting in pneumonia has been relegated to the past. Yet we are often confronted with the question as to whether it would not have relieved arterial tension and thereby alleviated the engorgement of the lung tissue, and at least modified the course of the disease. In veratrum viride we have the lance, now discarded by many, that will slow the circulation, relieve arterial tension, stay the engorgement, and modify the disease, by bleeding the patient in his own veins, thus conserving his strength for the struggle he has entered upon. I was taught more than twenty years ago to rely upon a good quality of veratrum viride (Norwood's tincture), to give it intelligently, and to watch its effects. The indications for its use are the early stages of engorged lung tissue or a harsh bounding pulse of 108 to 120. It has ever been a faithful, reliable friend, as positive in its effects as almost any drug we possess.

It has been claimed that veratrum is too depressing. I would ask which is ultimately the more depressing, a heart with the brakes off, clipping away at a rate of 120 to the minute, or a heart held down to 70 or 80 with veratrum viride? In sthenic subjects, with a tense, bounding pulse of 120, three to five drops of Norwood's tincture of veratrum viride, guarded by $\frac{1}{60}$ of a grain of strychnin every two or three hours will many times bring the pulse to 70 or 80, with a soft natural feeling, the patient expressing relief from pain and oppression in breathing. If the temperature is not correspondingly reduced, which I think is seldom the case, small doses of phenacetin, 5 grains, guarded with 2 grains of caffein, may be given between doses of veratrum and strychnin. If nausea occurs the veratrum viride should be withdrawn and good whisky given, which will relieve the sick stomach.

Veratrum viride, in my opinion, is much safer than the coal-tar preparations. If the patient gets an overdose of veratrum he is nauseated and vomits it. Later, after the active inflammatory stage has subsided, the veratrum should be stopped and stimulants, such as strychnin, the ammonias, and whisky relied on,—strychnin in large doses if there be stupor, shallow respirations, and cyanosis. The poisonous action of veratrum viride upon the system may be alarming, yet I have never seen any deaths reported from its use and it is not accumulative.

Z. T. Magill, M.D.

Winters, Cal., April 1, 1899.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

PUBLIC HEALTH OFFICERS IN COUNTIES AND TOWNSHIPS OF THE STATE—ANNUAL MEETING OF THE STATE MEDICAL EXAMINING BOARD — A HOMEOPATHIC HOSPITAL FOR THE INSANE — REPORT OF THE NORRISTOWN HOSPITAL FOR THE INSANE—AN OFFICIAL'S VIEWS ON TYPHOID FEVER—SOME STATE APPROPRIATIONS—REPORT OF THE EPILEPTIC COLONY AT OAKBURN — PERSONAL NOTES — HEALTH STATISTICS.

Philadelphia, April 11, 1899.

An act to provide for the appointment of medical officers of public health in the counties and townships of this State failed to pass the House of Representatives last week because of lack of a constitutional majority. Under the prevailing law all complaints within municipal limits can be enforced but, as Dr. Lee points out, "Objectionable establishments being warned by the local board of health that certain improvements must be introduced in order to abate the nuisance which they are causing, simply remove just outside municipal limits where they continue to be a menace to the public health. In the second place although every possible precaution be taken to prevent the spread of contagious diseases within the municipal limits, ordinances cannot be enforced beyond a certain line, and in many cases that line may be the middle of a street built up on both sides. It is evident, therefore, that while infection can be prevented from spreading on one side of the street there is no control over the residents upon the other side. It is necessary, therefore, that steps be taken to protect cities and boroughs from nuisances and epidemics in their suburbs which are yet outside their jurisdiction."

In the last annual report of the State Board of Health Dr. Lee states that appeals are constantly addressed to him asking why those living in rural districts and villages are not equally entitled to protection for their lives and health as are those living in large cities. There is a mistaken impression abroad that the country districts are naturally so healthy as to need no laws for the prevention of disease. There could be no greater mistake. Typhoid fever has long been known to be a disease of the country village and farm, and all of the contagious diseases peculiar to childhood, such as scarlet fever, diphtheria, and

measels, run riot in the children who attend public schools.

The next annual meeting of the State Medical Examining Board will be held June 20th to 23d for the purpose of examining applicants for a license to practise medicine in Pennsylvania. The State Medical Society will held its examinations in Philadelphia and Pittsburg, the Homeopathic Board in Philadelphia, and the Eclectic Board will meet in Harrisburg.

The Homeopaths of Pennsylvania have good reason to rejoice for their tireless efforts to secure a State institution seem about to bear fruit. The bill appropriating $150,000 for the purchase of grounds and the erection of a building to be used as a hospital for the homeopathic treatment of the insane of this State was reported favorably from committee last week, and in all probability will now become a law. At the same time comes the monthly report of the Norristown State Insane Asylum which shows, according to the Resident Physician, Dr. D. D. Richardson, that the hospital is so overcrowded as to compel 314 patients to sleep on the floor in the corridors. The trustees year after year vainly ask for more money for additional accommodations, but with the election of Dr. Joseph Thomas, who was chosen last week to fill the position of President of the Board, new energy will be infused, and success may at last crown their efforts.

It is not very often that a public official delivers opinions on medical subjects but Mayor Ashbridge, in his inaugural address, gave utterance to a few remarks upon the present epidemic of typhoid which are worth repeating: "While I am far from believing that there exists a typhoid epidemic, I cannot deny that there is more than there should be if the drinking-water is responsible. Statistics show that while the proportion of deaths elsewhere is as 1 to 5, yet in Philadelphia the rate is 1 to 11. I can scarcely believe that the practitioners in every other large city are so lacking in the knowledge of this disease as the figures seem to show. I am inclined to believe, on the contrary, that half the cases of so-called typhoid fever reported in this city are not typhoid at all but enteric or intermittent fevers." It is with such arguments and ignorance that the people at large are beguiled while the water-question remains the same in spite of all the indignation meetings, committees on pure water and newspaper complaints.

Among the items in the General Appropriation bill of the Legislature for 1899 are the following: Medical Council $3000; Dental Council, $1500; Hamet Hospital Association, Erie, $10,000; State Hospital of the Middle Coal Field, $40,000; Pennsylvania Institution for the Blind, $88,000; St. Vincent's Hospital, Erie, $16,000; Pennsylvania Training School for Feeble-minded Children at Elwyn, $210,000.

The annual report of the Pennsylvania Epileptic Hospital and Colony Farm at Oakburn gives a summary of the work accomplished during the past year, the third since its inauguration. During this year 31 patients were admitted and 25 discharged, of whom 14 were benefited. This institution is the only one in Pennsylvania where epileptics are received and given employment in order to improve their condition and it is hoped that the lack of funds which now exists will be remedied so that the many applicants which the institution is at present compelled to turn away may receive treatment. Dr. Wharton M. Sinkler is the president; Charles M. Lea, vice-president; Dr. S. W. Morton, secretary, and S. W. Climenson, treasurer.

At the conversational meeting of the Pathological Society to be held on April 27th, Professor R. H. Chittenden of Yale will be the speaker of the evening.

Mayor Jeffries of Chester has appointed Dr. S. V. Hoopman a member of the Board of Health to succeed Dr. F. Evans.

Dr. Addinel Hewson, Demonstrator of Anatomy at the Jefferson Medical College, was last week presented with a case of surgical instruments by the undergraduates on the occasion of the twentieth anniversary of his connection with the college. The Guiteras Medical Society of the University of Pennsylvania last week gave a farewell dinner to their patron, Dr. John Guiteras, who severs his connection with the university this spring to settle in Havana. R. K. McClanahan, assistant-surgeon, U.S.N., has been assigned to duty at the Naval Hospital in this city.

The total number of deaths occurring in Philadelphia during the week ending April 8th, as reported at the Health Office was 584, of which number 142 occurred in children under five years of age. The total number of new cases of contagious diseases was 365 reported as follows: Diphtheria, 38 cases with 2 deaths; scarlet fever, 31 cases with 3 deaths; typhoid fever, 296 cases with 48 deaths.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE "GOVERNMENT" SCHOOL OF TROPICAL DISEASES —DR. MURRAY'S LECTURES ON THE PATHOLOGY OF THE THYROID GLAND—PRAISE FOR GENERAL WOOD, THE AMERICAN GOVERNOR OF SANTIAGO—SIR DOUGLAS GALTON—CINNAMON AS A SPECIFIC IN INFLUENZA.

LONDON, March 29, 1899.

PRECISELY what we foreboded has happened in the development—proceeding with cretinic slowness—of the much-trumpeted "Government" School of Tropical Medicine. A committee has been formed headed by Sir Donald Currie the "Ship King," and a public dinner announced to be addressed by Secretary Chamberlain himself in a winning appeal to the dear public to come nobly forward and subscribe *four-fifths* of the building fund and *two-thirds* of the annual income of this "Imperial" scheme. Could a more disgraceful affair be imagined? In America we are quite accustomed to seeing private individuals or companies endeavoring to get the Government to bear the burden of their financial enterprises, while they draw the profit, but we are not quite familiar with the spectacle of a great government stooping to wheedle and cajole private charity into paying three-fourths of the expenses of a State enterprise of which the State is to have all the credit and two-thirds of the benefit. It is as if a fond parent were to say to a small college, "I

will build you a dormitory and pay full tuition-fees for the instruction of all my family of children if you will call the whole institution by my name!" All the Foreign Office promises toward the support of the school is to pay tuition-fees for its Colonial medical officers, *estimated* to reach *about* $5000 a year. The Honorable Joseph seems to have been taking a leaf out of the book of his illustrious namesake who engineered the celebrated "corner" in Egyptian wheat a few thousand years ago.

As a refreshing contrast the private School of Tropical Medicine at Liverpool has just called the foreign consuls of the port together, announced through Professor Boyce that they will be ready for students and patients April 22d and asked them to kindly bring the fact before the attention of their respective governments and assure them that either their sick seamen or ship-surgeons and colonial medical officers will be cordially welcome at the hospital and school. The "Government" School talks hopefully of an opening in October! But that largely depends on how the public responds and judging by its inadequate response to the Prince of Wales' Hospital Fund, it would seem as if the limit of its charity had been almost reached. No wonder the medical profession and hospitals were wary of the scheme.

Altogether the present Government and House are not exactly laying up for themselves treasure in Heaven by their conduct of questions of public health. Beginning by repudiating their promise to introduce a Revaccination bill, they continued two weeks ago by refusing to raise the flash-point of petroleum from its present disgracefully and murderously low standard of 73°, which stands responsible for nearly 200 deaths a year in London alone. While this week it has weakly surrendered to railroad clamor and "taken the starch out of" the bill compelling railroad companies to equip their cars with automatic couplers and thus save a terrible waste of human life. In the petroleum debate several of the States, Iowa in particular with its flash-point at 103°, were held up as examples of perfection to their British cousin.

Dr. George R. Murray's lecture at the College of Physicians on the "Pathology of the Thyroid Gland" have been of great interest. In the one of last week he took the ground that exophthalmic goiter and myxedema are opposite poles of our secretion flow. This he graphically expressed in the form of a series of equations. Taking the normal amount of thyroid secretion at 100, secretion + 25 or 125 = mild exophthalmic symptoms, + 50 = moderate and + 100 or 200 = severe types of the disease. Conversely secretion − 25 or 75 = a mild form of myxedema, − 50 = a severe form and − 100 or complete suppression of the secretion = cachexia thyropriva. Exophthalmic is made worse, ordinary goiter better by thyroid extract and a series of most suggestive sections were shown in which the conditions of a monkey's thyroid hypertrophying after removal of the other lobe were almost identical with that of a thyroid from a fatal case of Graves' disease.

A number of cases are now reported where myxedema followed severe exophthalmic goiter, just as atrophy follows hypertrophy in other organs and Guriquez and Ballet have succeeded in producing typical exophthalmic symptoms in dogs by excessive thyroid feeding.

He advised removal of a part of the hypertrophied gland in exophthalmic goiter, a procedure which has given some admirable results, but which has been followed in some cases by a violent and in one instance fatal exaggeration of the symptoms, the pulse reaching 150 and even 180, believed to be due to squeezing and manipulating the gland during the operation and thus forcing out an excessive amount of its secretion into the blood-vessels. At all events in the later operations where such pressure was carefully avoided no such symptoms occurred.

The Ophthalmological Society of Great Britain at its last meeting voted to follow the example of the British Medical Association and admit women physicians to its membership.

The influenza epidemic still rages, and though the form continues mild and of the nervous type in the vast majority of cases, yet an unpleasant number of pneumonitic sequelæ developed last week and brought the death-rate for London up to 100 again from 90 of the week before.

Spurred by the sad death of Dr. Boyd, Rector of the University of Glasgow, from a dose of carbolic-acid solution taken in the night in mistake for a sleeping mixture of chloral hydrate, the Government has at last announced its intention of according to the oft-repeated urging of the profession that carbolic acid should be placed on the list of poisons and dispensed only as such. Had this been done a month ago this fatality, like many previous ones, would have been avoided, for, by an excellent provision the English law requires poisons not merely to be labelled as such, but dispensed only in deeply fluted bottles, so that warning would be given by the sense of touch, even in the dark.

Our General Wood is decidedly the popular hero of the day over here, now that the Sirdar has gone back. On all hands you hear, "That's what comes of having a man with medical training in a responsible official position." His achievements at Santiago are admired everywhere and regarded as a triumphant vindication of American unselfishness and competence, and no small object-lesson of the high civic value of modern medicine.

The death of Sir Douglas Galton has removed one of the pioneers of military hygiene. He early distinguished himself by insisting upon paying even more attention to the building of barracks and sanitation of camps than to the construction of earthworks and trenches, though only a Royal Engineer and not a medical officer. To him belongs the credit of many of the hygienic reforms in army management, and since his retirement he has been actively connected with the Parkes Museum of Hygiene, of which he was one of the founders.

The principal points of fresh interest brought out by Professor Burdon Sanderson of Oxford in his lecture upon "The Electric Concomitants of Motion in Animals and Plants," before the Royal Society last week, were two, one that the immediate result of stimulation of a muscle at any point is always oxidation of its tissue at the point of irritation, with liberation of acids. This breaking-down of tissue gives rise to a change of electric poten-

tial, so that if this point of the muscle be connected by a good conductor with any still unimpaired region of its mass a current is at once set up. This so-called "muscle-current" is, however, solely due to the differences in electric potential between the particular regions at which the electrodes are applied, and has no necessary effect whatever upon the stretch of muscle lying between these points. In fact the familiar electric changes in contracting muscle are merely a symptom of contraction-oxidation, and not its cause. The other, that a similar change of electic potential between the stimulated and non-stimulated areas of the leaf accompanies the movements of "sensitive" plants, *e.g.*, Dionæa and Drosera.

A writer in the *British Medical Journal* strongly recommends cinnamon as a "specific" in influenza. He has given it in the form of a decoction or tabloids in large doses in previous epidemics, and in no case where the treatment has been begun within twenty-four hours of the commencement of the attack has he failed to get his patients up and about again in five days.

Cinnamon, like nearly all other aromatic spices, is an excellent germicide, and has several times been recommended as a substitute for carbolic, iodoform, and other less fragrant antiseptics. Possibly it may have a discouraging effect upon the spirellum of Pfeiffer, but inasmuch as the period of prostration in uncomplicated cases of influenza averages only from three to five days, we must confess that we are of the opinion that the gentleman would have got nearly as good results by simply keeping his patients in bed and prescribing any other hot drink, such as lemonade. weak gin-sling, or even the renowned "slippery-ellum," in abundance.

ACUTE ELEPHANTIASIS OF THE SCROTUM—DANGER OF INFECTION IN TUBERCULOSIS—ON THE USE OF MASKS IN TUBERCULOSIS—RAISING THE ARM IN PARALYSIS OF THE DELTOID—APPENDICITIS IN SITUS INVERSUS—AFFECTIONS OF THE LUNGS IN TYPHOID FEVEK—A CASE OF PARTIAL HYPERIDROSIS — IMPROVEMENT OF DEAFNESS UNDER MECHANICAL EXERCISES.

AT the Berlin Medical Society, February 15th, RUBINSTEIN showed a case of acute elephantiasis of the scrotum occurring without immediate venereal precedent in a man aged twenty-three years, who lifted a very heavy weight and noticed almost immediately a swelling of both sides of the scrotum. One week later the scrotum was three or four times its normal size while the penis was not affected at all, nor were the testicles larger than normal. Two years previously, the glands in the right inguinal region had been resected on account of acute inflammation. A few similar cases have been reported, produced as was this case, by a sudden strain in a person suffering from chronic gonorrhea, but in all of them the inguinal glands of both sides had been resected. The swelling was considered that of elephantiasis since several punctures failed to extract any fluid.

At the session of February 22d, CORNET read a paper on the danger of infection in tuberculosis. It has been usually accepted that infection takes place through the dust of dried sputum. This view has been disputed, especially by Flugge, who holds that infection takes place almost exclusively from the fine drops which are expelled in coughing. If this view is accepted the prophylactic measures at present employed must be vastly altered. Cornet conducted a series of experiments in order to settle the question. He easily proved that the dust of dried sputum may be an important source of infection. The failure of some investigators to produce tuberculosis in animals by using such dust was one of the chief points in Flugge's argument. Cornet shows that such failures were due to errors in the technic. If the dust is fine enough to be breathed into the deepest portions of the lungs infection readily follows. A single mass of sputum expectorated by a phthisical patient contains more bacilli than are found in the fine drops which are coughed out into the air by dozens of patients. An estimate has been made from the examination of masks worn by these patients, that the number of bacilli so coughed up in one day, is only one three-millionth part of the number contained in the expectorations for one day. The testimony of experience coincides with that of these experiments. Under measures directed toward the prevention of infection through expectoration the percentage of cases of tuberculosis in Prussia has steadily diminished. Under these circumstances, it seems that it is an unnecessary hardship to compel a phthisical patient to wear a mask day and night, as some physicians have advised.

In the discussion of this paper HAUPT said that he looked upon tuberculosis as a constitutional disease, rather than as an infectious one. Therefore, it was a matter of indifference to him whether the statement of Cornet or that of Flugge was accepted. If either theory was correct, tuberculosis ought to be conveyed from husband to wife or vice versa far oftener than is the case. He once investigated 1500 cases of phthisis in married people, and found that in 93 per cent. the surviving party remained healthy. In the 7 per cent. of instances in which the surviving party suffered from phthisis he often found a hereditary taint. The most important factor in reducing tuberculosis in a community is to improve the conditions of life of the people.

FRAENKEL insisted on the value of a mask of gauze for phthisical patients. It is the duty of a physician, he said, to do all in his power to limit the spread of disease, and the infectious power of the sputum is beyond all doubt. These masks have been shown to catch a certain number of bacilli, and they therefore are of use in limiting the spread of the disease. They are only advised under those circumstances in which the patient is in a closed room with other individuals, for example in the family or in a hospital. While out of doors it is not necessary to wear them, as the danger of infecting others by coughing is under those circumstances at a minimum.

LAZARUS objected to the use of masks because they make it more of an effort for the patient to breathe. He considered that the proper disposition of the sputum is a sufficient safeguard against the spread of the disease. In

proof of this he called to mind the fact that in his hospital service, although phthisical patients and others were mixed indiscriminately in the wards, he had seen no case of infection arising in the hospital. He warmly advocated the erection of sanataria in suitable localities, rather than the setting aside of certain hospital wards for the use of phthisical patients. In the former institutions not only are many patients benefited to the extent which it is possible for any such patient to improve, but they learn how to take care of themselves so as not to be a source of danger for those around them, and with this knowledge their spirits return, and the depression leaves them which has come upon them as the result of the widespread feeling in the community that every phthisical patient is a possible source of contagion to his fellows.

At the session of March 1st, KRON showed a patient aged ten years, who had a complete paralysis of the deltoid muscle, due to an anterior poliomyelitis in the first year of life. In a short time after treatment was begun, he had succeeded in developing the use of the trapezius, serratus, supraspinatus and pectoralis major muscles, until the arm could be raised above the head. The arm was first raised forward by the clavicular portion of the pectoral and held there until the muscle was exhausted. When this exercise had developed its strength, attempts to move the arm sidewise from its elevated position were made, and after a short time the arm could be raised direct from the side of the patient.

RATKOWSKY mentioned a case of recurrent appendicitis occurring in a physician who had complete situs inversus of all the organs. The left-sided attacks were at first ascribed to a stenosis of the sigmoid flexure, but their further recurrence, led to the discovery of the inversion of the organs, and as all the symptoms and the results of physical examination agreed with this theory, there seemed to be no reason to doubt that the diagnosis was the correct one. The remarkable thing about the history of the case is that the inversion of the organs had not been discovered either by the numerous physicians who had examined the patient in these attacks, nor by the military examiners, nor by the patient himself in his student days. The heart sounds could be heard on the left side, though feebly.

At the Berlin Union for Internal Medicine, February 26th, FRAENKEL spoke of the affections of the respiratory apparatus in typhoid fever. He mentioned three classes of such cases: (1) those of fibrinous pneumonia with typhoidal symptoms; (2) those in which a typhoid fever is complicated with true fibrinous pneumonia, and (3) pneumotyphoid, in which the lesions are caused solely by the typhoid bacilli. The first form corresponds to the so-called asthenic pneumonia, which cannot be sharply differentiated from the sthenic form. The typhoidal symptoms are often combined with diarrhea and meteorism. In the first days there is nothing definite in the lungs, as the disease begins in the central portions. In these cases the pneumococcus was regularly found, especially in fluid from the middle portion of the lung. The second form was seen by Fraenkel only 6 times in 500 cases of typhoid observed by him in the past 9 years. This mixed infection may occur in any stage of typhoid fever, but it gives only a faint picture of pneumonia, altering the typhoid curve only slightly, causing a slight rise of temperature, but not the crisis seen in pneumonia alone. The diagnosis is more easy to make if it occurs during the convalescence. In reference to the third form there are two secondary questions to answer: Can the typhoid bacillus produce pneumonia? and if so in what form? and, is there such a thing as a primary pneumotyphoid? Of the latter there is yet no positive evidence. There is a secondary migration of the typhoid bacilli from the blood into the lungs, producing a hypostatic pneumonia. But under these circumstances they only act in conjunction with other germs in setting up the pulmonary inflammation. But typhoid bacilli may cause pneumonia, as the following case shows: A young man convalescing from typhoid fever, in the fifth week from defervescence, developed a new rise of temperature. There was an area of dulness found posteriorly, and a needle thrust through the chest wall at this point drew out reddish pus. Later a serofibrinous exudate formed there. From both of these, pure cultures of the typhoid bacillus were obtained. The case was a typical pleuropneumonia which went on into contraction, the disease tending to spontaneous cure.

At the Imperio-Royal Society of Physicians, at Vienna, March 3d, KAPOSI showed a case of partial hyperidrosis in a boy aged fifteen years. In the first year of life he had perspired profusely from the skin over the nose. Until the eight year the area so affected gradually increased until the sweat came from lips, chin, ears, front of the neck, arms, and chest, as far as the sixth rib. In the seven years following, the condition spread very little so that at the fifteenth year the skin was affected only a finger's breadth below the costal margin. The sweat pours out quickly the moment anything cold comes in contact with the skin or mucous membranes. When the patient takes violent exercise and becomes warm, especially in the summer, this abnormal secretion of sweat does not occur. There was no organic lesion demonstrated except a cyanosis of the fingers, nose, etc. The patient had also a kyphoscoliotic spine, which, however, gave him no trouble. Ligature of the arm prevented the occurrence of sweating in it, but as soon as the ligature was removed the sweat poured out in more than its usual volume. The diagnosis of the condition was thought to be a hydromyelia of the cervical and dorsal cord.

URBANTSCHITSCH replied to the criticisms which had been made of his method of treatment of deafness by systematic exercise (MEDICAL NEWS, March 25th, p. 381), saying that the pathological anatomy of the middle ear is not so well known that one could disprove the results of treatment by an appeal to the impossibility of changing pathological conditions. He had seen, for example, good results follow the exercises in patients who were deaf for ten or fifteen years as a result of meningitis. The exercises are sometimes not carried out with sufficient persistence. He had been able to achieve considerable improvement in the case of a girl who had been treated without benefit by another physician by the same method, but less vigorously. It has been estimated that

twenty-seven per cent. of the deaf are amenable to treatment by this method; and as there are about 200,000 deaf persons in Europe, the total number that may receive benefit is no inconsiderable one. He emphasized again the fact that the treatment does not need to be carried on by a specialist, but that any physician, or any intelligent patient or friend can look after its faithful performance.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Regular Meeting, Held February 25, 1899.

THE President, DR. HENRY C. COE, in the Chair.

The paper of the evening, entitled

EMPYEMA OF THE FRONTAL SINUSES AND INTRACRANIAL INFECTION

was read by DR. CHARLES L. GIBSON. Suppurative conditions of the frontal sinuses are comparatively rare so that it seems worth the while to report the following case which has some special and interesting features:

J. C., male, aged thirty-two years. Entered St. Luke's Hospital, February, 1897. In September, 1895, a swelling which had appeared at the inner angle of the left orbit was lanced and pus evacuated. A suppurating sinus was left which failed to close. About a year later the frontal sinus was opened and the cavity drained extensively. No opening was made into the nose. The sinus persisted, continuing to discharge a small amount of pus. The patient had had several polypi removed from his nose during the past two years. On entering St. Luke's Hospital he complained of the discharging sinus and persistent frontal headache, most marked on the right side. He had besides lost some weight. Physical examination revealed nothing new.

An operation under ether was performed, a horizontal incision being made in the line of the left eyebrow, including the fistulous tract at its central portion. This tract was freely enlarged and considerable pus evacuated. The cavity was scraped with a curette, except the posterior wall, which was not touched for fear of perforating the softened bone. The curette easily penetrated the septum into the right frontal sinus and let out two drams of pus. This appeared to be under tension, though there was no pulsation. An attempt to pass a probe on the left side downward into the nose failed, but it passed easily from the nose upward into the left sinus. It was considered unnecessary to make a second opening over the right sinus on account of the opening externally through the left sinus, and below into the meatus of the nose. A rubber drainage-tube was passed from the external opening through the nose. Two days after operation meningitis developed and the patient died after nine days. It had been noticed that washing out of the frontal sinuses aggravated the symptoms, and it was judged from this that a communication with the brain cavity existed. The autopsy showed pus in the pit of the base of the brain. Flattening of the under surface of the frontal lobe on the left side was also noted. The posterior cranial wall of the right frontal sinus was entirely wanting, there being a loss of substance one inch in diameter. The opening was in the form of a circle with smooth, well-defined edges. The dura here was very much thickened and covered with granulation tissue and blood. Both cribriform plates were carious but especially the right one. The cerebral wall of the left frontal sinus was eroded and showed two minute openings into the cranial cavity.

The condition of the left sinus had been known, though erosion of the posterior wall had been suspected as a probability during life, but the failure to open the right sinus externally rendered exploration of its walls and the recognition of its condition impossible.

This condition of almost complete absence of cranial wall on the right side was tried to be accounted for in three ways: (1) Destruction of the bony wall by extension of a suppurative process originating in the frontal sinus. (2) Destructive inflammation in the inner table of the frontal bone. (3) Structural deficiency of the inner table at the usual site of the cerebral wall of the frontal sinus.

It was first thought that it was a result of the empyema, but the extent and symmetry, the well-defined and smooth edges of the bony defect made it difficult to reconcile these appearances with the ones usually due to erosion. In the latter case we ought to find softened, carious, irregular edges, or a cribriform appearance, such as was found more or less on the left side. Osteomyelitis of the bone itself was then considered because it was possible that a process originating in the bone would be more likely to result in a loss of substance of better defined limits than in destruction by erosion. But this condition, osteomyelitis, must be exceedingly rare. The speaker quoted three cases detailed in the literature as osteomyelitis, but which he concluded were called so on insufficient grounds, the symptoms, etc., pointing as well to empyema as to osteomyelitis. Moreover in his own case he was unable to make the primary symptoms agree with a beginning osteomyelitis, and he consequently thought that this was not to be considered. There remained then the structural defect. He was able to find but one case of such a malformation in the literature. This was an opening about the size of a lentil, the edges being sharp and thin in the orbital roof of the left side. The lining membrane of the frontal sinus was directly in contact with the dura.

In this case there was no disease present. This except for the empyema corresponds with the opening found in this case. Defects of the outer table leading to the orbit have been noted with comparative frequency, and it seems reasonable to believe that the causes responsible for the latter condition may sometimes affect the cerebral wall also. The speaker believed these are more common than suspected but have been overlooked.

This case also illustrates the fact that in double empyema one should not be satisfied with an opening into one cavity even though the cavities communicate. If an external opening had been made in this case into the right frontal sinus the condition found at autopsy would have been recognized during life.

Discussion.

In response to the question as to what he thought of the advisability of flushing out the sinuses after freely opening them in such cases Dr. Gibson said that theoretically it would seem usually to be good surgery, but that in case long continued pressure might have worn the inner bony plate of the sinus very thin, or where long-continued chronic inflammation had weakened its resisting ability to external force it was very necessary not to make the irrigation under any pressure. It seems clear also from the present case that there may exist certain congenital defects of the posterior bony plate of the frontal sinus especially which may make flushing of the sinus after and during the operation dangerous. This last danger can only be anticipated and avoided by making a good-sized external opening that will permit of free inspection of the field of operation and its immediate neighborhood.

Dr. Royal Whitman thought that in cases of persistent frontal sinusitis, such as this, operation is indicated even though it involves a certain amount of risk and would be accompanied by a certain amount of mortality. As is the case of chronic mastoiditis, a purulent focus in these cases continually exists close to the cranial cavity separated from the membranes of the brain only by a comparatively thin bony plate which the pressure of a purulent collection and chronic inflammation are continually making weaker. The indication is evidently to open it freely and allow it to drain, and if possible to remove all sources of infection in the diseased region.

In conclusion Dr. Gibson said that he does not think that the mortality of operations for frontal sinusitis need be large, but where anomalous conditions exist as in the present case the patient's chances of recovery are very much lessened after operative manipulation and especially irrigation unless the condition has been recognized and special precautions taken.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held February 15, 1899.

The President, William Stevens, M.D., in the Chair.

HAIR-PIN REMOVED FROM THE BLADDER.

Dr. S. H. Dessau: Some weeks ago a young woman was brought to me by her mother with the following history: Five years ago she suffered from some uterine trouble, for which a pessary was introduced. This she had been taught to remove for the purpose of cleansing it. Two months previous to being seen by me she had attempted to remove the pessary, as usual, but was unable to do so. Being of an ingenious turn of mind, she took a hair-pin, bent the blunt end of it, and tried to hook the pessary down. She failed to do this, but lost the hair-pin, which slipped out of her fingers and entered the uterus, as she supposed. She told no one of this, and soon after began to feel some discomfort, especially during micturition, and this increased to such an extent that the family physician was consulted. It is said that he made a thorough examination, and came to the conclusion that the girl was hysterical, and that there was nothing the matter with her. The symptoms became more aggravated, and she soon was unable to attend to her duties as buyer for a millinery store. Micturition was very frequent, and was accompanied by violent pains, and it was decided to seek further advice.

After hearing this history, I decided that the case was worth looking into, and sent her to my friend, Dr. Vineberg, who is skilled in the use of the cystoscope, to have her bladder examined, and he discovered the hair-pin lying transversely across the bladder, and removed it with considerable difficulty through the cystoscope. On the posterior wall of the bladder there were a couple of inflamed areas which he touched with nitrate of silver. The symptoms, of course, have since disappeared. In using the cystoscope, Dr. Vineberg employs the Kelly method of inflating the bladder with air while the patient is in the knee-and-elbow position. I imagine that it would be much easier to explore the bladder in this way than when it is filled with water, as in the Nitze method. The interesting feature of the case is that the patient before coming to me was under the care of two other physicians, one of whom made a vaginal examination, and yet neither suspected that the bladder was the cause of the symptoms.

Dr. A. M. Jacobus: I have met with several instances in which hysterical girls have introduced various articles, such as glass and hair-pains, into the vagina or bladder, and have operated for the latter condition. In another case which came under my observation the patient had introduced a hair-pin into the uterus in order to bring on an abortion. It was removed with great difficulty, as it had passed beyond the os internum, and the points were directed downward and were widely separated.

In regard to the indiscriminate use of the pessary, I recently saw a woman who was wearing a pessary which had been introduced by a physician while she was in Dresden last August, and had not been looked after subsequently. She complained of great pain, and had a bloody leucorrhea. Upon making an examination I found that the pessary, which was of the ordinary Smith pattern, had cut several grooves which were raw and bleeding on each side of the vagina. It was too wide and too long, and entirely unsuitable. The woman had a retroflexed uterus, firmly bound down by adhesions, and it was criminal to apply a pessary in such a condition. Pessaries are often used unnecessarily, particularly in single women, in whom they should never be used. At best, they are merely temporary makeshifts.

NEW METHOD OF OPERATION FOR CONVERGENT STRABISMUS.

Dr. Edward S. Peck: I wish to call the attention of the Society to a new method of operating upon squint-eyes which has been suggested by Professor Panas of Paris, whose operation for cataract is so much in vogue at the present time. I have employed this method with

success in the case of a boy, fourteen years of age, who had squinted for thirteen years. If my memory serves me right, Professor Sayre employed the same principle in treating contracted tendons, and the maneuver is so simple and easy that it seems to me worthy of mention. It consists merely of stretching the muscle by means of strabismus hooks before it is cut in order to overcome the dynamic contracture of the muscle. Dr. Roosa, who has operated in more than twenty cases by this method, recently called the attention of the New York State Medical Society to the procedure. Simple tenotomy is exceedingly unsatisfactory in many cases of strabismus—even in a young subject the result is doubtful, and often the operation has to be repeated again and again. I think the profession should know that success does not follow in fifty per cent. of the cases, and that something besides mere cutting of the muscle is necessary.

ANTITOXIN IN DIPHTHERIA.

DR. DESSAU: Last winter I reported a case in which I had successfully employed antitoxin in diphtheria, and this evening I desire to report another. There seem to be efforts made in the neighborhood of New York to cry down the use of antitoxin, and I think we should fight them. To-day I received a pamphlet consisting of an argument against this method of treatment in the shape of three papers which have appeared in the *Medical Record*. My experience with antitoxin has been most satisfactory. The last case in which I employed it was an especially bad one of pharyngeal and nasal diphtheria, seen on the third day of the disease. The dose employed was 2500 units, the largest I have ever given. The only other treatment employed was a 1-to-3000 solution of bichlorid of mercury, containing a little tartaric acid, and thorough irrigation of the nose with normal salt solution by means of a fountain-syringe. It was a tenement-house case, but the mother carried out this part of the treatment better than do most women of her class. Improvement was noticed at once. A second dose, which I had expected to give, was not required, and the child is now up and about. An immunizing dose of 750 units was given to a year-and-a-half-old baby in the same family with the result that it has escaped infection.

TWO CASES OF PERFORATIVE ULCER OF THE DUODENUM.

DR. JOHN F. ERDMANN: I have here two specimens of perforative ulcer of the duodenum which were removed within two or three days of each other. Operation was performed thirty-six hours after perforation in the first case, and twenty hours after in the second case. The result in both instances was unfortunate, neither patient surviving. Both were males, about thirty years of age, who had previously been healthy. Perforation took place in the first portion of the duodenum in each case. Abdominal distention was a marked symptom.

DR. CHARLES H. KNIGHT then read the paper of the evening, entitled

FOREIGN BODIES IN THE LARYNX. (See page 458.)

DISCUSSION.

DR. PECK: I was impressed with the closing paragraph of the paper in regard to partial section of the thyroid cartilage in which the author says that the section should be confined to the lower part of the cartilage, leaving intact the upper part where the vocal cords are attached. I was also impressed by the ingenuity which was employed in the removal of foreign bodies from the larynx. I have removed more neoplasms than foreign bodies, and in some of the cases it was necessary to make a very extensive section of the thyroid cartilage but I have never seen this followed by bad results.

DR. NEWMAN: Two instances of foreign body in the larynx which have come to my knowledge deserve mention. In the first the patient was taken to a drug-store and a passing physician was called in to attend her. Having no instruments with him he administered separately the two parts of a Seidlitz powder and the effervescence which was produced in the stomach caused vomiting and the expulsion of the foreign body from the larynx.

The second case was that of a little girl who had inhaled a sprig of a cedar tree about an inch and a quarter long. It could be felt in the larynx but was so firmly lodged that it could not be gotten out by the usual methods. It was finally removed by means of a pair of forceps. A very useful instrument for the removal of foreign bodies in the larynx is made of stiff bristles in the form of an umbrella which is introduced closed and then opened. Upon removing it the foreign body will usually be found on the upper surface of the bristles.

DR. BLAKE WHITE: A feature which has impressed me greatly is the remarkable degree of tolerance shown by the larynx for foreign bodies which have passed the epiglottic plane. Comparatively very little annoyance is caused after this point has been passed. The author has well illustrated this fact by narrating cases in which foreign bodies were detected only by the use of the laryngoscope. It is well known that oily solutions and even solutions of glycerin cause but little disturbance when injected into the bronchi. By way of emphasizing this point I recall an operation skilfully performed by Dr. S. H. Weeks of Portland, Maine, which I had the pleasure of witnessing. A boy of fifteen had inhaled a small tin-whistle which had traversed the trachea and become lodged at the bifurcation of the bronchi, where it was located by means of the X-ray. Tracheotomy was performed and several fruitless attempts made to remove it with forceps. Finally, by inverting the patient, the whistle was dislodged so that it was easily removed by long tracheal forceps. In another case a penny was expelled from the larynx of a child by the colored nurse seizing him by the feet and shaking him violently—a simple but effective method.

DR. DESSAU: I wish to emphasize the point referred to in the paper in regard to the frequency with which this accident occurs. The condition is often overlooked and the symptoms may be ascribed to croup. For example, a child was once brought to me with symptoms of croup. I examined the throat but found it normal. On the fol-

lowing day the condition was the same, but the mother mentioned the fact that before the onset of the throat-symptoms the child had been playing with a safety-pin, which had mysteriously disappeared. Upon introducing my finger into the child's throat I at once felt the point of the pin and was able to remove it without difficulty. Exploration of the larynx with the finger is of great value in these cases. I would like to ask the author if he considers it possible to employ the laryngoscope in young children, say from two to three years of age.

Dr. Frank Grauer: I once made an autopsy in a case in which death was produced by the presence of a foreign body in the air-passages. A young lad was playin Bryant Park when he suddenly dropped dead. The coronor gave a certificate giving heart failure as the cause of death. Later, however, it was decided to hold an autopsy, and it was then found that the boy had swallowed a collar-button, which had lodged in the lower part of the rima glottidis, completely closing it.

I know of another instance in which a German died suddenly in a Bowery restaurant. Autopsy showed a piece of frankfurter in the man's larynx. In still another case death was caused by sauerkraut getting into the air-passages. All these cases show that instances of sudden death should always be investigated.

Dr. Erdmann: I would like to ask Dr. Knight if he has ever heard of removing foreign bodies from the air-passages by means of suction. In discussing Rushmore's celebrated case, that of a man who inhaled a cork, Gersster referred to a method of removing foreign bodies by means of a rubber tube introduced into the larynx or bronchi and producing suction.

Dr. Knight, in closing: The great obstacle to the removal of a subglottic foreign body is spasm of the vocal bands.

In regard to suction, I have never seen any mention made of the method referred to by Dr. Erdmann. It might be feasible under certain circumstances. There is a case on record in which intubation was performed with the result that the foreign body was coughed up into the tube and removed with it.

With reference to the use of the laryngoscope in young children, I do not think it is possible to employ it satisfactorily in the majority of cases. Children are so intractable that a laryngoscopic examination should be made under anesthesia if it is to be of any service. The method of Kirstein is especially recommended for children. It is, however, very disagreeable and painful because the head is so much extended.

There seems to be a difference of opinion in regard to the inversion of children who have inhaled a foreign body. Some say that this should never be done without preliminary tracheotomy as there is danger of the foreign body becoming lodged in the rima glottidis and in this way completely shutting off the air. The majority of authorities are in favor of it, nevertheless, especially if the nature of the foreign body be known. I once saw a child who was almost moribund cough up a piece of coal as large as the tip of my finger after inversion and a good shaking.

I do not wish to claim originality in making partial section of the thyroid cartilage. I have seen this method described in some foreign medical journal. In cases of removal of neoplasms in children I am of the opinion that complete division of the thyroid should be avoided because of the difficulty in approximating the vocal bands when the wound is closed. When partial section is made we have a guide by which they may be accurately adjusted.

SCIENTIFIC JOTTINGS FROM TROPICAL COUNTRIES.

YELLOW-FEVER FOCI ON THE MEXICAN COAST—ANESTHESIA AT HIGH TEMPERATURES AND LOW BAROMETER—CALOMEL IN PNEUMONIA—THE YELLOW-FEVER BACILLUS AND MOLDS — PRESENT MORTALITY OF YELLOW FEVER.

In the *Boletin del Consejo Superior de Salubridad*, No. 5 (City of Mexico), Dr. Liceaga-who in July, 1898, in a communication to the Committee on Yellow Fever of the American Association of Public Health, declared that there were but two foci of yellow fever along the Mexican coast bathed by the waters of the Gulf of Mexico, these two foci being in the Canton of Vera Cruz and the districts situated to the north of the peninsula of Yucatan, now wishes to modify this declaration. At the time it was made the epidemic at Tampico and the cases at Campeche had not been studied sufficiently to make one sure that they had not been imported. It seems clear now, however, that the infection was not imported into these localities so that he does not feel in a position to state positively at how many points on the Mexican Gulf coast yellow fever may be endemic.

. . . . . .

The *Gaceta Central de Mexico*, tomo XXXV., No. 22, reports a discussion before the National Academy of Medicine, in which it was agreed by those who had been present at operations in Paris and in the Northern part of the United States, that much less chloroform or ether was required to produce anesthesia and the patients were gotten under the influence of the anesthetic sooner than in Mexico. Two factors were suggested as bringing about these differences, first, and most important, the low atmospheric pressure of the high tableland upon which Mexico is situated, and secondly, the higher average temperature of the Mexican climate, both these factors leading to a vaporization and waste of the anesthetic. [It would be interesting to know from those accustomed to anesthetize in very warm rooms and from our Southern medical men if they have noticed that climate makes a difference in the amount of the anesthetic required, and from the profession in Denver and places at correspondingly high altitudes if they have noted the influence of the low barometer in the same way.]

. . . . . .

In *El Monitor médico* of Lima, Peru, No. 248–9, Dr. C. M. Vivanco reports fifteen cases of pneumonia treated by small doses of calomel in which the results obtained, as regards comfort of the patient, lessening of fever, completeness and promptness of the crisis were so

satisfactory that he thinks some derivative of calomel in the circulation has a direct bactericidal action upon the pneumococcus.

. . . . . .

In a clinical lecture published in the same journal Sanarelli insists on the symbiotic relations between molds and his bacillus icteroides. In cultures the bacillus icteroides grows much more luxuriously in the presence of a mold and the radius of influence of the mold can be easily distinguished. In general Sanarelli thinks that it is in molds that the bacillus icteroides is sheltered during seasons of abeyance of the fever. This microbic saprophytism he considers very interesting and an exemplification of a biologic principle to which not sufficient attention has been called. It is this symbiosis or parasitism of the bacillus icteroides and molds that causes yellow fever to break out so often on shipboard where molds, because of the constant dampness are especially luxuriant. This fact explains also the affinity of yellow fever for river bottoms, for coasts, and for marshy or swampy, low-lying, moist neighborhoods generally.

. . . . . .

According to the *Revista Medica de S. Paolo* (Brazil, Portugese) the number of cases of yellow fever during the three months, June to September, in the Province of Santos (40,000 inhabitants) was 294. Of these 178 died, a mortality of 60.54 per cent. In the little watering-place of Guaruja where the sanitary conditions were considered reasonably good 18 cases occurred with 12 deaths. All but 7 of the cases were in foreigners, all of whom had been less than four years in the country and most of them only a few months. [An interesting comparison at once suggests itself between these statistics and the much-better results secured by the much-civilized army medical department in its experience with yellow fever during the late war.]

REVIEWS.

GLAUCOMA; ITS SYMPTOMS, VARIETIES, PATHOLOGY, AND TREATMENT. By ALEX. W. STERLING, M.D., C.M. (Edin.), D.P.H.(Lond.), Atlanta, Georgia. St. Louis: Jones H. Parker, 1898.

THIS wide and intricate subject is of the greatest interest to the ophthalmologist, whether it be from the theoretical standpoint of etiology, of the various hypotheses as to pathogenesis, or of the dynamic mechanism involved. The practical interest in the symptomatology and treatment of glaucoma, is, however, shared by many general practitioners, as the manifestations of this ocular affection may, at times, so closely resemble those of other diseases that their true origin is easily overlooked. The unfortunate result is that valuable time is wasted, or improper remedies applied. Not infrequently vision has been irreparably damaged before the real nature of the case was recognized.

As the author pertinently remarks: "This is a condition of matters which every ophthalmic surgeon of any experience has had frequently to deplore for a tentative diagnosis is usually easy without an ophthalmoscope, and all that is wanted is that the practitioner bear in mind, firstly, that there *is* such a disease as glaucoma, whose symptoms may much resemble rheumatism and neuralgia of the head and face, including the teeth and ear, sick headache, as well as some common forms of inflammation of the eyes, and that it is sometimes attended by fever and vomiting; secondly, that atropine *is not* a panacea for every ocular ill, but on the contrary is harmful in many, especially in glaucoma, and should never be used except with full understanding of its action in the disease for which it is employed, and thirdly, that he make himself acquainted with the resistance or "tension" of normal eyes when palpated as for an abscess, and remember that in glaucoma this tension is greater than normal."

The volume, whose contents were put together in great part in connection with a course of lectures to post-graduate students, is a monument of industrious research and of critical study which presents, in a concise and logical manner, the manifold data of the subject of glaucoma, the history of its investigation, and the practical management of the disease. Dr. Sterling's discussion of the various etiological theories is especially valuable, the basis of arrangement being clear and scientific. It is to be regretted that this important contribution to ophthalmology should be handicapped by inferior press work, and by indistinct half-tone reproductions of microphotographs. Many of the illustrations are practically unintelligible. The bibliography is unusually complete and well arranged, although a number of errors may be found in the list.

RADIOSCOPIE ET RADIOGRAPHIE CLINIQUES. Par le DR. L. R. REGNIER, Chef du Laboratoire d' électrothérapie et de radiographie de l'hôpital de la Charité. Paris: J. B. Baillière et Fils, 1899.

THIS little manual gives, in a succinct and interesting review, the history of experimentation with static electricity *in vacuo*, and of the successive steps by which the nature of the cathodal rays, and later that of the X-rays of Röntgen, was determined. Succeeding chapters are devoted to the means of producing these rays by the Holtz machine, or by induction-coils, the preparation of photographic plates and the fluoroscopic screen. The application of these methods to special uses of surgery and medicine is fully discussed, the subject of fractures and dislocations, foreign bodies, osseous disease, and skeletal deformity being considered at length. The work just misses being extremely valuable. The illustrations of apparatus are good, but the mechanism employed is much more complicated than need be. There are a number of radiographs, reproduced by the half-tone process, which are so indistinct as to be practically useless for purposes of demonstration. This is the more remarkable when we consider the exceedingly fine results obtained of late in this field, and the sharp pictures in recent English and American publications. The practical managment of X-ray apparatus is well presented, but the author seems to have overlooked all but French bibliography. This appears most noticeably in the chapters on foreign bodies in the cranial cavity, and on ophthalmic

radiography. Here the complicated procedures of Morize and of Contremoulins are described at length, only to conclude with an admission that the results obtained with them are neither exact nor conclusive. No mention is made of the excellent practical results obtained with much simpler methods by Williams of Boston, Clark, Hansell, De Schweintz, and Fridenberg, while the suggestion of the last-named writer to produce combination views, especially in cases of intra-ocular foreign body, by profile and "en face" radiography is credited to no one in particular, and vitiated by a number of unpractical recommendations. It may be stated, in conclusion, that nowhere in this book do we find a definition of the X-ray, or any description of its physical characteristics, form of vibration, or mode of action, which might assist our understanding of the subject.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Cloth, 490 pages, 28 illustrations, and 3 colored plates. Philadelphia and New York: Lea Brothers & Co., 1899.

This new quarterly makes undoubtedly the best, completest, and most authoritive review of advances in scientific medical literature with special reference to its practical applications that has yet been made. The editor is to be congratulated on the set of contributors secured, the contributors on their thorough, painstaking work, and the publishers on the excellent combined result that editor's, contributors', and publishers' efforts have reached.

It seems almost invidious to pick out special parts for commendation from amidst the general excellence and we mention only some of the striking discussions of practical subjects. Dr. J. Chalmers Da Costa in the section of surgery of the head, neck, and chest gives thoroughly up-to-date reviews of the practical aspect of such questions as harelip, operations for brain-tumor, and for epilepsy. The possibility of successful suture of wounds of the heart is brought out and operative technic as gathered from successful operators in heart-surgery discussed. A very encouraging conclusion as to the expectancy of life after operation for mammary cancer is drawn from the collation of current statistics, and this very satisfying phase of the new surgery properly emphasized. The surgical treatment of idiocy is discouraged on clinical grounds and the utter uselessness of craniectomy except in extremely rare cases made clear from the best surgical experience in the matter.

Dr. Clackader of Montreal, in children's diseases collects some very practical points on two subjects that will be of special interest now that the warm weather is approaching, infant feeding and the treatment of diarrheas in children. Recent analyses have modified somewhat our ideas as to the constancy in composition of mother's milk and have suggested a doubt as to lactose being the only form of sugar present in the milk. Gärtner's modification of milk "*fett milch*," as the Germans call it, is given the place in the review that the popularity it has achieved in Germany and Austria entitles it to. In the diarrheas of infancy he says: "Recent writers agree that opium should be avoided at the outset of all forms of bacterial infection until the stomach and bowels have been thoroughly emptied by purgatives and lavage. It may then be employed *in small doses only* to relieve colicky pain and secure moderate rest. It is distinctly contraindicated where pain is not severe and where the evacuations are foul-smelling and ill digested and are not watery or very frequent."

Dr. Hektoen of Chicago in the pages devoted to pathology has a very interesting review of the burning questions on which so much work is being done in recent years. The present status of pathological theories with regard to inflammation is especially clear, concise, and complete in its brevity. The fifteen pages devoted to tumors show how much is being done on this subject, sometimes considered the most definitely settled chapter of pathology. There is an excellent colored plate of the streptothrix homini, the branching micro-organisms described recently by Flexner and certain German observers as pathogenic to man. There is a very striking illustration in colors, from Craig, of branching forms of the tubercle bacillus as found in the sputum and some suggestive material in the text as to the important question whether all of these branching micro-organisms have certain natural affinities that should make us conclude that in the microbic causes of the infectious granulomata we are dealing with a family of micro organisms rather than distinct species.

In the chapter on the infectious fevers Thayer has a most valuable review of the latest practical conclusions as to the treatment of typhoid fever, especially as to the limitations of the bath treatment. Children, the old, the feeble, and those whose fever causes no symptoms are questionable subjects for regular tub treatment unless there are special indications. Under malaria there is an excellent review of the use of quinin in malaria with no halting half-hearted commendation of its free administration whenever there are unmistakable symptoms of active malaria no matter what complications may be present. There is a very judicious discussion of the significance and treatment of such complications as malarial hemoglobinuria and malarial nephritis, and a good review of the recent work on the estivo-autumnal type of malaria which has of late acquired so much practical interest for Americans.

The Sexual Instinct; Its Uses and Dangers as Affecting Heredity and Morals. Essentials to the welfare of the individual and the future of the race. By James Foster Scott, B.A. (Yale), M.D., C.M. (Edinburgh). Late Obstetrician to Columbia Hospital for Women and Lying-in Asylum, Washington, D. C. New York: E. B. Treat & Co., 1899.

The preface of this book begins with the quotation from Descartes, "If it is possible to perfect mankind the means of doing so will be found in the medical sciences."

With an aim as high as is thus implied it is needless to say that the author is thoroughly justified in treating perfectly plainly a set of subjects that are unfortunately too much tabooed and as a consequence too little understood in our day. The book, intended, as the author says, primarily for laymen, not for women and boys, contains a good deal of plain talk, which, however, we cannot but think will be always wholesome in its effect.

Some of the chapters, as "Woman and the Unmanliness of Degrading Her," "Prostitution and the Influences That Lead to It," and "Criminal Abortion," form excellent practical résumés of elusively detailed subjects not easy of condensed treatment.

We are inclined to think that the tendency to preach in the book is a little too pronounced. The facts of the matter are so striking that we consider their simple presentation more forcible than any rhetorical argument and additions of this kind weaken the effect by their apparent approach to special pleading.

ACROMEGALY. An essay to which was awarded the Boylston prize of Harvard University, for the year 1898. By GUY HINSDALE, A.M., M.D. Reprinted from *Medicine*, Detroit, 1898.

SINCE Collins' critical digest of the literature of acromegaly appeared in 1893, no work of any considerable size on this most interesting condition has been published in English, although both the home and foreign literature has been very rich in reprints of cases and in studies of the disease; hence Hinsdale s work is particularly acceptable. It reviews, in a very thorough manner, all the literature on the subject which had been given out up to the date of its publication. The style in which the paper is written is especially commendable, and the arrangement and indexing is logical and convenient. The illustrations are chosen with discrimination and are fairly well reproduced: unfortunately, however, the plates give but few instances of the microscopic pathology of the disease. The greater number of the plates have been previously published and are now thoroughly familiar to those conversant with the literature of the disease. No new cases are reported, but the author includes an excellent study of the skeleton of a giant, probably an acromegalic.

While Hinsdale has very carefully reviewed the literature of acromegaly, he has presented but very little original material and no doubt the weakest points of the paper are the discussions of the etiology and pathogenesis of the malady. Nothing new or encouraging in the treatment of acromegaly is advanced. The long and complete bibliography which closes the paper will be found of great service to those who desire to become thoroughly familiar with the disease.

A PRACTICAL HANDBOOK ON THE MUSCULAR ANOMALIES OF THE EYE By HOWARD F. HANSELL, A. M., M.D., Clinical Professor of Ophthalmology in the Jefferson Medical College; Professor of Diseases of the Eye in the Philadelphia Polyclinic, and WENDELL REBER, M.D., Instructor in Ophthalmology in the Philadelphia Polyclinic. Philadelphia: P. Blakiston's, Son & Co., 1899.

THE subject-matter of this little treatise is an elaboration of a short series of lectures delivered in successive winter courses at the Philadelphia Polyclinic, and designed to present to beginners in ophthalmic work the principal facts in the diagnosis and treatment of abnormal states of the eye-muscles. An introductory chapter presents concisely yet fully the important facts necessary to thorough understanding of the structure and innervation of the ocular muscles, their relations to the orbit and to the globe, and their dynamics. This is followed by a consideration of structural anomalies and of the functional derangements, the numerous "phorias" and "tropias." The functional tests for these conditions are described with the aid of numerous illustrations in the text.

Concluding chapters deal with the operations of tenotomy and advancement in a rather superficial way; the mechanical principles involved, their bearing on muscular dynamics, and the question of "dosage," of the operative effect, are practically neglected. In the after-treatment of tenotomies the use of a conjunctival suture is said to be "an unnecessary precaution for a skilful operator," and "a bandage is seldom useful; on the contrary, it may be positively harmful, in that, in the exclusion of binocular fixation, the important factor to success, namely, the unconscious effort at fusion, is prohibited." These statements will hardly go unchallenged. While following quite closely the classification and views of Stevens in regard to functional deviations, the authors vigorously reject his claims and those of Ranney as to the causation of reflex neurosis by muscular anomaly.

It may be well to repeat that "such cases are exceptional in even the largest experience, and the theory that a considerable proportion of the insane, of the epileptic, of the choreic, owe their disease wholly to the existence of either a refractive error or a consequent muscular anomaly is dangerous and unsound."

THERAPEUTIC HINTS.

For Eczema of the External Auditory Canal.—Clean the ear, not with soap and water or other fluids which are generally deleterious, but with the ointment given below, using cotton on an applicator. Then apply the same ointment freely to the walls of the canal. Attention to the general health is of course indicated.

℞ Ac. carbolici . . . . gr. xx
Ung. zinci oxidi . . . . ℥ i.

M. Sig. External use.

For Acute Nephritis During Mumps. — Irrigate the colon with hot saline solution to induce activity of the kidneys and give the following medicine by mouth:

℞ Hydrarg. bichlor. . . . gr. i–iii
Potassii iodi . . . . gr. xx
Syr. simpl. . . . . ℥ i
Inf. gentianæ . . . . ℥ vii.

M. Sig. One teaspoonful three times a day.—*Kerley.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIV. NEW YORK, SATURDAY, APRIL 22, 1899. NO. 16.

ORIGINAL ARTICLES.

CHRONIC NEPHRITIS AFFECTING A MOVABLE KIDNEY AS AN INDICATION FOR NEPHROPEXY.

BY GEORGE M. EDEBOHLS, M.D.,
OF NEW YORK;
PROFESSOR OF DISEASES OF WOMEN IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; GYNECOLOGIST TO ST. FRANCIS HOSPITAL.

THE voluminous literature of movable kidney is practically silent upon the subject matter indicated in the title of this paper. The few and scattered words devoted to the matter serve simply to give expression to the sentiment that in the presence of chronic nephritis nephropexy for movable kidney is to be avoided in common with all other operations not called for as a vital indication. In quite an extensive search of the literature I have been unable to find the record of a single case of nephropexy for movable kidney performed upon a patient suffering at the time of operation from either acute or chronic nephritis.

While recently reviewing the clinical records of 154 nephropexies performed by myself upon 118 patients during the past nine years, with a view to ascertaining the final results, I found that I had anchored the kidney or kidneys of six patients, who, at the time of operation and for a greater or less period preceding were known to have had chronic nephritis. In view of the paucity, or rather non-existence of similar records, I may be pardoned a little prolixity. I will premise by stating, and wish to emphasize the point, that in none of the five first cases was the nephropexy undertaken with any idea of favorably influencing the chronic nephritis known to exist; the indication for operation was given simply by the existence, in an aggravated degree, of the usual symptoms due to *mobility* of the kidney or kidneys. The effects of the nephropexy upon the chronic renal inflammation, whatever they might prove to be, were simply hazarded in view of the necessity of relieving the patient of a number of intolerable symptoms. The fortunate effects in three of these five cases influenced me to regard the chronic nephritis of the sixth as a new indication, additional to other well recognized and admitted existing indications, of nephropexy for movable kidney. I have recently seen two further cases of chronic nephritis associated with movable kidney, and have advised nephropexy in the hope of favorably influencing the kidney inflammation; both patients are having operation under consideration.

CASE I.—Miss A. B., eighteen years of age, came under my care in November, 1891, suffering from chronic metritis and anteflexion, for which curettage and amputation of the cervix were performed in December, 1891. Cysts of both ovaries subsequently developed and grew to a considerable size during the first half of 1892. On June 28, 1892, I performed bilateral ovariotomy and ventral fixation of the uterus. Examination of urine preceding these operations showed diffuse chronic nephritis. Soon after the removal of the ovarian tumors the right kidney became movable, producing serious derangement of health, the chronic nephritis at the same time persisting. Right nephropexy was performed on November 29, 1892. At operation the structural changes in the right kidney due to chronic inflammation were plainly recognizable. Primary union. Two months after nephropexy the albumin and casts disappeared permanently from the urine. The left kidney subsequently became movable but, causing no symptoms, did not and does not to this day call for nephropexy. The patient has now been under constant observation for a period of more than six years, during all of which time she has enjoyed perfect health. The right kidney remains securely anchored and the urine free from albumin and casts.

CASE II.—Mrs. G. H., aged thirty-nine years, came under my care in March, 1893. The conditions recorded as found on examination were: Right kidney movable 12 cm.; left kidney movable 10 cm.; endometritis; salpingo oophoritis sinistra; nephritis diffusa chronica; hysteria. Bilateral nephropexy, March 10, 1893. My records do not contain any note of the appearance and feel of the kidneys at operation. The wilful and unmanageable patient repeatedly sat up in bed and removed the dressings during the first days following operation with resultant infection of both wounds, necessitating healing by granulation The nephritis still persisted on her discharge from hospital six weeks after operation. A year and a half after operation I learned from Dr. Ernest Palmer of Brooklyn that the right kidney was again movable, the left remaining firmly anchored. No information as to the presence or absence of nephritis.

CASE III.—Mrs. M. M., aged twenty-eight years, was seen by me in consultation with her physician, Dr. R. G. Wiener, in May, 1893. She had a movable large right kidney, chronic interstitial nephritis, endometritis, and bilateral salpingo-oophoritis. The nephritis to Dr. Wiener's personal knowledge was of

several years' standing. The symptoms due to the mobility of the right kidney were so urgent that both Dr. Wiener and his patient, the latter also with a full knowledge of her nephritis, desired nephropexy. The operation was performed at the home of the patient, with the kind assistance of Dr. Wiener, on May 11, 1893. The kidney was found extensively diseased, its surface being nodular and the capsule irregularly thickened and very adherent as a result of inflammatory changes. On the posterior aspect of the kidney, near its lower pole, squarely in the center of that portion of the kidney we depended upon for adhesion to the lumbar incision, a cyst nearly four centimeters in diameter was encountered. The contents of the cyst, a turbid serum, were evacuated by incision through the kidney substance, the wound of the kidney being closed by running catgut suture. The kidney was then anchored in the usual way.

The wound healed by primary union throughout. Dr. Wiener informs me that all the symptoms due to the movable kidney disappeared for a period of eight to ten months when the kidney again became as movable as ever with a return of all her former symptoms. The nephritis remains uninfluenced for better or for worse.

Case IV.—Miss L. G., aged twenty-five years, was referred to me by Dr. B. R. Morrow in January, 1896. She presented movable right and left kidneys causing symptoms, chronic appendicitis, bilateral oophoritis, and chronic nephritis, although the duration of the latter could not be ascertained. Bilateral nephropexy, January 11, 1896, on which occasion the left kidney was found to be the seat of chronic interstitial nephritis, the right kidney being healthy. Primary union of both wounds. A pain persisting after operation in the region of the left kidney disappeared after inversion of the vermiform appendix and breaking up of ovarian adhesions on May 31, 1898. Both albumin and casts permanently disappeared from the urine some four months after bilateral nephropexy. It is now two years since operation and the patient remains well and free from nephritis. Both kidneys securely anchored.

Case V.—Mrs. M. F., aged forty-two years, came under my care in April, 1897, with movable right kidney, chronic metritis, chronic pelviperitonitis, chronic appendicitis, and chronic interstitial nephritis. She had previously had several operations for pelvic abscess by various operators. The symptoms due to *mobility* of the right kidney were so distressing as to lead me to advise nephropexy in spite of the fact that she was known to have had chronic nephritis for six years past and had been under treatment for that condition constantly during all that time. On April 1, 1897, at the home of the patient, I performed curettage of the uterus, amputation of the cervix, and right nephropexy, the kidney at operation being found the seat of chronic interstitial nephritis. Primary union, uneventful convalescence, and marked and progressive improvement of general health followed operation.

Oft-repeated careful chemical and microscopical examinations of the urine were made before and after operation by Professor H. T. Brooks, who, one year after operation, pronounced the nephritis as practically cured. During this year she received absolutely no treatment for the nephritis, so the gratifying result may fairly be ascribed solely to the operation. The patient remains well with well-anchored right kidney and with urine free from albumin and casts at the present writing, nearly two years after operation.

Case VI.—Miss S. O., aged twenty years, came under observation in January, 1898, suffering from mobility of both kidneys, endometritis, and interstitial nephritis. The duration of the latter could not be ascertained. In view of the favorable results obtained in the cases already cited bilateral nephropexy was advised, both to relieve the symptoms due to mobility of the kidney, and with the hope of favorably influencing the nephritis. Both kidneys were anchored and the uterus curetted, January 10, 1898.

At operation the right kidney was found perfectly healthy. The left kidney on the other hand was large, irregular in shape, hard from increase of connective tissue, and with firmly adherent capsule proper; in short it presented the changes characteristic of chronic interstitial nephritis. Primary union of both wounds, uneventful convalescence, and rapid disappearance of every former symptom. Frequent examinations of the urine were made by Professor H. T. Brooks and by Dr. A. Strong, who kindly assumed the treatment of patient after operation. Albumin and casts disappeared permanently from the urine one month after operation. One year after operation patient perfectly well, both kidneys securely anchored and urine free from albumin and casts.

The fact that stands out strikingly in the above record of clinical experience is the disappearance of all symptoms and signs of chronic nephritis in four out of six patients after and, in all human probability, as a consequence of nephropexy. For, be it recalled, none of the patients subsequently to nephropexy received any treatment whatsoever directed to the nephritis. In one patient with extensive interstitial and cystic changes in the anchored kidney the latter became detached eight to ten months after operation and the nephritis persists. The redetachment of the kidney in this case was probably due to the advanced cystic degeneration. One patient finally has been lost track of after bilateral nephropexy and nothing is known respecting the continuance of her nephritis except that it still persisted six weeks after operation.

An important clinical fact indicated by the four successful cases is that chronic nephritis is probably unilateral much oftener than is usually suspected. In two of the four cases all the symptoms and signs of chronic nephritis disappeared after fixation of a

movable right kidney proved at operation to be the seat of chronic interstitial changes. The left kidney in these cases must have been healthy, otherwise the urine would have continued to furnish albumin and casts even after convalescence of the right kidney. In each of the other two patients upon whom bilateral nephropexy was performed the nephritis was found unilateral, affecting the right kidney in one and the left in the other. In all of these four cases the chronic nephritis was unilateral, *i.e.*, it affected only one organ, a fact pregnant with hope and comfort to sufferers from chronic nephritis.

Judging from the evidence afforded by frequent examinations of the urine the chronic nephritis in each of the four cases disappeared in two months, four months, one year, and one month respectively after nephropexy. The fact of the disappearance of chronic nephritis without further treatment after nephropexy amounts to almost proof positive that the displacement of the kidney was the original cause of the nephritis. My own not inconsiderable experience with movable kidney has furnished numerous examples of congestion of the kidney, as evidenced by traces of albumin and hyalin casts in the urine accompanying this condition. This congestion of the kidney, due to displacement with consequent distortion and greater or less obstruction of the renal vessels, and especially of the renal vein, is as good as uniformly relieved by a successful nephropexy. If displacement of the kidney gives rise to congestion why may not he latter condition occasionally progress to inflammation? And if nephropexy of a movable kidney will do away with renal congestion why may not the beneficial effects of the operation, occasionally at least, assert themselves even when the circulatory disturbances have already progressed so far and been so long maintained as to result in the changes characteristic of chronic nephritis?

That a well-anchored kidney is in a better position and condition to maintain or regain its organic integrity, as the case may be, than a movable kidney, is patent from the evidence already adduced. An added proof is afforded by the investigations of Wolff into the subsequent histories of fourteen cases of nephropexy performed by E. Rose, and corroborated by my own observations upon a much larger number of patients upon whom I have performed nephropexy, unilateral or bilateral. In not one of Rose's cases and in none of my own, except the cases of chronic nephritis existing at operation detailed in this paper, could any evidences of renal changes as evidenced by the presence of albumin or casts in the urine be found at the last examination, made from six months to fourteen years after operation.

The various experiences and observations recorded in this paper, will, if corroborated in larger numbers, necessitate a modification of current opinions on the etiology of chronic nephritis. Mobility of the kidney will probably be found as playing a *very* important part in the causation of chronic nephritis. Just as probably the therapy of chronic nephritis, in so far as the latter be found to be dependent upon and connected with movable kidney, will become surgical. My own favorable experience warrants me for the present in regarding chronic nephritis affecting a movable kidney as an important indication for nephropexy.

THE GALVANOCAUSTIC RADICAL TREATMENT OF HYPERTROPHY OF THE PROSTATE.

By F. KREISSL, M.D.,
of Chicago, Ill.;
Professor of Genito-Urinary Surgery in the Chicago Clinical School.

Bottini's method and Freudenberg's modifications of the galvanocaustic incision have, judging from the increasing favorable reports, apparently solved the problem of successfully dealing with the so-called senile enlargement of the prostate, a problem which has worried surgeons for more than a century, which has led to the most heroic and yet not satisfactory measures, and which has produced the strangest, most fantastic, and yet most useless apparatus without giving the sufferer only the slightest and often but temporary relief. It is not the premature enthusiasm closely following upon one successful operation which dictates these words, nor is it the outgrowth of a mere theoretical speculation reached by a consideration of the instrument and a description of its use in this connection. The following opinion is formed from the results of my own experience, together with the reports of competent men, and by a comparison of Bottini's method with other well-known procedures having a similar purpose

Bottini's method is not of very recent date. He described it, and reported cases in *Langenbeck's Archiv* in 1877, but at that time there were mechanical reasons, such as poor galvanocaustic batteries, etc., that prevented the construction of a more perfect instrument. Several fatal cases, some independent of the operation, and perhaps also the disinclination of the German and French surgeons to adopt or even try a foreign discovery, helped to shelve the method before it was given a chance to show its merits. Moreover, Guyon's theory of the etiology of the hypertrophy of the prostate predominated in Europe, and could not be reconciled with Bottini's method of a cure by means of a division

of the prostate lobes. It is impossible, indeed, to understand how and why such a division should remove arteriosclerosis in the gland and the bladder wall, which, according to Guyon, is the supposed cause of obstruction and retention in prostatitics. Even so liberal-minded a surgeon as Sir Henry Thompson, always ready to accept new and promising methods regardless where they come from, said under the strong influence of Guyon's theory some fifteen years ago: "There is no reason to believe that an incision or resection in cases of ordinary hypertrophy of the prostate can restitute somebody's functions of voluntary urination after it has once been lost. On the other hand, we must consider such attempts as extremely dangerous when a considerable enlargement of the gland exists, and it is highly improbable that any operation, even if it remove the obstruction, can restitute the normal function of the bladder and free the patient from catheter life. And I undertake to say that my friend Professor Bottini in Pavia, on whom I but recently called, is of my opinion, no matter how strong a defender of the galvanocaustic incision he may be. To be sure, patients were operated upon for retention caused by temporary though chronic local disturbances, and the results announced as successful operations of hypertrophy of the prostate, but the age of the patients in several instances is sufficient proof to contradict the statement, because they had not reached that age in which hypertrophy in the gland appears."

I do not know if Sir Henry Thompson has changed his views on this subject since he wrote these words. I do not know if he still believes with Sir Henry Brodie that "the prostate grows when the hair turns gray and starts coming out," but I do know that prostatic enlargement and urine retention cannot be considered a disease peculiar to old men only, although I admit that it may be found much more frequently past Thompson's age-limit of fifty-six years than before. I have met these symptoms time and again in patients at the beginning of the fortieth year, and in cases in which the most thorough examination did not allow of another diagnosis than hypertrophy of the prostate. In these cases there was no evidence of sclerosis, which is held as responsible and cited against any attempt at surgical interference.

In consideration of these facts and the results of Bottini's operation, and without prejudice from deep-rooted theories, one cannot help but agree that galvanocaustic incision is apparently the operation likely to relieve radically, and perhaps permanently, the most distressing symptoms of prostatic enlargement, sclerosis or no sclerosis. Naturally we will find in advanced age an enlarged gland quite often accompanied by sclerosis. Through the cystoscope we see the enlarged blood-vessels in the bladder wall, and on the prostate we often encounter hemorrhages, the blood flowing back into the viscus, clots in the vesical neck acting as obstructions. But this condition cannot be recognized as the cause of all the symptoms in prostatics. I have seen such cases, and could not find a drop of residual urine after the act of micturition, and yet the calls to urinate come as often and are as urgent as in true prostatic obstruction associated with retention. But this frequent micturition is caused by the sclerotic and enlarged vessels, similar to those which we see in the female bladder and urethra, where we simply pronounce them to be hemorrhoids.

It cannot be the purpose of this paper to discuss the etiology or pathology of the hypertrophy of the prostate, but I consider it important to dwell on this subject because it is necessary to point out why resection and excision do not always give satisfactory results, while Bottini's operation is gaining ground daily. A partially or totally enlarged prostate does not necessarily cause retention, nor does retention constitute the pathologic picture of hypertrophy or sclerosis. But enlargement of the gland, residual urine, and in most cases elongation of the posterior urethra are significant factors, provided other diseases are excluded or exist as accessory only. The obstruction must be regarded as the primary cause of all the symptoms, and it is but reasonable to consider its removal in a way which does not destroy the functions of the sphincter apparatus. But Bottini's operation is a typical one, which requires a correct diagnosis and also a close acquaintance with the use of instruments in the bladder and urethra, without which failures and even disagreeable or fatal complications are unavoidable. It is not sufficient to establish the fact of an existing obstruction and to incise the prostate desultorily, and it is not less erroneous to act according to a set rule, incising the median lobe, one lateral lobe, and the anterior surface of the gland. In case of enlargement we must determine its character. True, the hypertrophied prostate is voluminous, but many large prostates are not hypertrophied. One should not confuse hypertrophy, which is a disease, with prostatomegaly, which is only a symptom accompanying prostatic edema, congestion in old people, and hypersecretion with glandular stagnation. Prostatomegaly will also be found in chronic prostatitis and tumors of the gland, but with the exception of the last condition mentioned it hardly requires surgical interference. We have to determine if this enlargement is a general and uniform one, or if

only parts of the gland are involved, and which parts, and if the projecting nodules are confined to the prostatic urethra or to the viscus, or to both. We have to search for strictures in the urethra, diverticula, concrements, and tumors in the bladder cavum and chronic inflammatory conditions outside of, but close to the bladder-wall. The presence of residual urine and its amount on various occasions has to be investigated, and remote causes of retention, like paresis and paralysis of the bladder excluded. All these conditions can be revealed or excluded by an exhaustive examination, including palpation, the use of probe-pointed bougies, and whenever the local configuration permits, by the urethro- and cystoscopes. From the latter I have gained most valuable information regarding the size and location of projections into the viscus, and the unmistakable direction at which point the incision will have to strike. Another point of importance is the establishment of the elongation of the posterior urethra, which, with very few exceptions, will be the case in prostatitics, and, for instance, will help avoiding mistakes in diagnosticating hypertrophy of a normal gland, which does not show a demarcating upper margin on account of a concentric hypertrophied bladder.

The technic of the operation may be described in a few words. It is performed without chloroform, cocain only being applied as a local anesthetic. The bladder is emptied by a catheter before the introduction of the incisor, which should be tested previously in regard to the temperature necessary to produce a slight degree of white heat in the blade. This amount is registered by the amperemeter, and can be kept up while the blade is beyond the control of the eye. After having introduced the instrument very much like an ordinary steel sound, so far that the beak is well in the bladder, one turns it to the lobe which it is wished to incise, and at the same time brings the cooling apparatus into action. This done, it is necessary to pull the instrument downward until the point of the beak is well hooked to the upper margin of the gland, and to close the current. From ten to fifteen seconds are allowed to pass, which time is necessary to heat the blade up to the temperature desired, and then the incision is made by slowly turning the screw to the right. This, as one will see, on the downward motion of the outer piston, brings the blade out of the protecting groove and into the gland. The graduated scale on the piston allows an exact estimate to be made of the length of the incision. Having obtained this, one must reverse the direction of the screw until satisfied that the blade is back again in the groove, then interrupt the current, and remove the instrument. If more than one incision is desired the instrument may be turned toward the lobe it is wished to incise, and the procedure repeated in exactly the same way devised for the first incision. The operation requires from two to five minutes, after which there is very little, if any, complaint on the part of the patient—a slight burning sensation during micturition, and slightly bloody urine during the first twenty-four or forty-eight hours. In two cases I have satisfactorily employed a ten-per-cent. antipyrin solution instead of cocain as a local anesthetic, because at the preceding cystoscopic inspection I found ulcers in the trigonum, in which event I consider cocain absorption very likely. In a passing way I wish to say that the application of antipyrin as a local anesthetic in the bladder and urethra is not of recent date. It was used in Vienna, Paris, and Budapest for litholapaxy and internal urethrotomy some years ago.

I do not consider it of paramount importance to fill the bladder with a small amount of fluid before the operation, as advised by Freudenberg and Viertel. It only makes the use of much more powerful and voluminous batteries necessary. A slight degree of white heat will be sufficient for operating when the bladder is empty, but when the bladder is filled with water the platinum burner requires much more heat to work effectively than ordinary portable batteries can produce. The danger of perforating the empty bladder by hooking a transverse vesical fold with the point of the instrument, as happened to Freudenberg, seems very remote, and was, perhaps, caused by working too high up in the viscus. If one thinks it safer to operate while the bladder is distended, he may follow the advice of Lewis and inflate the viscus with air, which does not interfere with the platinum burner, and, it is claimed, renders the operation absolutely painless. Thompson's objection that working in the dark with a cautery-knife is rather dangerous cannot stand the test better than the same scruples entertained in connection with litholapaxy or curetting the uterus. It is more a question of skill and experience than anything else, as an ordinary pin might become a deadly weapon in a clumsy hand.

No uniform rule for the after-treatment can be given. Some operators counsel the use of the retention catheter, some advise daily catheterization with or without irrigation, and others leave the bladder altogether alone. I should say all this depends on what the moment requires. I do not favor daily and repeated catheterization, which certainly interferes with the normal healing process and causes profuse hemorrhages. When considerable retention after the incision exists a catheter

should be left in the urethra for a while, establishing free drainage of the bladder. In cases in which the urine contains micro-organisms, urotropin in small doses will give much satisfaction until the surgeon can, without danger of hemorrhage, start with local treatment for lesions in the bladder.

The efficiency of the Bottini treatment may be partly explained by the fact that the actual cautery in all organs and tumors supplied with very much connective tissue displays not only a limited, but also a remote effect, or, in short, every cauterized spot forms a shrinking center for the surrounding tissues. The cautery, therefore, will reconstruct the normal caliber of the prostatic urethra, while in cases in which the projections form a bar between the urethra and the trigonum pit or bas-fond, it will bring the bottom of the latter to the level of the vesical outlet into the urethra, or, so to speak, artificially extend the urethra into the pit. In by far the majority of cases the operation will have to answer both purposes. The bar is mostly built up by the median lobe while the projections narrowing the prostatic urethra originate in the lateral lobes, and from this we will understand that the incisions will have to be made according to the location of the obstruction, and not in every case in "the same three spots." I cannot too strongly advise against the incision of the anterior part of the prostate, which is not only painful and useless, but directly dangerous. It is just the place where we have to expect the most profuse hemorrhages from the paraprostatic venous plexus, and, moreover, this part of the gland, as we all know, never plays any active part in the obstruction.

In concluding I wish to report five cases in which I have successfully operated, stating that the patients presented unmistakable subjective and objective symptoms of prostatic hypertrophy.

CASE I.—Patient fifty-six years old. Uniform enlargement of the prostate; length of urethra from meatus to the viscus 10½ inches; length of posterior urethra 4¾ inches. Stricture in membranous urethra of the size 16 of the French scale. Urinated with great pain about every fifteen minutes, from ten drops to half an ounce at a time. Residual urine from ten to twelve ounces. First symptoms about seven years ago, gradually getting worse. Electrolytic treatment of stricture in January, 1898; afterward 26 French steel sound could be passed into the bladder and calls to urinate came only every two or three hours in the daytime, while tenesmus during the night remained as bad as before

Bottini's operation in April, 1898; three incisions, one into each lobe, three centimeters in length. Six weeks after the operation patient was presented before the Chicago Medical Society. At that time the length of the posterior urethra was 2¾ inches; patient could hold his urine for six hours during the day and urinated once during the night. Urination free, in full streams; passed eight to ten ounces; residual urine one-quarter to one-half an ounce. Saw patient five months after operation; had no residual urine and felt perfectly well.

CASE II.—Patient fifty-two years old; almost identical symptoms as in Case 1. Length of entire urethra 9½ inches; posterior urethra 3½ inches; introduction of steel sound impossible on account of projecting hard nodule of right lobe; median lobe enlarged; left lobe much smaller than the right. Cystitis. Urethra had to be prepared for a week before it became passable for Bottini's instrument.

Operation June 15, 1898. Three weeks later one ounce of residual urine; cystitis much better; urination every two hours in daytime, every three hours during night; eight weeks after the operation, every four hours during the day and once during the night; no residual urine. Cystoscopic examination showed mild catarrh of the trigonum, which under local treatment was cured within six weeks.

CASE III —Patient fifty-four years old. Complete retention for nearly two weeks; had had a similar attack about eight years before (then only forty-six years old) from which time frequent and unsatisfactory urination remained and grew worse from year to year. Prostate the size of a large orange; the right and median lobes mostly involved; length of urethra 12 inches (for which reason cystoscopic examination was impossible). Stone searcher did not disclose presence of concretions. In spite of regular catheterization for eight days condition remained unchanged.

Bottini's operation, July 23, 1898. The next day voluntary urination set in; about one half an ounce expelled every fifteen to twenty minutes; five days afterward continence for two hours, amount of urine passed increased accordingly. Five weeks after the operation continence for three hours during the night and two hours during the daytime; residual urine one-half of one ounce; urination free, painless, and satisfactory. Strange to say about eight weeks after the operation the patient got worse; passed bloody urine which, upon microscopic examination did not show evidence of a tumor, and by rectal palpation the left lobe was found considerably enlarged and rather painful. Several days afterward, while passing urine with great pain in my presence he expelled a very small phosphatic concrement which was followed by similar ones during the next four weeks. As his condition became unbearable and a stone could not be detected by the steel sound, and as cystoscopic examination was impracticable I advised a suprapubic cystotomy, thinking of the presence of an encysted or sacculated stone and perhaps a tumor of the left lobe and explained my views to the patient, who was ready to submit to any operation that promised relief.

Suprapubic operation performed November 30, 1898. Trabecular bladder, and between the trabeculæ, covered by secondary tissue, fourteen phos-

phatic concrements were found, each the size of a small bean. Left prostate lobe ulcerated in its vesical portion; curetted and cauterized. Lips of bladder-wound sutured to the skin. Patient had an uneventful recovery; fistula closed five weeks after operation. About one week afterward recurrence of painful micturition and bloody urine, apparently caused by malignant disease of the left lobe. Continence hour and a half in daytime, about three hours at night; one-half to one ounce residual urine.

Case IV.—Patient seventy-four years old. Symptoms of obstruction and retention for two years. Length of urethra 7¼ inches; length of anterior urethra 5 inches; residual urine from 1 to 5½ ounces at various times; urination every two hours in daytime and every half hour during the night. Digital examination did not ascertain enlargement, but cystoscopic examination revealed prostatic bar of median lobe and a few small ulcers at bas-fond.

Bottini's operation under antipyrin anesthesia, October 12, 1898. One incision two centimeters long through the median lobe; tenesmus for several days, then intervals between urination increasing until continence for four hours day and night set in toward the end of the third week. Under local treatment of ulcers in bladder for three weeks cystitis was cured. Saw patient in the early part of January, 1899, when he had but a few drops of residual urine.

Case V.—Patient sixty-four years old. Symptoms of prostatic obstruction appeared first about nine years ago. About six years ago complete retention for twenty-four hours. Saw the patient first about four months ago. At that time he had cystitis and alkaline urine; tenesmus day and night; temperature 103° F.; bilateral epididymitis. He had been in the habit of catheterizing himself during the previous two years. The calls to urinate came as often as ten to fourteen times during the night and about every hour during the day. Patient could only press out a few drops of urine at a time. Residual urine measured on various occasions between 5 and 8 ounces. Upon rectal examination the right and the median lobe were found considerably enlarged and hard. Entire length of urethra 10 inches; posterior urethra 3½ inches. Cystoscopic examination corroborated the results of rectal palpation and disclosed two gonorrheal ulcers the size of a small bean in the trigonum where the latter was elevated by the enlarged right lobe.

Regular catheterizing and irrigations of the bladder gave some relief but otherwise condition remained unchanged. Bottini's operation was performed December 28, 1898. On account of ulcers in the trigonum I used antipyrin as a local anesthetic. Two incisions were made, each three centimeters in length, one in the right lobe and one in the median lobe. Left soft catheter in bladder during the first three days. Eight days after the operation patient had continence for about three hours; residual urine half an ounce. Five weeks after the operation continence for six hours day and night; residual urine a few drops. Cystitis under local treatment improved rapidly. Length of posterior urethra 2½ inches.

Quite a number of other operations which I have since performed on patients with equally good results are of too recent date to be reported as cures. Judging by the present condition of the patients the final result will be satisfactory.

When I said that Bottini's operation apparently solves the problem of successfully dealing with hypertrophy of the prostate I did not mean that it is the only operation or treatment for the disease in question, but in reviewing the other methods we will gradually understand the value of a method which is not attended by the dangers of the others and yet brings about normal or almost normal conditions and functions in the distorted and obstructed urinary passage, results not usually following the others. Suprapubic puncture or perineal drainage gives but momentary relief from embarrassment. Prostatectomy is expedient in pediculated lobes only, and dangerous because it requires general anesthesia and confines the patient to bed for many days and weeks, enhancing the risk of affections of a deleterious character of the heart, lungs, and kidneys.

Castration has its advantages in a limited number of cases in which the gland appears diffusely enlarged and soft but in which very little or no projections in the viscus are found. But castration is a mutilating operation and very uncertain in its results, and it seems to me that Bottini's operation can accomplish the same result without the obnoxious features of the first. The report on the effect of vasectomy are so contradictory and often so discouraging that I have not yet felt tempted to try it, but it will certainly not help in removing projections from the urethra or the vesical neck. The method is not past the experimental stage, while Bottini's operation has conquered its well-deserved place, and as I hope, will keep its ground. It must be considered the mildest surgical act in hypertrophy of the prostate and should be tried first. There will always be time to castrate or to perform prostatectomy provided galvanocaustic incision has failed, while, when the latter has failed and the patient is still in the land of the living he will hardly approve of your belated suggestion of Bottini's operation.

THE DIFFERENTIAL DIAGNOSIS OF PELVIC AND ABDOMINAL DISEASES IN THE FEMALE.

By PAUL F. MUNDE, M.D.,
of New York;
Gynecologist to Mt. Sinai Hospital.

(Concluded from page 453.)

The distinction between *inflammatory masses in the peritoneal cavity* (salpingo-oophoritis, pus-tube,

pus ovary, with usual enveloping exudate) and *exudates or blood-coagula in the pelvic cellular tissue* (pelvic cellulitis or abscess, hematoma) can usually be made by remembering, first, that where there is no peritoneum there can be no peritonitis or no intraperitoneal body; hence, an exudate in the rectovaginal septum reaching almost down to the perineum cannot be in Douglas' pouch and must be extraperitoneal, as also an exudate occupying the vesicovaginal septum, or firmly attached to the lateral wall of the pelvis. Such an extraperitoneal exudate is always immovable; it cannot be otherwise, and it is usually situated to either side of the cervix or, if in the median line in front or behind, extends below the level of the external os. No large extraperitoneal exudate is ever found directly behind the uterus, for there is very little cellular tissue there and Douglas' pouch extends to within one inch of the tip of the cervix.

Intraperitoneal exudates, inclosing the ovary and tube on one or both sides, seldom reach low into the pelvic cavity, scarcely ever to the level of the external os; they are lateral and slightly movable up and down on bimanual pressure, but still evidently attached, for the whole vaginal vault and broad ligament move with the mass. If in the median line the mass of exudate is immovable, and the uterus pushed forward; if lateral, the uterus is dislocated to the opposite side. In intraperitoneal exudates, unilateral or bilateral, the uterus is always slightly movable up and down, but not laterally. In extraperitoneal exudates (cellulitis) the uterus is always as immovable in the position to which it has been pushed by the exudate, as the exudate itself. This is an important distinction between extraperitoneal and intraperitoneal inflammatory exudations.

An intraperitoneal exudate may be so large as to become adherent to the parietal peritoneum of the abdominal wall of the affected side, usually at a point between the iliac fossa and the middle of the subumbilical line. An extraperitoneal exudate may, on the other hand, force itself up between visceral peritoneum and submuscular fascia so as to infiltrate a large part of the lateral abdominal wall, and then it may be exceedingly difficult on external examination to decide whether the hard mass felt through the abdominal skin is extra or intraperitoneal. A vaginal examination will usually settle the question, for the cellular exudate extends deeper into the pelvic cavity and hugs the pelvic wall, while the intraperitoneal mass is very little prominent in the vagina and evidently is not attached closely to the pelvic wall. Unless there happens to be intestine adherent over the intraperitoneal exudate, the percussion-sound is dull in both cases.

If suppuration takes places in such a case both the intraperitoneal and the extraperitoneal abscess may point through the abdominal skin and be opened there. If the pointing occurs *deep* in the vagina, the abscess is probably extraperitoneal, and the pus may then burrow so widely as to necessitate both an abdominal and a vaginal opening.

I have twice found the kidney probably congenitally displaced behind the uterus deep in the pelvic cavity, as it happened both on the left side. Supposing the immovable tender tumor to be an ovary and tube bound down by exudate, I attempted removal by abdominal section, and it was not until I had forced my finger tips through the supposed adhesions and brought the tumor out through the abdominal incision that I realized that I had peeled the kidney out of its capsule. Of course I was obliged to ligate the pedicle and remove it; the woman recovered. In the second case I remembered this experience and after satisfying myself by digital exploration through the abdominal incision that the left kidney was absent from, and the right kidney present in, its normal position, I left the former untouched and closed the wound.

The pus from a *perityphlitic abscess* or from an *appendical abscess*, which has burst into the cellular tissue of the iliac fossa, may burrow down behind the pelvic peritoneum and point between the folds of the right broad ligament, or through the right vaginal wall, or in the rectovaginal septum, or even on the abdomen in the median line just above the symphysis pubis; or it may burst into the bowel and be discharged per rectum, after forming a mysterious globular tumor in the suprapubic region. I have seen all this occur, and only the peculiar fetid, fecal odor and the direction from which the pus came, as shown by a probe passed up through the hole of escape, revealed the true nature of the case.

An *abscess of the ovary* is usually surrounded by copious exudate or adhesions and is spherical or irregular in outline; a *pyosalpinx* is often long, like a sausage, tapering down to its uterine attachment, often again curled on itself, twisted, encircling the ovary. The thickened, inflamed tube wound around the ovary—the typical picture of so-called "chronic salpingo-oophoritis" forms a flat, irregular mass of the size and shape of a small mandarin orange, adherent to the posterior fold of the broad ligament, at one side of the uterus, or in Douglas' pouch. This mass is more or less tender, and slightly movable with the broad ligament. The uterus is not freely movable *laterally*, but perfectly so up and down. There is no displacement of the uterus, necessarily, although there may be a retroversion or a slight lateroversion.

When the tube and ovary form a smaller, flatter, more elliptical swelling which does not project into Douglas' pouch, and can only be felt bimanually on a level with the normal location of the appendages and with difficulty through the vaginal vault only, the presence of pus in appreciable quantity in tube or ovary can usually be excluded. Both organs are glued together by adhesions and constitute a distinct swelling, a so-called "thickening" of the broad ligament on the affected side. But there is no free pus in either tube or ovary; and instead of being hypertrophied by the inflammation, or cystic, there is more likely to be an atrophy of the appendages, the swelling being produced by the effused plastic lymph. Such a condition usually denotes frequent mild attacks of local inflammation, none of which has been sufficiently intense to induce suppuration The pain in such cases may be severe and permanent, but there is no danger of rupture of a pus-sac, and therefore no indication for a speedy operative removal of the diseased organs, however necessary such removal may be eventually to effect a cure.

An *ovarian tumor*, when small, drops into Douglas' pouch and pushes the uterus upward and forward; when the tumor grows too large for the pelvic cavity its pedicle permits it to escape into the abdominal cavity and the uterus drops behind the tumor.

Intraligamentous ovarian tumors and *cysts of the broad ligament* grow downward first and push the uterus upward and to the opposite side. As they grow larger they may dissect the peritoneum away from the posterior surface of the uterus (this is particularly the case if there is such a cyst on both sides) and then the latter is carried straight upward and forward so that it can be felt and even seen through the skin of the abdomen. When the tumor has filled the pelvic cavity it rises above and enters the abdomen, always, however, retaining its pelvic position. This is one of the distinguishing features of an intraligamentous cyst, which if ovarian may be fluid or semi-solid, if parovarian always fluid.

As regards the *differential diagnosis of strictly intra-abdominal tumors* as opposed to tumors which become such only by their upward growth from the pelvic cavity, it is a general rule that tumors growing upward force the intestines before them, and that therefore the percussion-sound is dull from the symphysis pubis up to the upper border of the tumor; in originally abdominal tumors the reverse is the case, thus hepatic, renal, splenic, gastric, intestinal tumors grow downward, and the resonant percussion-sound is below the lower border of the growth, between it and the symphysis. Of course, intestine may be adherent to the anterior surface of the tumor and thus spoil this sign; but the rule still holds good.

The sensitiveness, rigidity, adiposity, tympany of the abdominal walls interferes greatly with the exercise of palpation, on which method we chiefly rely for the diagnosis of abdominal tumors. Besides, the tactile sense of different individuals varies so greatly that an entirely opposite conclusion may be arrived at by two equally competent examiners. I have seen a tumor pronounced to be a fibroid of the uterus which turned out to be a dermoid ovarian cyst; I have myself hesitated on account of the peculiar shape of the tumor between a hypertrophied spleen and an ovarian polycyst, which latter the operation showed it to be; I have operated for what I thought to be a large ovarian polycyst and found it to be a fibrocystic uterus, as, indeed, probably have all abdominal surgeons; I have seen the peritoneum stripped partly away from the anterior abdominal wall in the supposition that it was the adherent wall of an ovarian cyst, until accidental rupture of the peritoneum revealed general ascites from tubercular peritonitis; the pregnant uterus has been tapped and even incised through an abdominal incision in the belief that it was an ovarian cyst; a woman was allowed to die of exhaustion from a supposed ovarian tumor, in whom the autopsy disclosed an enormous coprostasis through which ran a channel for the diarrheal discharges which were supposed to be the cause of the patient's death (in the clinic of Professor Von Bamberger at the Julius Hospital, Würburg, some thirty years ago, while I was house-surgeon to the Maternity Hospital there); and I have seen a supposed appendical abscess opened and an ovarian tumor with twisted pedicle found instead; and I myself have operated for supposed appendicitis and found an adherent abscess of the right ovary. And all the instances cited occurred in the hands of experienced operators, men of skill and wide reputation.

Careful examination with hands, eyes, ears, with the patient in varying positions, under inspiration and expiration, coughing, straining with empty bowels, relaxed abdomen, even ander anesthesia if otherwise impossible—together with a critical consideration of the history, endeavoring to allow for exaggerations, misstatements, improbabilities, etc.—all these precautions must be employed to enable the examiner to make a correct diagnosis, and still frequently all prove inadequate. At times all signs fail.

I have in mind three recent examples of the fallacy of both subjective and objective symptoms, as it happens, all relating to cases of presumable *ectopic pregnancy*.

Case I.—Married, thirty-three years of age, no children, one miscarriage nine months before; menstruation regular every four weeks, lasting three days; since five months irregular; skipped two months, since then spotting every four weeks with pain in the left ovarian region, the last ten days before examination; nausea and vomiting since three months; pain in left inguinal region. Diagnosis of ectopic pregnancy was made by two physicians, one a gentleman of great eminence, although not a gynecologist; patient was referred to me by both physicians independently. I could find absolutely no evidence of gestation, ectopic, or normal; but as the woman's abdomen was very fat, bimanual examination was unsatisfactory, and I therefore advised exploration under anesthesia. This was done and then both adnexa could be distinctly felt to be normal and uterus empty.

Case II.—Age twenty-one, married eight months, menstruations regular up to three months before marriage, then no menstruations until one month ago, since then twice, last just over. Admitted coition three months before marriage, feared conception, was pronounced pregnant then by physician, hence marriage. Abdomen increased steadily in size until two months ago, that is nine months after exposure and supposed conception, since two months has diminished in size. Mass in abdomen extending from brim of pelvis to epigastric region solid, fairly movable, kidney-shaped with larger end at pelvis. General health good, no cachexia. Uterus empty. Diagnosis: Abdominal pregnancy, dead fetus—based on history and physical signs. Abdominal section revealed sarcomatous tumor of left ovary.

If ever there were two cases with a clear history of ectopic pregnancy these were the two. In contrast is the following:

Case III.—Multipara, forty years, youngest child eight years old; menstruations always regular, last four weeks ago; no sharp or steady pain, merely in rectum during defecation for last week; anemic. Behind uterus (not sounded) small, soft, irregular mass of doubtful character, possible coagulum, malignant, omentum, not like tubal or ovarian (quotation from my office case-book); very fat. Referred back to family physician for later examination under anesthesia. Three weeks afterward examination under chloroform, pelvis filled with firm mass extending above pelvic brim; diagnosis, hematocele, probably steadily growing. Abdominal section, large mass of solid coagula, ruptured right ectopic tube—and still not a menstrual period had been missed and there was no stillicidium sanguinis until after my first examination.

I have seen so many cases of ectopic pregnancy that I am more than ever impressed with the difficulty of diagnosis in some of the cases, mainly from the absence of the usually most characteristic signs: Irregularity of menstruation, even an arrearage of only one or two weeks; bloody oozing, paroxysmal pains, fainting, or collapse. To differentiate between incomplete uterine abortion and ectopic pregnancy of a doubtful type seems to me one of the most difficult problems; only the removal of distinct placental fragments from the uterus and the utter absence of an extra-uterine swelling, corresponding to a pregnant tube or a hematocele, would decide in favor of an abortion.

A *movable kidney* is often to blame for abdominal pains and digestive disturbances. I see many cases where I find nothing in the pelvic organs to explain these pains, but on palpating the renal regions with the woman in the recumbent dorsal or lateral, or erect prone position, I have easily detected the displaced kidney or kidneys, and recommended the abdominal laced bandage, or flannel roller bandage, which latter I find to give the most relief in these cases. The paroxysmal attacks of pain running down the flanks from the renal to the suprapubic region I have already referred to as probably indicating the passage of small renal calculi, gushes of concentrated urine or discharges of pus from the kidney, suppositions which an examination of the urine will confirm or refute. I lately did a nephrotomy on a woman with such symptoms entirely on the left side, whose urine showed copious pus, and my diagnosis was triumphantly verified. As the pains were confined to the left side it was not necessary to catheterize the ureters to decide which kidney was diseased, although as a rule I would advise this precaution before operating on the kidney.

It may seem strange that there should be any difficulty in deciding whether an abdominal tumor is intra-abdominal, or situated in the abdominal wall only, but such is the case. *Desmoid tumors*, as these growths in the abdominal wall are termed, often puzzle even the most expert examiners as to their location, the reason being that they usually are closely attached to the peritoneum, being muscular (mostly sarcoma of the rectus muscle).

Appendicitis and *salpingitis dextra* are frequently associated and noticeable in the interval of the chronic cases by a small tumor situated midway between the ovarian and appendical regions, tube and appendix being co-adherent. The swelling of an appendicitis should not ordinarily be mistaken for a salpingitis, since the former can never be touched from the vagina unless the appendix is displaced or the exudate has migrated downward, and the tube does not extend as high up as the supra-iliac region. Still, even experts may at times be in doubt in such cases.

As I have already said, it is not my object to exhaust this subject. My paper has already grown far beyond the length I had proposed for it. That even the most expert may err in abdominal and pelvic

diagnosis is well known. I for one freely acknowledge that I have made mistakes of this kind, mistakes at times which I was ashamed of. I do not, therefore, feel justified in criticizing too severely the errors of others. "Those who live in glass houses should not throw stones." And "*Erare humanum est.*" Many diagnostic blunders are unavoidable, hence in abdominal cases the welcome expedient of "exploratory celiotomy." Nevertheless, the plan adopted by some abdominal operators, to operate first and make the diagnosis afterward is scarcely to be commended. If we have exhausted all available means to solve the difficulty, and have even called in a competent consultant, we may surely be excused if after all our diagnosis proves to have been wrong. We can, at all events, not be accused of having failed to do our duty.

CLINICAL MEMORANDUM.

A CASE OF TETANUS TREATED WITH ANTITOXIN; A CASE OF TETANY; A CASE OF PHARYNGEAL ABSCESS DIAGNOSED AS TETANUS.

By JAMES R. ARNEILL, M.D.,
of Ann Arbor, Mich.;
Demonstrator of Physical Diagnosis in the University of Michigan.

In a recent communication,[1] G. G. Rambaud of the Pasteur Institute, New York, abstracted reports of the experiments of Roux and Borrel[2] in the intracerebral injection of antitoxin in tetanus. They treated forty-five tetanized guinea-pigs by intracerebral injections of antitoxin; thirty-five recovered. Seventeen others were treated by subcutaneous injections; two recovered. Of seventeen check guinea-pigs not treated with serum, all died. Rambaud collected from literature reports of twelve cases in man in which intracerebral injections had been employed. Of these five recovered. So large a percentage of recoveries in this ordinarily fatal disease eloquently recommends this treatment to our consideration and trial. The subcutaneous and intravenous injection of antitoxin have proved to be nearly worthless in severe cases of tetanus, scarcely more valuable than the drugs which were used previous to the days of serum-therapy, such as chloral, bromids, and morphin. The experiments of Roux and Borrel demonstrate plainly why intracerebral are more successful than subcutaneous or intravenous injections. They took a portion of the brain substance of a guinea-pig, crushed it with some tetanic toxin and centrifugalized the mixture. This separated into two layers, the upper layer being an opalescent fluid, the lower the nervous substance. The upper layer was found to contain very little toxin, or none at all, while the nervous substance contained the tetanic poison.

In the body as in the test-tube cerebral and spinal nerve-cells have a peculiar selective action upon tetanus toxin, but not upon antitoxin. The poison reaches the nerve-centers by two routes: a part follows the course of the nerves, and another part enters the blood, where it is extracted by the nerve-cells.

Evidently subcutaneous or intravenous injections would be more often successful if given sufficiently early, while most of the toxin is yet in the blood, the toxin and antitoxin thus being brought into intimate contact and antagonizing each other in this tissue. Intravenous injection is almost useless if delayed till the spinal and cerebral cells have extracted the toxin, the period when most tetanus patients come under treatment. At this stage almost the only hope of recovery lies in intracerebral injection. A question immediately arises, Is this selective action upon tetanus toxin equally distributed among all cerebral and spinal nerve-cells? If so, can the comparatively small quantity of antitoxin injected into the frontal lobe reach a sufficient number of cells by diffusing from one to the other to bring toxin and antitoxin into sufficiently large contact to control the disease? Is it because of a failure to do this that the majority of these patients die? An important point to remember in the treatment is that toxin is being continually generated at the site of injury and taken up by the blood. Therefore subcutaneous injections should always be continued and the wound treated while intracerebral injections are being given. To the three cases in America, mentioned in this article, must be added the fatal case under the care of Dr. Arthur Le Febvre of Detroit, by the intracerebral method.

Tetanus.—Harry West, colored, aged sixteen years, hostler, was admitted to the University Hospital November 9, 1898. While working in a stable, October 29, 1898, he stepped on a rusty nail which penetrated his shoe and entered the outer side of the sole of his right foot, making a small puncture. No attention was paid to the wound, which healed and was promptly forgotten. On November 5th, eight days after the accident, he began to feel sick, with stiffness in the neck and pain in the region of the heart. On November 7th he had spasms of the muscles of the right shoulder and right leg. When admitted to the hospital, twelve days after receipt of the injury, he could not walk, the muscles of the neck, trunk, and legs being tonically contracted, producing a condition of opisthotonos. The chin was drawn around to the left. The slightest irritation, such as questioning, touching or feeding him, started the convulsions. These involved especially the right side. After a careful examination of the right foot I found a sealed puncture from which only a few drops of bloody serum could be squeezed. Cultures were made by Dr. Novy and the bacillus of tetanus was demonstrated. The case was referred to Dr. Nancrede who began treatment by incising and cauterizing the wound, and giving chloral, 20 grains, and bromid, 40 grains, every two hours, per rectum, and morphin hypodermatically. A subcutaneous injection of 10 c.c. of Parke, Davis & Co.'s antitoxin was given at four o'clock on the day of his admission and repeated every four hours until the death of the patient which occurred on October 11th at 4.30 A.M., four days after his first convulsion. Ninety c.c. of antitoxin in all was in-

[1] *New York Med. Jour.*, December 17, 1898.
[2] *Annals de l'Institute Pasteur*, April, 1898.

jected. The bowels remained obstinately constipated. All attempts at feeding either by the mouth or rectum brought on convulsions. These gradually increased from about thirteen per hour until just before death, when he was in an almost continuous convulsion. The highest temperature noted was 101.6° F. His pulse ranged from 90 to 160, and respirations from 20 to 46.

The most interesting points about the case are the classical development of the convulsions ten days after the injury, and the death of the patient four days after the convulsions began. A Hippocratic aphorism says, "Such persons as are seized with tetanus die within four days, or if they pass these they recover." The absence of trismus is also worthy of note. The limitation of the convulsions chiefly to the right side, the side of injury, bears out the statement of Marie: "A part of the poison follows the course of the nerves and is fixed by the cells of the spinal cord; for this reason in animals contractions begin in the region in which the injection is made, and in man generally in the wounded part." The failure of the antitoxin to relieve any of the symptoms should be emphasized.

Tetany.—Mrs. R., a woman of middle age, came to the hospital because of periodical attacks of griping pain in the umbilical region, occurring at intervals of two weeks to two months. There was a family history of weak stomach. The trouble began when the patient was eighteen years old, with griping pains in the stomach, nausea, and vomiting. Rarely a heavy meal seemed to be the causal factor. Eating at this time made the attacks worse. At first they occurred about once a year; gradually they became more frequent, until at the time of admission they occurred as often as once every two weeks. The pain was so severe that hypodermics of morphin were always given. The patient vomited from a pint to a quart of material in which she detected particles of food which had been eaten the day before. During the previous year she had vomited blood in amounts ranging from a trace to two tablespoonfuls. During the previous twelve years a numb feeling and cramps over the entire body had been associated with these attacks. At this time both wrists are flexed toward the trunk, the fingers were flexed at the metacarpophalangeal articulation but remained stiff and straight, and the thumb was flexed into the palm of the hand. The ankles were also flexed inward and the toes bent like the fingers. At times the most trivial blow or pressure upon any part of the body would be followed immediately by a large swelling. After riding a few miles on a cramped carriage-seat the leg which was pressed against the outside of the seat became enormously swollen.

The patient was well nourished though a trifle pale. There was a very soft murmur associated with the first sound of the heart at the apex. Over the aortic area a louder and harsher murmur could be heard. The kidneys were not palpable. The stomach, when distended by means of tartaric acid and bicarbonate of soda, was found to be dislocated: the lesser curvature was two inches above the navel, the greater two inches below. Marked succussion-sounds were elicited over this area.

The diagnosis was tetany associated with dilatation and dislocation of the stomach, first described by Kussmaul. The association of angioneurotic edema is of interest.

Pharyngeal Abscess Diagnosed as Tetanus.—A Spaniard, about thirty years of age. When first seen his jaws were firmly locked. His mind was clear and there were no spasms of muscles in other parts of the body. The following history was obtained from friends: Four weeks previous to my visit a molar tooth was extracted in a bungling way, with considerable laceration of tissue. Soon the patient found it impossible to open his mouth. This condition persisted for a month and was diagnosed as lock-jaw. A surgeon of eminent ability was summoned, and being familiar with the frequency of hysteria among this nationality, made the tentative diagnosis of hysterical spasm. At his suggestion I inserted a gag and by means of a screwing motion succeded in opening the jaws about a third of an inch. The gag remained in place several hours, the patient suffering considerably as a result. Following several insertions of the gag I succeeded in obtaining a poor view of the posterior pharynx. The tissues appeared inflamed and swollen. It was impossible for me to use finger palpation. Suspecting a pharyngeal abscess, an incision was made in the anterior pillar and a large quantity of pus was evacuated, with great relief to the patient. The tissues cut with considerable resistance, suggesting a fibrous condition. From this time improvement was progressive but gradual, owing to the indurated condition of the tissues surrounding the temporomaxillary articulation.

The diagnosis of tetanus is usually easy. The diseases from which it must be differentiated are the convulsions of strychnin poisoning, thyroidism, hysterical spasms, and the above-mentioned diseases. The history of injury, the period of incubation, and the character of the convulsions are sufficient data to prevent error.

MEDICAL PROGRESS.

Resection of the Cervical Sympathetic in Epilepsy, Exophthalmic Goiter and Glaucoma.—JONNESCO (*Centrabl. f. Chir.*, February 11, 1899) published a brief article upon the above subject two years ago. Since that time he has performed the operation upon fifty-four patients, making altogether sixty-one patients operated upon in this manner. No bad effects were observed after the operations. There were no trophic disturbances nor was any influence noticeable on the general or mental condition of the patient. In ten cases of true exophthalmic goiter, a cure was six times obtained, and an improvement four times. The exophthalmos first disappeared, then the nervousness and tachycardia, and then the goiter. The results upon cases of secondary exophthalmic goiter were less satisfactory. Forty-five epileptics were operated upon, of whom six died in a shorter or longer time, either in an epileptic attack, or of some other trouble. Of nineteen patients who were observed for a considerable length of time, 55 per cent. were cured, 28 per cent. improved, and 15 per

cent. were not improved. It must not be inferred that the operation is indicated in all cases of epilepsy. In old cases with either mania or dementia, there are already changes in the brain, which no operation can help. In recent uncomplicated cases on the other hand, there is every reason to look for a brilliant result. In glaucoma the results were equally good. They consisted in lessening of the ocular tension, contraction of the pupil, lessening or disappearance of the peri-orbital pain and headache, disappearance of the attacks in the irritative form of the disease, and an improvement of vision with increase in the field, in those patients in whom atrophy of the papillary layer was not absolute.

Lifting the Uterus to Control Post-Partum Hemorrhage.—Dickinson (*Brooklyn Med. Jour.*, March, 1899) advocates the lifting up of the uterus against the lumbar, or even dorsal spinal column with one hand, while the other placed below it, grasps and compresses and rolls the lower part of the uterus including the cervix. In this manner the cavity of the uterus is obliterated, and the walls pressed together as cannot be done by methods which force the body of the uterus down into the pelvis, either with or without counter pressure made through the vagina. The claims are substantiated by frozen sections. This procedure can be carried out, while waiting for the hot douche to be prepared, or for the ergot to take effect. It has the advantage of giving no risk of infection.

Another good point mentioned by Dickinson is the method of separating an adherent placenta. It is usually not necessary to separate more than half of the placenta, when the whole organ will become loosened. It is of course best to begin at the bottom and work up. His proposal is to introduce the hand within the membranes instead of outside of them, so that the fingers in digging up between the placenta and uterine wall may be always covered by the membranes like a mitten and danger of infection be thus avoided. As the membranes tear readily, it is necessary to rotate the hand a little, and to "pick up a little slack on the way in," before pushing the fingers up between the placenta and the wall of the uterus.

Habitual Constipation in Infancy.—Blackader (*Progressive Medicine*, vol. i, March, 1899) states that habitual constipation in infants may depend on the anatomic peculiarity of the bowel, which exists in the early months of life and may persist to the twelfth or eighteenth month, or even later. This peculiarity consists in an undue length of the descending colon, and the presence of two or three distinct flexures of the sigmoid instead of one. This condition retards the movement of feces, favors absorbtion of fluids, and leads to the formation of large, hard masses difficult of expulsion. In these cases constipation is best treated by massage, and the daily employment of either enemata or suppositories. Or the disturbance may be due to deficient muscular power, abnormal consistence of the intestinal contents and decreased peristalsis. The feces should be carefully inspected in order to determine this point. The food-supply is often the source of the difficulty. If the proteids exist in too high a percentage, colic and loose movements may result instead of constipation. A low percentage may influence injuriously the development of the intestinal muscles. Malt preparations are said to raise the percentage of fat. In artificially fed infants, constipation may also be due to an insufficiency in the fats or proteids. The addition of a teaspoonful of fresh cream for each teaspoonful of condensed milk used is an effective way of relieving the constipation following feedings of condensed milk which is low in fats. Beef-juice is occasionally laxative in effect. In the constipation of rickets, the diet must be carefully regulated and the usual antirachitic treatment, including the administration of cod-liver oil instituted. When constipation is due to congenital stricture of the anus or rectum, rectal examination will reveal the seat of the difficulty. A careful examination should always be made in persistent cases. When nutrition is defective, malt extracts and cod-liver oil may be tried. Enemata should be employed for a comparatively short period only—and saline solution is recommended as being less irritating to the mucosa than plain water. A teaspoonful of glycerin in a tablespoonful of water is a stimulant, and will frequently be found an excellent means of securing a proper evacuation.

Wore a Pessary for Thirty-two Years without Change.—Blondel (*La Gynecol.*, February 15, 1899) examined an old woman who came to him complaining of pain and a foul bloody discharge from the vagina. He thought that she had a cancer, but instead he found a completely incrusted pessary so firmly embedded in the vagina that its removal was a serious undertaking. Posteriorly it had cut though the rectovaginal membrane until only the mucous membrane of the rectum intervened between it and the rectal cavity. As the last local treatment she had had was four years after the birth of her youngest child, who at the time of her visit was thirty-six years of age, it followed that the pessary had been in position for at least thirty-two years.

General Gonorrheal Infection.—Colombini (*Centralbl. für Bakter.*, etc., December 30, 1898) describes a case in which the gonococci were found not only in the urethra, and in an inguinal abscess, but also in pus from suppurative processes in the testis epididymis, and parotid gland, and later in the blood and urine. This is the only case, as far as known, in which an infective process has attacked, first, the testicle, and then the parotid gland. The reverse of this order, the testicle being attacked after the parotid gland, is common enough; for example, in mumps.

On Prolonged Decubitus after Childbirth. — Desplats (*Jour. des Sciences Med. de Lille*, January 28, 1899) says that the idea of keeping a woman absolutely quiet in bed for a long period after childbirth, is calculated to do her more harm than good. Such a treatment has been insisted upon because of the fear of (1) infection, (2) displacement, (3) the fear of uterine subinvolution. He insists that if the patient be allowed to sit up, or better to stand up, from time to time that fluids will be drained away from the vagina and cavity of the uterus, and the

risk of infection will therefore be lessened. Moreover, changes in the position of the patient and movements assist in the return of the uterus to its normal size and position, by favoring the intra-abdominal circulation, and re-establishment of the actions of the intestines, stomach, liver, bladder, and kidneys. Patients treated in this manner will not only recover their health more quickly, but will be better able to nurse their infants during convalescence. The writer has followed this plan of treatment for thirty years, and has never seen an accident which he could ascribe to it.

Formalin in Whooping-cough.—OLLIPHANT (*New York Med. Jour.*, March 4, 1899), after a year's trial of formalin in the treatment of whooping-cough, is convinced that it is as much of a specific for this disease as mercury is for syphilis, or quinin for malaria. The results seem to prove that whooping-cough is a disease having a purely local lesion, the infection beginning in the fauces, and by the multiplication of the germs infecting later the air-passages, and then the general system. This idea is borne out by the fact that carbolic acid, menthol, and other antiseptics, have been used in the throat with benefit, but the results obtained by them have not been so uniformly good as those which have followed the application of a solution of formalin. Out of twenty cases so treated not one failed to be cured in less than eight days; while some were cured in three days. The application of the formalin solution to the fauces is followed by free emesis, so that the solution used in young or debilitated children should be weak.

Technic of Suturing a Fractured Patella. — CUMSTON (*Annals of Surg.*, March, 1899) finds the best incision for fracture of the patella, in case it is desired to suture the fragments is one shaped like a horseshoe, the base of the flap being broad and well supplied with vessels, while the incision is everywhere 1½ or 2 inches from the edges of the patella. The base of the flap may be downward or to the inner side, the former being preferable in recent cases without much separation. By such a large incision, the parts can be thoroughly exposed and cleaned. Particular attention must be paid to the removal of all clots from the joint and from between the bones, for such clots often contain bits of periosteum or aponeurosis which may interfere with the restoration of the parts ad integrum. Silver wire is used for the suture, and each fragment is bored in three directions, the lines making a triangle in each fragment, and the apices of these triangles coming together in the line of fracture. In this manner the whole wire can be buried, except the ends, which come out at the side of one of the fragments and are twisted together.

Fractures of the Astragalus.—BASTIAN (*Rev. de Chir.*, March, 1899) made an experimental study of fracture of the astragalus, bringing a known pressure or blow upon the bone while it was either held firmly between fixed objects representing the bones with which it is articulated or rested in its natural relations in the human foot. He found that fracture of the astragalus can be produced in four ways: by crushing, by penetrating, by tearing and by a special wrenching, which the author calls avulsion.

Crushing fractures are produced when the astragalus is compressed between plane surfaces. They are situated in an approximately frontal plane, at the neck, and are dependent upon the configuration of the bone. Their especial characteristic is that the widest separation of the fragments occurs on the side opposite to that from which the force acted

Fractures by penetration occur when the bone is subjected to a pressure between two cuneiform surfaces. The maximum of separation occurs on the side of the violence. Oblique fractures are produced in this manner. They are associated with luxations or subluxations of the bone. These two methods of compression and penetration may be associated and give rise to T-shaped or Y-shaped or stellate fractures. In certain movements of the foot, the ligaments can tear off certain portions of the bone. These occur most often in its posterior portion. The posterior apophysis may break as a result of a special mechanism called avulsion. This is indeed a partial crushing but it differs from the ordinary crushing by the especial characteristics of that portion of the bone.

THERAPEUTIC NOTES.

Camphoric Acid for Night-sweats. — COSTON (*Therap. Gaz.*, March 15, 1899) has tried camphoric acid in ½-dram doses one hour before bedtime, with a glass of milk or water, for night-sweats. He mentions three cases in which the remedy sufficed to control absolutely the sweats, both in fatal cases of tuberculosis and in rheumatism. In debilitated patients during recovery from typhoid fever, the patient is often as much weakened by the sweat as he gains by the sleep. In such instances 30 grains of the camphoric acid will often suffice, and may not need to be repeated for several days. The medicine is best given dry on the tongue, and then washed down with water or milk. The writer has never known it to fail to give relief.

For Pelvic Neuralgia and Vaginismus. — For these affections when due to inflammatory conditions of the uterus or adnexa, or to the existence of inoperable tumors, the section of branches of the sacral nerves has been tried with benefit. PONCET of Lyons has devised a more simply procedure based on this fact. He dilates the anus, under anesthesia, as if for fissure, and follows this by very gentle dilatation of the rectum, either by the fingers or by means of a large speculum. He has found much improvement to result from this treatment, which may, however, have to be repeated at intervals.

For Cough During Measles.—

SATURDAY, APRIL 22, 1899.

THE NEW PHILOSOPHY OF OLD CLOTHES.

There has always existed a very natural feeling of objection to the use of second-hand clothing, which, for the needy, however, the stress of poverty has always overcome. In cases where the former owner died of acute contagious disease the dangers that lurked in the use of such clothing by others was evident. Only of late has come the realization that where chronic contagious disease, as, for instance, tuberculosis, has existed in the owner of the clothing, it becomes so saturated with infectious material that only the most careful and prolonged sterilization renders it safe for subsequent use. Even where the first owner has been of reasonably cleanly habits the danger still exists.

In a paper read at the last meeting of the American Climatological Society it was shown that the hands of consumptives are nearly always contaminated by the bacillus tuberculosis. The pockets of garments can scarcely fail under these circumstances to contain large numbers of bacilli. Dr. Bissell, the City Bacteriologist of Buffalo, has recently taken a favorable opportunity that chanced to present itself, to investigate clothing that was actually about to be transferred to others. Certain soldiers suffering from phthisis were being mustered out of the 74th Regiment at Buffalo. According to custom in the National Guard their uniforms were to be reissued to incoming recruits. Dr. Bissell secured the pockets of the uniforms, and having soaked them for some time in water, centrifugated the resulting liquid and injected the sediment into guinea-pigs. Of sixteen animals so injected seven died within forty-eight hours of acute septic infection. Of the nine others five recovered, one was killed by accident, one died without discoverable cause, and two died of tuberculosis.

It seems clear that there is in this matter of the sale of old clothes a subject that requires the attention of boards of health. If sources of active contagion are to be eliminated, all second-hand garments should be subjected to effective sterilization before being exposed for sale. Even where the former possessor was presumably healthy he may have been carrying around with him certain micro-organisms to which he himself was immune, but which would seriously affect others. The whole subject is of great practical and scientific importance and involving, as it does, certain of the unsolved problems of infection and infectiousness, deserves the serious attention of public-health authorities generally.

APPENDICITIS AND TERMINOLOGY.

We are wont to hear a good deal of the awful philological crime of using such hybrid words as appendicitis and other kindred arbitrary compounds of Latin and Greek, or Latin words with Greek endings. Not a little of the objection in this respect has come from foreign medical men whose nice esthetic etymological sense has been so cruelly tortured by these barbaric combinations. Perhaps it is some compensation to their feelings that they are able to roundly abuse the name, since they have to admit at last that American medicine has in the discovery of the etiology and treatment of appendicitis added a new and important chapter to medicine and surgery.

It is refreshing under the circumstances to read the account, which we publish this week, of the proceedings of the last meeting of the New York German Medical Society containing the discussion of the propriety of the term appendicitis. Our

German-American brethren have proved thoroughly conservative in the matter, and have shown a very commendable hesitancy in suggesting any far-reaching reforms in our good English medical vocabulary. All are agreed that we may let well enough alone.

Words are but arbitrary signs. In the living language their elements are often absolutely without significance. It is usage, not nice rules of etymology, that decrees life or death to a word. The words over whose birth geniuses watch with the intent that every detail of structure shall be correct often prove still-born or short-lived. Once words have come into general use it is labor lost to attempt to displace them and the reasons for attempting it are often questionable enough. There is much of pretense in the supposedly pious zeal of the utterly pure in etymology. Perhaps the discussions aroused over appendicitis will lead to the adoption in future of philologically better terms for new ideas in medicine, but even that is doubtful. And then did anyone ever know a philologist (save the mark!) who was ever quite satisfied with a new term? Certain it is that it is now too late to work reform in words that have become part and parcel, not alone of medical language, but of the English tongue itself.

SUCCESS OF PYLORECTOMY FOR MALIGNANT DISEASE.

Since Schlatter's removal of the entire stomach, with good functional results, surgeons have been even bolder than before in removing portions of that viscus and the results have justified their apparent hardihood. The operation of gastro-enterostomy, done for its palliative effect in malignant disease of the pylorus, is evidently destined to be reserved only for the most extreme cases, in which the malignant tumor has invaded surrounding tissues extensively and in which there can be absolutely no hope of the complete removal of all the involved structures.

At the last meeting of the Clinical Society of London, held March 24th, Dr. Rutherford Morrison presented four patients on whom he had performed pylorectomy for malignant disease. The patients ranged from thirty-eight to forty-eight years of age; the tumors were, one encephaloid cancer, one colloid cancer, one adeno-carcinoma, and one scirrhus. They varied in size from that of a walnut to an orange. All of the patients had gained remarkably in weight since the operation, the smallest amount gained being fifteen pounds. This was in a man on whom the operation had been performed only six weeks before. The functional result was excellent; the patients could eat whatever they desired and suffered no inconvenience or discomfort. In two of the cases considerable portions of the stomach-wall had been removed during the operation, in one nearly the whole stomach. Notwithstanding this recovery had been uneventful and satisfactory.

Dr. Morrison gives it as his opinion that the size of even a malignant tumor of the stomach should never constitute a contraindication to its removal. If it is movable, the tumor should be excised no matter what its size. Pylorectomy is in his experience no more dangerous than gastro-enterostomy and looked at even as only a palliative operation gives much more satisfactory results. He considers that gastro-enterostomy has been greatly overdone and its supposed lesser danger over lauded. Of course there is the added advantage in pylorectomy that it gives the patient at least a fair chance for radical cure. Recurrences may and will take place in some cases even when immediate results are most satisfactory. In Dr. Morrison's cases it is probable there will be some recurrences either local or metastatic but meantime the best interests of the patient have been consulted. The operative measure he advises is undoubtedly in line with the best conservative surgery.

GLYCERINATED VACCINE LYMPH.

We noted last week in our column of "Echoes and News" that the Fothergill medal for 1899 has been awarded to Dr. Copeman for his researches on the preservative effect of glycerin on vaccine lymph. We shall shortly in our column of "Notable Books" give a résumé of Dr. Copeman's recent work on the general subject of vaccination. Meantime, the subject is one deserving of more than passing attention. The recent passage of the conscientious objection law in England that has led to so much strenuous protest on the part of British and other medical men shows that a great deal of influence is accumulating, at least among English-speaking people, against the rigorous enforcement of present laws with regard to vaccination. The antivaccination-

ists are about to invade the Continent, too, an anti-vaccination congress having been actually appointed to convene during the summer in the very stronghold of belief in vaccination—Berlin. We await the outcome of it with interest.

Opposition to vaccination is founded, in addition to certain fanatical objections to the assumed horror of communicating a cattle disease to man, on the morbidity and mortality that, in a limited number of cases, accompanies vaccinia. While a certain amount of indisposition inevitably attaches to vaccination, there is no unavoidable reason why it should ever produce serious illness or lead to a fatal issue. In the collection and preservation of vaccine lymph from the calf there was formerly almost inevitably involved the contamination of the vaccine virus with other infective agents. Practically all of the complications accompanying vaccination in former times were due to mixed infection. It was not uncommon to inoculate the patient with pyogenic or erysipelatous germs which were mingled with the vaccine matter, and which produced their accustomed effect. Indeed, it must be admitted that many of the supposedly excellent vaccine scars of the olden time are really only marks of the purulent process that accompanied the vaccination.

A vast amount of painstaking work has been necessary to secure the elimination of these extraneous infective agents without lowering the value of the vaccinating material proper. Dr. Copeman's work has shown that this can be best accomplished by the addition of glycerin to calf vaccine. Under its protecting powers other micro-organisms lose their vitality, but the specific vaccine matter retains all its power, and may be thus preserved for long periods.

It seems almost needless to say that proper precautions should be taken to secure the vaccination wound from any secondary infection during the progress of the vaccinia. Some one has recently said that the wound made in vaccination seems to be the only one that the Doctor does not deem it advisable to protect from infection. It must not be forgotten that the vaccinal inoculation, during the absorbing and healing process, far from protecting against secondary infection, rather favors it by keeping the lymph paths open. The necessity for such protection, while not disturbing the progress of vaccinal absorption, as will preclude the possibility of extraneous germ material from getting into the wound is evident.

QUININ IN MALARIAL HEMOGLOBINURIA.

Dr. Lynch's very valuable and practical contribution on "African Black-water Fever" to the recent discussion on malaria before the New York Academy of Medicine, an abstract of which will be found in our present issue, affords an opportunity to say a last word on the use of quinin in hemoglobinuric conditions. The position we took on this subject at the time of the last malarial discussion at the Academy was criticised in certain quarters. In response we showed that the therapeutic principles we advocated with regard to the use of quinin were supported by the best authorities on malaria. The matter is an extremely practical and important one for our Southern medical men, and because of its bearing on the contraindications to the use of quinin in general, is of interest to the profession wherever malaria exists.

As there have been several recent important contributions to the subject we shall briefly set them before our readers. Evidence is accumulating more and more from those who have been intimately in contact with the disease in Africa that Koch's declaration of the etiological influence of quinin in the affection was not only ill advised but unfounded. Dr. Lynch notes that the disease occurs especially among those who have neglected to take quinin either for prophylactic purposes or for slight symptoms of malaria. All of the English medical men whose service in South Africa has made them practically familiar with the disease and who have put themselves on record in this matter, have announced just this same opinion. All of them, too, have agreed in saying that the one hope for patients suffering from African black-water fever is quinin promptly and liberally given. Several of them even insist that when the state of the digestive organs gives small hope for the prompt absorption of the drug—and this is not infrequent because of persistent vomiting—that it should be given hypodermically.

It is interesting to note that several of these contributions to the subject have appeared in the columns of the London *Lancet*. The journal saw fit to express editorially its disaccord with our views on the use of quinin in malarial hemoglobinuria, though it agreed substantially with them when enunciated by its

own contributors who had had experience with the disease. Dr. Walter Fisher, L.R.C.P., of Nana, Candunu, in the Lovale country, Central Africa, in a letter (*Lancet*, March 18, 1899) says:

Koch's statement that "the treatment of black-water fever with quinin must absolutely cease" may lead to very disastrous results. After more than eight-years' experience in Central Africa, I feel sure that if quinin is not used in these severe cases the death-rate will increase enormously. I have tried latterly the giving of smaller doses, but in the end have had to go back to the larger doses, before the fever would break. To give up quinin in our hemoglobinuric fevers would, to my mind, take away from patients their best chance of recovery. I have never seen a case in which quinin has caused hemoglobinuria.

Dr. W. H. Crosse, formerly chief medical officer for the Royal Niger Company of Central Africa, publishes an article on black-water fever (*Lancet*, April 1, 1899) which was read before the English Epidermological Society, in which he says:

Quinin should always be administered in doses sufficient to make it certain that the blood is freed from the malarial parasites. It is frequently difficult to efficiently administer quinin by the mouth on account of the persistent vomiting, and administration by the rectum is unsatisfactory. I am myself a strong advocate, under these circumstances, of the hypodermic administration of quinin. In a recent case under my observation here in England, quinin was first given by the mouth and the patient had a relapse. It was then given hypodermically and he recovered without further relapse.

In the first number of "Progressive Medicine," Dr. Thayer has an excellent review of all the recent literature of malarial hemoglobinuria in which he comes to the following conservative, practical conclusions:

In certain severely malarious districts, repeated infections result in the development of an individual predisposition to hemoglobinuria. In some instances the attack seems to be provoked by the actual malarial paroxysm. The immediate provoking cause is often impossible to determine. In certain tropical regions the ingestion of quinin may provoke the hemoglobinuric paroxysm. . . . It is certain that a large proportion of the so-called "malarial" hemoglobinurias have no relation whatever to the taking of quinin.

We think that the citation of these authorities makes it perfectly clear that fear of doing harm, by the administration of quinin freely, is unfounded and apt to do much more harm than good. Especially is the practical conclusion important for those of our citizens about to go to our tropical possessions. Quinin as a prophylactic against malaria is efficient and except where idiosyncrasy for the drug exists its use to ward off malaria is associated with no serious dangers.

ECHOES AND NEWS

A Pathologist to the City Hospital.—Dr. Walter Bensel has been appointed Pathologist to the New York City (Charity) Hospital.

Bill Signed by Governor Roosevelt. — Mr. Kelsey's bill appropriating $105,000 for the Gray colony for epileptics has received Governor Roosevelt's signature.

State Board of Charities Re-election. — At the annual meeting of the State Board of Charities at Albany, on April 13th, William Rhinelander Stewart of New York, and Enoch V. Stoddard of Rochester, were re-elected president and vice-president, respectively.

The Price of Quinin Rises.—A scarcity of quinin has led to its advance in price by more than 100 per cent. in the wholesale market, where it now sells at thirty-five or forty cents an ounce. A few months ago it sold at from fourteen to sixteen cents an ounce in bulk.

The Cavendish Lecture.—Professor William Osler of Johns Hopkins will deliver the Cavendish lecture before the West London Medico-Chirurgical Society on June 13th. By special arrangement through the kindness of the lecturer we shall present the lecture to our readers immediately after its delivery and simultaneously with its publication in England.

"Missouri" brings Sick Soldiers.—The army transport "Missouri" arrived at Old Point, Virginia, on April 12th, having on board 210 sick soldiers from Havana. Of these only 27 are regarded as being dangerously ill. Sixty of the men have been ill with typhoid fever, and 59 with malarial fever. All were transferred to the Josiah Simpson General Hospital; most of them walked ashore.

Professor Rutherford's Successor.—Among the candidates prominently mentioned, according to *Science*, for the chair of Physiology left vacant by the death of Professor Rutherford, the late Professor of Physiology at Edinburgh, are Professor E. A. Shäfer, Dr. William Stirling, the English editor of Landors' "Text-Book of Physiology," Drs. D. N. Paton, E. Waymouth Read, and at least one American, Dr. G. N. Stewart.

Obituary.—At a recent meeting of the Harlem Medical Association of New York resolutions of regret and sympathy were adopted expressing appreciation of the scientific work and high character of Dr. Willard A. Heacock, whose death has been reported. The New York Celtic Medical Society has also recently passed resolutions of sorrow and regret at the death of one of its fellow-members, Dr. T. J. McGillicuddy.

New York Dispensary Report. — In the 109th annual report of the Board of Trustees of the New York Dispensary for the year 1898 it is stated that the Treasurer has

received from all sources $28,060.11, and had a balance January 1st of $10,892.94. Since its foundation in 1790 there have been treated in the dispensary 2,666,218 patients; during the past year 50,133 patients were treated at the dispensary, and 3214 at their homes.

The American Medical Association.—The secretaries of the various sections of the Association are now making up the final programs of the meetings. It is important, therefore, that all those who desire to present papers should send at once the titles and their names in full to the secretary of the section before which they wish to appear. The officers of the various sections and their addresses were published in full in the MEDICAL NEWS of April 1st.

Money for Free Hospitals.—The Distributing Committee of the Hospital Saturday and Sunday Association of New York City, met on April 15th and apportioned about $70,000 to hospital funds. About $9000 was disposed of in accordance with special bequests. After deducting $3000 for general expenses $58,000 was apportioned among the various free hospitals in this city, the apportionment being based on the number of days of free treatment in each hospital.

The New York Colored Home and Hospital.—The sixtieth anniversary of this institution is to be celebrated on Saturday, April 29th. The main feature is to be the dedication of the new buildings erected last year at One Hundred and Forty-first street and the Southern Boulevard. These buildings include a district general hospital department, with a modernly equipped operating-room; a maternity pavilion, and a phthisis pavilion, in addition to a convalescent and home department.

"The Practitioner's" Cancer Number.—The last number of *The Practitioner*, the London monthly medical journal which, under the able editorship of Mr. Malcolm Morris has come to be one of the best of the medical monthlies published in English, is entirely devoted to cancer. Among the articles are: "A Further Inquiry into the Frequency and Nature of Cancer," by Roswell Park, which appeared simultaneously in the MEDICAL NEWS; "The Medical Geography of Cancer in England and Wales," by Alfred Haviland; "The Local Distribution of Cancer and Cancer Houses," by Darcy Power, and "The Treatment of Inoperable Cancer," by William Coley of New York.

The Insane in the State of New York.—The annual report of the New York State Commission in Lunacy was presented to the Legislature at Albany on April 10th. The committed insane of the State, public and private, at the close of the year numbered 22,386, of whom 20,845 were in the State hospitals, 686 in the Matteawan State Hospital for Insane Criminals, and 855 in private institutions. The number of original admissions during the year was 4473. There were 1757 deaths, and 1018 patients were discharged from the State hospitals as recovered. The net increase in asylum population was 683. The average daily per capita cost of food supplied for the insane of the State is now 15⅓ cents.

The Army Beef.—Most of the testimony given concerning the beef used by the United States Army in the late war has been condemnatory. It is only fair to present some which is the reverse. On March 31st Colonel and Assistant Surgeon-General Charles R. Greenleaf, who was with General Miles at Puerto Rico, testified that he had no fault to find with the refrigerated beef; that the only important complaints he had heard related to the character of the cooking; that the canned beef, although unpalatable, did not seem to him detrimental to health, and that he attributed the sickness among the soldiers solely to the climate. On April 5th Professor Chittenden of Yale testified before the Court of Inquiry that all the canned samples were within the range of good food, that his analyses failed to disclose any trace of salicylic or boric acid, and that all the canned beef contained proteids in good proportion.

The Health of the Pope.—So much that is contradictory has appeared in the daily papers as to the Pope's health that the following account of it gathered from authentic sources by the Roman correspondent of the *British Medical Journal* will be of interest to medical men. He says: "Notwithstanding the alarming reports that have lately appeared in some of the English and Continental papers I am able to state on the authority of Professor Mazzoni (who did the operation) that the health of the Pope is now (end of March) very satisfactory. The operation wound has been quite healed for some time and His Holiness has resumed his ordinary duties and occupations. He naturally still feels a little weak from loss of blood and the effect of the operation; but I learn from other sources that he is very cheerful, that his mind is as clear as it has ever been and that he has lately seen many persons besides those he has to see in an official capacity."

The American Public Health Association.—At the meeting of this Association, held in September, 1898, it was decided to organize a standing committee of the Association, composed of those actively engaged in laboratory work in connection with health boards. The chief development in sanitary science is dependent upon laboratory work, especially bacteriology, and therefore it has seemed desirable to have some central organization which could further this work both in scientific and practical directions. A temporary organization has been effected, and the first general session of the committee will be held October 30, 1899, the day previous to the opening session of the general meeting at Minneapolis. Professor Welch of Baltimore will act as honorary chairman. The line of work proposed is the presentation of original short papers giving summary reports of work accomplished during the year; also reports of cooperative investigations, etc. Further information may be obtained from Dr. Wyatt Johnston, 74 Shuter street, Montreal.

The New York Board of Health May Stop the Sale of Its Serum.—On Saturday morning, April 15th, by special appointment Colonel Michael C. Murphy, President of the Department of Health, gave an audience to a delegation of

physicians, druggists, and business men who presented the desirability of discontinuing the sale, by the Board, of its surplus serum. The office of the President of the Board of Health was crowded with those who appeared in favor of this movement. President Murphy replied in very frank and encouraging statements of his aims in the matter. He deprecated anything which might seem to be a reflection on the probity of the department involved in some late criticisms in the lay press. He said that at the present time the ablest of the clerical staff of the department were engaged in compiling for his information the full figures of the business done in the sales of antitoxin and other statistics which would assist him in coming to a decision. He said that he had been informed by some physicians that antitoxin would keep for but fifteen days, and if that were so it seemed to be an argument in favor of the sale of the article by the city. He had just been told by Dr. Wilcox of the opinion of one expert that antitoxin would keep for eighteen months, and after that would deteriorate but slowly. This was new to him, and he should like further information on that point. Colonel Murphy spoke with much feeling of the care which he gave to superintending the operations of the Department of Health and made it plain that in all that was done in this antitoxin, as in other matters, his first thought was to secure the best results for the city. Further, he said that he was convinced that the Department should stop the manufacture of antitoxin except for its own use or for any emergency that might arise. In this friendly interchange of opinion evidently lies the hope of this reform. It is entirely in consonance with the suggestion recently advanced by the MEDICAL NEWS.

Loomis Laboratory Is Sued.—The New York University has applied for an injunction to restrain the Loomis Laboratory from in any way excluding the professors and students of the university from enjoying its use. It is further claimed that the Laboratory Trustees have threatened to hand it over to another institution. The complaint states that the university was incorporated in 1831, and that the Loomis Laboratory was founded by Dr. Alfred L. Loomis in 1887. Afterward a friend of Dr. Loomis, who belonged to the New York University, contributed a large sum of money and the laboratory was built, privileges to use and enjoy it being extended to the faculty and students of the university. It is alleged that in 1897 certain of the trustees of the laboratory became disaffected and resigned, and then took advantage of the positions which they had held to deprive the professors and students of the university of the privileges which they had enjoyed. On April 14th a bill was passed in the Senate at Albany authorizing the Loomis Laboratory to convey its real and personal property to Cornell University.

Prussian Hospital Investigation of Experiments on Patients.—Dr. Bosse, the Prussian Minister of Education, has ordered an investigation into Professor Foerster's charges that experiments, sometimes of a serious, even dangerous character, are performed upon patients in Prussian hospitals. The University Clinic at Breslau is especially charged with being the seat of such experiments. The matter came up first in the Reichstag on March 11th. Undoubtedly much exaggeration has been indulged in in the statement of the liberties taken with patients, but there seems to be reason to infer that indiscretions had been tolerated. A thorough investigation, in which both sides may be heard, will be welcome to the medical world. For some time we have been flooded by a deluge of unsubstantiated reports of experiments upon human beings in various Continental clinics. The names of certain men, well-known in medical literature, and whose work for medical science places them deservedly high in the estimation of the medical profession, have been dragged into the matter, and an opportunity will be afforded them to rebut the exaggerated, detracting reports that have gone abroad.

CORRESPONDENCE.

THE DANGERS OF INCOMPLETE ANESTHESIA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—The MEDICAL NEWS in a recent number gives a note of a death during tooth extraction, and giving advice never to begin operative procedures in chloroform narcosis until the patient is completely anesthetized.

I believe if reliable statistics were prepared they would show that more deaths were caused by chloroform, when being given for small operations, and especially those due to the extraction of teeth, than by any other cause. On investigation of these deaths it is generally shown that a very small amount of the anesthetic was used. This is where the danger lies, especially during the extraction of teeth. The clearest article on this subject is given by T. Lauder Brunton in "Disorders of Digestion." It is thus explained: "I mentioned that one cause of death during the extraction of teeth, under chloroform, was probably the stoppage of the heart's action through the inhibitory fibers of the vagus, associated with a reflex depression of tone in the blood-vessels. The reason why the extraction of a tooth in a person who is not under the influence of an anesthetic is followed by no ill effects is probably this: that in him the irritation of the fifth nerve produces two distinct actions which counterbalance each other. It may cause reflex stoppage of the heart through the vagus; but at the same time it causes reflex contraction of the vessels through the vasomotor center. This contraction of the vessels maintains the pressure in the arterial system during the stoppage of the heart, and thus no harm whatever is done. When an anesthetic is used, however, one of these pieces of nervous mechanism may be paralyzed by it while the other is not, and thus the extraction of the tooth may stop the heart without causing contraction of the vessels. The blood-pressure will then sink very rapidly in the arterial system and fatal syncope may be produced. If, however, the anesthetic be pushed to a greater extent, so that both parts of the nervous mechanism just mentioned are paralyzed, the vessels are not contracted, but neither is the heart stopped. The

operation is, therefore, comparatively free from danger when no anesthetic has been given, or when the anesthesia is perfectly complete, *the period of danger being that of imperfect anesthesia.*"

HARRY MORELL, M.D.

SLAYTON, MINN., April 12, 1899.

CONSCIOUSNESS DURING ANESTHESIA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In reference to the very interesting communication from Dr. Goldan, published in the last issue of your journal, in regard to the persistence of consciousness during chloroform anesthesia, I beg leave to report the following very similar case: Last spring I performed a plastic operation upon a patient for an extremely marked relaxation of the pelvic floor. The anesthetic—chloroform—was administered by Dr. G. G. Fischlowitz, and when the patient was put upon the table she was completely "under." During the course of the operation the doctor let her "come out" somewhat and noticed that she winced slightly. To test the depth of the narcosis he asked her whether she felt any pain, and was surprised to see that she nodded her head in response to his query. He thereupon added a few more drops of the chloroform on the mask, and this time his question as to pain met with an answer in the form of a negative shake of her head. He then, with great ease, kept her in the condition in which she was conscious of all that went on around her, yet had absolutely no pain. After her recovery from the effects of the anesthetic she assured me that, while fully aware of each time that I touched her, she had felt no pain whatsoever, and that, moreover, she knew all that had gone on about her, repeating conversation, recalling incidents, etc., exactly as Dr. Goldan's patient did. Her "coming out" was simply a restoration to full from slightly clouded consciousness and was characterized by an evident desire on her part to be left quiet and undisturbed, instead of the usual manifestations under such circumstances. She vomited some during the operation. Were it not for the total absence of pain throughout the operation one would readily and justly conclude that the case was one of incomplete anesthesia, but that one fact makes it clear to my mind that it was one which can well be classed with that reported in your journal.

Yours very truly,

L. M. MICHAELIS, M.D.

NEW YORK, April 15, 1899.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

STATE APPROPRIATIONS FOR HOSPITAL MAINTENANCE—THE NEW BUILDINGS OF THE GERMAN HOSPITAL—DANGERS OF HYDROGEN PEROXID IN SURGICAL CASES—EXTRA-PERITONEAL EFFUSION DUE TO SPONTANEOUS RUPTURE OF THE UTERUS—PERSONAL NOTES—OBITUARY—HEALTH NOTES—HEALTH STATISTICS.

PHILADELPHIA, April 18, 1899.

A DEPLETED State treasury is responsible for the lack of many appropriations which were counted upon for the erection of new buildings for various hospitals in this city and throughout the State, and for the small maintenance appropriations which have been made to many. All sums of money asked for erecting new buildings or improving old ones have been vetoed, and thus many contemplated improvements have been put aside for two years at least. Among the larger sums granted for maintenance for the two years of the present Legislature are the following: South Side Hospital, Pittsburg, $20,000; Philadelphia Polyclinic, $25,000; Pottsville Hospital, $20,000; St. Luke's Hospital, Bethlehem, $22,000; University of Pennsylvania Hospital, $50,000; Gynecean Hospital, Philadelphia, $20,000; Homeopathic Hospital, Pittsburg, $50,000; German Hospital, Philadelphia, $20,000; Allegheny General Hospital, $40,000; Jefferson Medical College Hospital, $50,000; Mercy Hospital, Pittsburg, $20,000; Hahnemann Hospital, Philadelphia, $50,000; Homeopathic Medical and Surgical Hospital Dispensary, Pittsburg, $50,000; Medico-Chirurgical Hospital, Philadelphia, $70,000.

While a vast amount more has been apportioned among several minor hospitals, the appropriations in general force the conviction that in this question, as in every other in which politics enter at all, political pull is much more a factor than merit, and some of the above allotments are as manifestly unnecessary as others are inadequate to meet the needs of the case.

John D. Lankenau, President of the Board of Trustees, last week formally turned over to the German Hospital, in addition to the Mary J. Drexel Home, which he erected, the new buildings which he has also erected in memory of his wife. The new buildings consist of a completely equipped hydropathic establishment, an enlarged and improved laundry plant, a new mortuary chamber, with additions for all scientific work which can be done close at hand. Extensive alterations and improvements in the three upper stories of the main hospital building have also been made.

At a meeting of the Philadelphia County Medical Society, April 12th, Dr. George W. Spencer read a paper on "The Dangers of Hydrogen Peroxid in Surgical Cases," in which he advised the utmost caution in using this agent in certain conditions. He believes that it has the power of forcing pyogenic organisms from the original focus to the deeper parts, thus setting up secondary infections, and quoted several cases to substantiate his views. One case was that of carcinoma of the left breast, in which, after the breast and axillary glands had been removed, peroxid was used to cleanse a small granulating surface. At the end of a few days, new sinuses had developed in various directions, and had extended down between the muscular layers. Spencer believes, further, that its explosive force in the tissues is very great, and that nerves, tendon-sheaths, and muscle-planes offer every advantage for its track. He gave a useful summary of the conditions and localities in which it is distinctly contraindicated. Dr. H. Augustus Wilson, in the discussion, called attention to the danger of using it in any cavity where the opening is small, and recalled a case of psoas abscess, which he knew of,

where the injection of peroxid was followed by a rupture of the abdominal wall, with protrusion of the intestines. He advises the use of compressed oxygen in place of peroxid, and said that he and his assistant, Dr. Rugh, had used oxygen with very satisfactory results. Dr. Mordecai Price protested against the use of injections of peroxid in any case, and said that if micro-organisms were found in places where the peroxid had burrowed, it would certainly show the uselessness of employing it, for it was evidently not only harmless to the organisms but harmful, in that it caused them to spread, and forced them into clean tissues. Dr. S. Solis-Cohen said that many labored under the delusion that peroxid was a germicide while it was not, its sole property being that of a cleansing agent for the removal of débris.

Dr. Reynolds Wilson reported a case of "Extra-Peritoneal Effusion Due to Spontaneous Rupture of the Uterus; Death from Pyemia." Labor progressed normally, the placenta being delivered fifteen minutes after the child was born, and until six hours later nothing wrong was suspected. As in most cases of "silent-rupture" pain, referred to the rectum, was not felt until this time, when it became quite severe, and was accompanied by uterine bleeding. On the second day, abdominal distention, bloody stools, and tenderness on pressure became manifest, and a tumor could be palpated. As the diagnosis was uncertain and the patient's condition poor, surgical interference was not resorted to, and death took place on the forty-fourth day from pyemia. The post-mortem showed that a hematoma had formed in the broad ligament, which had increased in size so as to finally give rise to pain and other symptoms. Later, infection had taken place from the vagina. In the discussion which followed, Dr. Richard Norris said that he had never had a case of uterine rupture, but, in his opinion, surgical interference was called for. Dr. Price spoke of three cases of rupture which he had seen, and stated that it was, in his opinion, generally due to version. He also believes in early surgical interference, and does not believe in running any chances with the idea that the hematoma may be absorbed.

Dr. Henry C. Chapman sails for Europe on Saturday, partly for pleasure and partly for the purpose of purchasing instruments for the laboratories of physiology which are to be opened in the new buildings of Jefferson Medical College next fall. A thorough practical course is to be given in physiology, with experimental work.

Dr. A. Robin of Philadelphia has been appointed State Bacteriologist of Delaware, and is to have charge of the bacteriology station at Delaware College. Dr. E. W. Cooper of Camden has been elected president of the State Board of Health, and Dr. Alexander Lomber of Wilmington, secretary.

Dr. James McAlpin Sommerville died at his residence in this city on April 11th of Bright's disease, aged seventy-four. He was celebrated as an artist, scientist, and scholar. Dr. D. L. McDonald died April 11th at his home in Shiremanstown, aged fifty-seven. Dr. William Blackwood, president of the Lancaster City and County Medical Society, died April 12th, aged seventy-one.

The epidemic of cerebrospinal meningitis which has been ravaging Lancaster seems to be about over, no cases having been reported for nearly a week. During the epidemic fifty cases with thirty-one deaths were reported to the Lancaster Board of Health.

The total number of deaths occurring in Philadelphia during the week ending April 15th, as reported at the Health Office, was 520, of which number 153 occurred in children under five years of age. The total number of new cases of contagious diseases was 351, reported as follows: Diphtheria, 50 cases with 18 deaths; scarlet fever, 50 cases with 4 deaths; typhoid fever, 251 cases with 38 deaths.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

MEDICAL LEGISLATION IN ILLINOIS—MAYOR HARRISON ON SANITARY IMPROVEMENTS—SCARLET FEVER IN CHICAGO.

CHICAGO, April 18, 1899.

THE Illinois Medical Practice Act has passed the Senate and has been read a second time in the House. This act provides, as amended, that all candidates for the practice of medicine, except graduates of legally chartered medical colleges of good standing in Illinois, shall be examined by the State Board of Health. It also provides for partial examination for special departments or systems, but only those licensed fully in medicine and surgery shall have the right to call or advertise themselves physicians or doctors, and licentiates of other systems cannot use drugs or perform surgical operations, or those in midwifery attend other than labor cases. The State Board of Health can refuse certificates for conviction of criminal abortion or to those who have made fraudulent representations or been guilty of other dishonorable or unprofessional conduct, and can revoke them for the same reasons after hearing before the Board. Itinerant venders of nostrums, etc., shall pay a license fee of $100 per month. The usual exceptions of those already licensed, medical officers of the army or navy or Marine Hospital Service are made, aud there is also a special exception of those who treat the sick by mental or spiritual means without drugs or material remedy. Penalties are provided for infraction of the law.

Another bill of medical interest, now on second reading in the House, having passed the Senate, is one amending the law of corporations which requires the Secretary of State, on recommendation of the Attorney-General, to revoke the charters of fraudulent diploma mills. Still another bill before the House is one to establish an epileptic colony, and making a preliminary appropriation for selecting a site for the same.

Carter H. Harrison, who was reelected Mayor of Chicago, in his second inaugural address, April 10th, took occasion to pay a tribute to the Chicago Health Department, in speaking of the financial value of sanitary improvements. He said: "The tabulations and deductions indicate, among other things, the unceasing vigilance of the Health Department in all matters affecting the public health. In many respects it now stands among the very

foremost of similar establishments in the world. It was the first to use the glycerinated vaccine, which has done more to popularize vaccination than anything in this connection since Jenner's day. Its work in the treatment of diphtheria, by which the mortality of the disease in this city has been reduced from more than thirty-five to less than seven in every hundred cases treated by its medical inspectors, its investigations of the germ of influenza and the resulting improvement in the methods of dealing with this disease, and, still more recently, its identification of the organism of scarlet fever which makes it possible that this scourge of the nursery shall be handled as successfully as diphtheria now is—are attracting the attention of sanitarians both in this country and abroad. The *British Medical Journal* has editorially commended to the attention of the local Government Board of London the sanitary machinery of Chicago in dealing not only with smallpox, but with diphtheria and dangerous infectious diseases. Chicago has reason to be proud of its Department of Health."

Scarlet fever is prevalent in several of the school districts and every precaution is being taken to prevent a spread of the disease among the children. The Department of Health has had reported to it by physicians, during the last week, one hundred cases of scarlet fever and diphtheria, principally among children.

The number of diphtheria cases among adults has been so large during the same time that the wards of the county hospital are too crowded to admit more patients. This also applies to the scarlet-fever ward. A number of cases reported to the hospital were refused admission because of lack of room. If the disease continues to increase until it assumes the proportions of an epidemic some provision for the care of the victims must necessarily be made by either the city or county. Chairman Healy of the Public Service Committee says that the county is powerless to act at present, and that, as it is the duty of the city to care for the indigent sick when the wards of the hospital can no longer receive patients, it is expected the city will make arrangements for caring for any more victims of either disease who might be thrown on public bounty.

The scarlet fever prevalent among children is of a mild type, and except in comparatively few cases has not proved fatal.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE PRESIDENCY OF THE COLLEGE OF PHYSICIANS CONFERRED ON DR. W. S. CHURCH—INHUMANITY OF MILITARY PUNISHMENT—ROYAL COMMISSION ON LONDON'S WATER-SUPPLY—THE MICRO-ORGANISM OF CANCER—WORTHLESSNESS OF CERTAIN WIDELY ADVERTISED SUBSTITUTES FOR COD-LIVER OIL—RANDOM NOTES.

LONDON, April 7, 1899.

THE annual election of the College of Physicians resulted in conferring the honor of the Presidency upon Dr. William S. Church, Senior Physician to St. Bartholomew's Hospital. The sacred principle of official seniority would appear to have been most potent in this selection, as, although the new president's scientific attainments are most respectable yet the bare list of some of the names which were prominently mentioned for the position—Hughlings Jackson, Dickinson, Broadbent, Gee — is enough to suggest at once the cynical old proverb about a prophet in his own country.

A good deal of unpleasant comment upon the inhumanity of the military authorities has been caused by the sudden death of a young private in the Lancers in a military prison. The young fellow had been guilty of some slight offense against discipline, for which he was condemned to imprisonment with hard labor, the latter taking the form known as "carrying the shot," in which a small cannon-ball is carried *ad infinitum* from one to another of a circle of iron cups or sockets arranged round the room or yard, a perfectly asinine survival of the old primitive labor of the treadmill type, which has been abandoned almost everywhere else in the civilized world. To this punishment the offender demurred on the ground of illness and physical incapacity and the prison physician was called in. After a brief examination this worthy declared him to be simply malingering as, of course, he was bound to out of proper respect for the powers that be, and the young fellow was set to work with the shot, but suddenly fell and died with symptoms of heart mischief, after some twenty rounds. Even the official mind could now see that there was probably something worthy of real investigation in his case and a post-mortem was held, upon which the fearful and wonderful finding was rendered by a cabinet minister to an indignant House of Commons, of death by "blood-clot in the aortic ventricle," whatever that may be. We have all heard of the German clinician who always preferred to check his diagnosis by a post-mortem before giving a definite opinion, but there appear to be some army surgeons in England who can't make a decent diagnosis even then. As far as can be gathered from the admissions of the report death was due to aneurism of the aorta. To make the matter worse it was elicited during the discussion in Parliament that the physician who made the disgraceful "malingering" diagnosis was not even a registered practitioner. The entire distressing episode is a typical example of the strong natural tendency of officialdom toward both brutality and stupidity unless sharply watched and controlled by public opinion, and it has raised such a storm of indignation as will hardly be appeased by less than a thorrough modernizing and humanizing, as far as may be, of military punishment and prison discipline.

The Royal Commission upon the water-supply of London has at last concluded its sittings and its report may be looked for at no distant date. The water-barons are making a desperate fight to hold their lucrative monopolies, and to prove that water from the Thames and the Lea is not only harmless but even nutritious and much preferable in every way, to the storm-washings of a Welsh mountain valley. In spite, however, of all this, and of the natural reluctance of the public to spend enormous sums for protection against a hitherto merely possible danger the conviction is steadily spreading that the only course which will be either safe or adequate will

lie in the direction of securing a new and distant source of supply. As was well said in the County Council's Committee report filtration can only be expected at best to remove ninety per cent. of the bacteria, and if but one per cent. of the "survivors" happen to be typhoid bacilli, it would be more tolerable for Sodom and Philadelphia in the day of judgment than for London with its enormous "submerged filth."

Dr. T. Grigor Brodie of St. Thomas' Hospital has been appointed Director of the Conjoint Laboratory of the Colleges of Physicians and Surgeons to fill the vacancy caused by Sims Woodhead's removal to Cambridge.

At the last Royal Society meeting a short report was read by Plimmer, alleging the discovery of a new solution of that pathological "squaring-the-circle" problem, the micro-organism of cancer. He has succeeded in isolating from human carcinomata a yeast (saccharomyces), pure cultures of which, on injection into the tissues of guinea-pigs, are capable, in a small percentage of cases, of producing a large number of disseminated nodes or tumors throughout the entire body of the animal. As, however, these growths are all confessedly of mesoblastic origin they can certainly hardly be claimed as carcinoma, and from their rapid course (death in twenty days) and histologic characters they decidedly suggest some form of infectious granuloma. In only one case did Plimmer succeed in getting any epithelial proliferation in buds or processes and that was in the cornea and precisely such as occurs in the process of repairs after injury.

Robert Hutchinson has done an excellent little piece of work and rendered the profession a real service by carefully analyzing the stools of individuals taking petroleum in any form. As was long ago declared upon chemical grounds petroleum, vaselin, paraffin, etc., were absolutely unassailable by any of the digestive fluids and yet a large vogue has of late years been given to various petroleum emulsions as "substitutes for cod-liver oil"—chiefly by ingenious and unterrified advertising. Hutchinson tested the question physiologically by administering an emulsion in varying doses to a number of persons, the fat content of whose stools had been carefully ascertained, and then collecting their feces and extracting and estimating the additional fatty matters. In every case he succeeded in recovering within a few grams, in some cases to the very gram, of the amount of petroleum administered by the mouth. So that the nutritive value of the emulsions is absolutely *nil*, and as substitutes for cod-liver oil they are impudent frauds upon public and professional credulity as we have long suspected in spite of the array of expert "testimonials" so skilfully paraded by "Terralene" and others of its class. They may have a small value as lubricants and protectives of the alimentary mucous membrane, indeed the only results we have ever seen from them was in a patient who was delighted with the "nice, easy, greasy stools" they produced, although he complained of the continual oiliness of his clothing in the neighborhood of the anus.

The formal opening conversazione of the London Polyclinic and Medical Graduates' College is announced for May 1st, in their new building in Chenies street. The lectures and demonstrations begin May 3d. The institution has adopted as its motto the strikingly appropriate line from Browning: "It is the taught already that profit by teaching."

The Cremation Society of England held its quarter centenary last week under the distinguished presidency of Dr. Henry Thompson, whose official address took the form of a brief sketch of the history of the organization. The severity of its struggle for existence, "not against flesh and blood, but against the powers of (scientific) darkness" in the form of the bishops, may be judged from the fact that it was prevented from erecting a plant at all for three years, and when at last it did attain one at Woking it lay absolutely idle for *nine years* under legal embargo except for the occasional cremation of a dog or sheep to prove to the local authorities that the process could really be carried out without giving rise to a public nuisance in the way of smells and fumes. And, in fact, the taboo was only removed at last by bringing a private case of cremation into court and getting a ruling from the bench declaring the process legal and permissible. Since this date its progress has been unhindered and the number of cremations rose from 3 in 1885 to 240 in 1898, making a total of 1283. A mere flea bite upon the total of burials in England of course, but a fair start has been made and the process given a chance of proving its value and desirability.

The report of the Royal Commission upon the question of lead as a glaze in the potteries is attracting wide attention. The commissioners show that about 1 in 300 of the workers employed in the glazing and firing departments of English potteries die of saturnism, and that for some curious reason girls are nearly three times as susceptible to the poison as boys and men. Probably from their inveterate habit of eating and "nibbling" between meals at their work. In view of these facts Drs. Oliver and Thorpe recommend that the use of raw lead as a glaze be absolutely forbidden, and the employment of girls in certain branches of the work be prohibited. Unfortunately, however, it seems to be admitted upon all sides, as confessed by Mr. William Rix in his recent lecture before the Society of Fine Arts, that while various leadless glazes have been invented, none of them will give the high gloss so dear to the housewives' hearts so certainly and so cheaply, nor is the finish produced by them as permanent. And as the dear public in spite of its sentimental sympathy for the workers, and enthusiasm for reform, will insist on having the handsomest pottery it can get for its money the conscientious manufacturer finds himself at a great disadvantage in the market. If, however, the Government would take vigorous action, as it certainly should, and place all makers upon the same level by absolutely forbidding the use of raw lead as a glaze no one could complain of unfairness, and both the worker and the public would be protected. We say the public because the experts have demonstrated the reassuring fact that some makers are so liberal with their beloved glaze that the pottery has enough plumbic deposit on its surface to impart distinct traces of lead to milk or other fluids kept in it.

The shameful injustice done poor Dr. Hunter, the L.S.A. who was prosecuted by a small-souled committee of the General Medical Council for putting "Physician" upon his door-plate is like Banquo's ghost, it "will not down" even after the victim's death. Some kind-hearted members of the profession whose humane feelings have not been frozen by lofty official position have been making inquiries into the financial condition of Dr. Hunter's young widow and find that their little all was invested—after the cheerful English fashion—in the purchase of a practice which was not only ruined, but its "reversion" rendered utterly valueless by the outrageous attack of the Penal Committee, so that the poor lady is practically destitute save for the outstanding accounts upon the doctor's books. A subscription for her benefit has accordingly been started in the columns of the medical journals and the profession is responding liberally. If the Penal Committee have any sense of the fitness of things left they will head the list as the least atonement they can offer.

EFFECT OF COLD ON THE LIFE OF NEW-BORN CHILDREN—MOTHER AND CHILD IN AN EXTRA-UTERINE PREGNANCY BOTH SAVED BY OPERATION—VOLVULUS OF THE SIGMOID FLEXURE—REDUCTION OF CONGENITAL DISLOCATED FEMUR—ANEURISMAL VARIX FOLLOWING A GUNSHOT WOUND—RESECTION OF THE SPERMATIC VESSELS FOR PROSTATIC HYPERTROPHY—A SPRAIN OF THE SACRO-ILIAC JOINT—OBSCURE SYMPTOMS OF GASTRIC ULCER—DISADVANTAGES OF PROLONGED INTUBATION—CHRONIC JAUNDICE FROM BILIARY INFECTION—ACTINOMYCOSIS OF THE JAW.

At the Academy of Medicine, March 14th, BUDIN said that he had observed 142 new-born children in whom the rectal temperature was 33° C. (91.4°F.) or less. Of these 139 died, giving a mortality of 98 per cent. The low temperature was not the only cause of death. Some of the children had syphilis, digestive disturbances, and so forth; but it is none the less true that the reduction in temperature was the chief factor. If every precaution is taken to keep up the temperature of the debilitated children from the time of birth, at least three-fourths of them can be saved, as statistics prove.

LUCAS CHAMPIONNIERE thought that cold plays an important part in the life and death of children which are born healthy, as well as those which are born debilitated. One cannot insist too much upon all measures which are calculated to keep up their heat. Among bad practices is the habit of nurses to bathe the child. Carried out as this usually is, the practice is none other than murderous.

PINARD showed a woman aged thirty-seven years, upon whom he had made a diagnosis of extra-uterine pregnancy at the sixth month. Six weeks later the abdomen was incised, and the child extracted. Both mother and child did well. The latter weighed 2875 grams (6 pounds) at the time of its extraction, but in three months its weight had nearly doubled. This might surely be spoken of as conservative obstetrical surgery.

At the Surgical Society, March 15th, ROUTIER mentioned a case of volvulus of the sigmoid flexure, treated with success by laparotomy. The patient was a woman who for five days preceding the operation had passed neither gas nor feces per anum, and whose abdomen had gradually distended in an even manner. The sigmoid was twisted from left to right, making a complete turn. For a year before the obstruction became complete, there had been several attacks of colic, which were explained, in the light of the lesion found at operation, as abortive attempts of the bowel to become obstructed.

MONOD showed a girl upon whom he had performed Lorenz' bloodless reduction of a congenital dislocated hip two years previous. The functional result was excellent.

KIRMISSON pointed out that the head of the femur in the case before them was not in the socket, but rested on the external surface of the ilium between the anterior superior and anterior inferior spines. While not denying the benefit obtained in a certain number of cases from Lorenz' operation, he thought that it was in only very rare instances that the head of the femur was really restored to its normal position.

BRUN said that he had employed the method referred to in many cases and that since seeing Lorenz himself operate he was convinced that imperfect results were due in part to a too gentle manipulation in the forcing of the head of the bone into its true position. He showed a number of radiographs, some of which proved that the head of the femur was in the cotyloid cavity, although the neck of the bone presented the characteristic deformity of coxa vera; while in others it could be seen how without the complete reduction there is sometimes a great improvement, and one capable of making still further progress. Perfect reduction is almost always possible in young persons, in whom the slightly developed muscular system opposes only a slight resistance comparatively speaking. His cases were too recent to permit him to speak of the final results.

CHAUVEL was called to see an officer who was shot in the hip. Six days later a swelling appeared at the lower and inner portion of the thigh, from which the ball was extracted, leaving a wound which healed by primary union. Later an aneurism appeared in Scarpa's triangle which had all the characteristics of an aneurismal varix. An incision was made over it, the vessels were ligated in four places, and the aneurism was dissected out. Such cases are extremely rare.

March 22d, MONOD spoke of a case of hypertrophy of the prostate causing retention of the urine. He punctured the bladder several times and then succeeded in getting a catheter into the bladder. He left the instrument in place but it was ill borne. The vessels of the cord were exposed and ligated, and in a very short time the catheter was well borne, and soon the patient was able to pass water voluntarily. The testicle underwent a slight atrophy, but did not at any time threaten to necrose.

REYNIER said that resection of the vas deferens gave the same relief as that mentioned by the speaker, and avoided the risk of affecting the testicle. He mentioned several successful cases, one that of a gentleman upon

whom a double operation had been performed. After three years there was still freedom from prostatic hypertrophy, while the sexual power persisted.

BAZY was unwilling to admit that resection of the vas deferens could produce any such results as had been attributed to it. He looked upon the cures narrated as mere coincidences. He had seen freedom from retention follow a simple catheterization. On the other hand, resection of the vessels of the cord, while it is often followed by atrophy of the testicle, has an undoubted effect upon hypertrophy of the prostate.

At the Medical Society of the Hospitals, March 10, 1899, GALLIARD told of a man who as the result of a violent effort, suffered a very acute pain at the lower end of the spinal column. The trouble was at first thought to be lumbago, but more careful examination showed the pain to be localized over the right sacro-iliac articulation, where there was a small ecchymosis. There was a sprain of this joint in other words. During a week's rest in bed the patient suffered no inconvenience, but when he got up and attempted to go to work, he had pain in the back of the hip and thigh, as low down as the knee. As there was no trouble with the bladder or rectum, it seemed probable that the pain was due to a neuritis of the lesser sciatic nerve.

FLORAND mentioned the case of a man aged forty years who died suddenly while at work with all the symptoms of internal hemorrhage. At autopsy there was found a stomach full of blood which had issued from a small ulcer of the lesser curvature. The man had never had symptoms which had been diagnosed as due to an ulcer of the stomach, but had complained of intense paroxysmal pain along the edge of the false ribs of the left side, and upward into the sternum. He was treated for this by several physicians, and once was put upon a milk diet, but all without benefit.

RENDU said that he had under his charge a girl with symptoms similar to those mentioned. She had attacks of pain radiating along the sternum. They only occurred when the stomach was full, and in the upright position. He thought that there was a perigastritis with an adhesion between stomach and diaphragm. Certainly such attacks of pseudo-angina ought to make one think of the possibility of a gastric ulcer.

March 17th, SEVESTRE spoke of the treatment of spasm of the larynx, necessitating prolonged intubation or tracheotomy. Under such circumstances there is generally an ulceration of the space below the glottis. In order to avoid this, the tube should be withdrawn after it has been in place for two or three days, and it should not be introduced again, unless threatened suffocation makes it imperative. Such attempts at discontinuance should be repeated at intervals for six or eight days, though if the tube comes out bright one may replace it with the knowledge that there is no ulceration. If, however, it is discolored, it should not be allowed to remain in place longer than a week. If then the child cannot get on without it it is better to perform a tracheotomy. Practised thus early the results which follow tracheotomy are better than if it is longer delayed. In any event the remedies likely to reduce spasm, such as bromids, chloral, codein, antipyrin, cold applications to the chest, etc., must not be neglected. If there exist foci of bronchopneumonia, it is a delicate question whether tracheotomy or prolonged intubation will be productive of the least harm.

MARCH 24th, HAYEM mentioned that he had recently seen four cases of chronic icterus, in which the skin was about the color of the skin in xanthochromia, rather than that seen in acute jaundice. The stools were neither decolorized nor bilious. There were no biliary pigments in the urine. The liver was slightly increased in size; the spleen was normal. The icterus developed gradually and persisted a long time in varying intensity. All of these patients suffered from indigestion, and all were neurasthenic with a marked tendency toward nosomania. In the light of these facts he looked upon the icterus as due to a secondary infection of the biliary passages.

At the Society of Dermatology and Syphilography, March 9th, LEGUEU showed a patient who began to complain last July of violent pain in the left side of the head without any apparent lesion. Five months later a swelling appeared in the mastoid region of that side, and still later at several points on the left side of the neck there appeared swellings which seemed to proceed from the deeper to the more superficial parts, and finally to reach the surface and discharge a thin fluid with characteristic grains of actinomycosis. The patient had been put upon the iodid of potash in large amounts, with an irregular improvement.

BESNIER mentioned a similar case in which the only symptoms for five or six months were pain and difficulty in opening the jaw. The diagnosis was not made until the swelling appeared and discharge took place. Now he endorsed the aphorism of Poncet, that "every patient who without apparent reason cannot open his mouth, has actinomycosis."

SOCIETY PROCEEDINGS.

THE GERMAN MEDICAL SOCIETY OF NEW YORK.

Regular Monthly Meeting, Held at the Academy of Medicine, April 3, 1899.

THE President, DR. HERMANN G. KLOTZ, in the Chair.

DR. FREUDENTHAL presented a case of osteosarcoma of the nose and of the upper jaw. The patient first presented herself for treatment only eight weeks ago because of what she thought was a cold in the head, with persistent plugging of the nostrils, especially the right one. Examination disclosed the presence of a hard tumor in the region alongside the right nostril, which bled very easily and invaded and occluded the nostril. The patient knew that there was a swelling in the upper jaw, but attributed it to a chronic inflammatory condition at the roots of the upper teeth, so that the tumor had been allowed to become inoperable before consulting a physician. It had been very difficult to secure from within the

nose portions of the tumor for microscopic examination. The snare slipped off the hard tumor itself and caught only portions of the overlying soft tissues. Enough however, had been secured to substantiate the diagnosis of sarcoma.

Dr. Heitzmann had examined portions of the tissue removed from within the nose, and said that it was sarcomatous, with a mixture of certain mucoid elements, that is, was a myxosarcoma. The only difficulty had been in differentiating it from syphilis. Typical granulomatous masses were not so frequent as they would have been if it were syphilitic, and the blood-vessel changes were rather those of a neoplasm than of syphilis.

Dr. Gerster presented a case of fracture of both bones of the arm, caused by a kneading-machine in a bakery, that had healed with considerable deformity and the production of a false joint, making the arm almost useless. He had grooved and morticed the bones so as to preclude motion in the ends, and had fastened them with silver wire. Good union it would appear was going to eventually result.

Dr. H. J. Boldt presented an eight-months fetus that had been removed from the abdominal cavity. The case had all the appearances of being one of primary abdominal pregnancy. The fetal sac had practically all disappeared. The specimens had been sent to Professor Welch at Baltimore, however, and he had found some of the fimbriæ of the tube still adherent to the sack. The right tube was lengthened but seemed healthy, and it had been thought to have been merely the seat of an old salpingitis. But it was evident on further consideration that the pregnancy had originally been tubal, but rupture had taken place at a very early period. The pregnancy had continued in the abdominal cavity, the placenta securing its nutrition by adhesions to the intestines. The patient recovered promptly after the operation for the removal of the products of the extra-uterine pregnancy had been done, and has had no sequelæ of the serious condition.

Dr. Achilles Rose read a paper on

THE TERM "APPENDICITIS" AND OTHER UNSCIENTIFIC WORDS THAT HAVE FOUND THEIR WAY INTO MEDICAL LITERATURE.

Dr. Rose considers that the hybrid term appendicitis, a Latin word with a Greek termination, and other such inconsistent compounds deserve no place in serious scientific medical literature, and suggests that in the formation of such words when they are to be Greek derivatives in form the genius of the living Greek language as it still exists and the usages of the modern Greeks in their own tongue should be consulted. The trouble in suggesting a substitute for our present hybrid term is that the idea conveyed by the word is comparatively new and has spread from America, the land of its discovery, but gradually. The modern Greek medical men have as yet adopted no definite medical term for themselves, but have clung for the most part to the old terms, paratyphlitis and perityphlitis, understanding of course that in the majority of these cases the appendix is primarily at fault.

The term for appendix in Greek is skolex, σκόληξ, so that it is probable that the term used by Professor Nothnagel, in the volume of his special pathology and therapy on "Intestinal Diseases," namely, skolekorditis, will be the one eventually adopted by the Greek physicians. It constitutes the most logical term and is philologically faultless. Other terms without the hybrid character of appendicitis have been suggested by various writers, but it does not seem that any of them will attract serious attention enough to be adopted. Professor Küster of Marburg, for instance, has suggested epityphlitis, the appendix being the epityphlon, or addition to the typhlon or cecum. Then ecphyaditis is unobjectionable, but too unfamiliar and unusual.

If the present agitation as to the undesirability of appendicitis and like terms does not accomplish any more than to arouse the attention of discoverers to the propriety of being sure of giving properly constructed names to their discoveries before launching them on the ocean of medical literature it will not be without an effect worthy in a certain degree of the effort expended on it. As it is we are being deluged with the most outlandish words—colpitis and pericolpitis, conjunctivitis, and the like. Even very familiar words of seemingly legitimate origin prove not to be so on closer examination. Polypragmasia, a word of Greek elements it is true, but utterly opposed to the genius of the Greek language, is coming in. The word polyclinic is open to the same objections. It would better be astyclinic, a city or public clinic. Pathology, in the sense it is used in the titles of German text-books on the practice of medicine, "Pathologie und Therapy," should rather be nosology. The science of diseases not the science of suffering is intended. Pathogeny, the origin of suffering, should always give way to nosogeny, the science of the origin of disease. To keep our Greek medical derivatives etymologically correct there should be an international committee of medical men, with regular sessions at Athens, a sort of academia della crusca græca,

In discussion Dr. Arpad Gerster said that while the term appendicitis is undesirable from a philological standpoint he thinks that it has secured such a firm foothold in medical literature all over the world that it will be impracticable to attempt at this late day to replace it by some more correctly derived term.

Dr. Abraham Jacobi said that entirely too much weight is given to the hybridity of appendicitis by advocates of consistency and correctness in terminology. These men, even so great a purist as Virchow himself, used the word terminology without objecting to it, and yet it is a compound of *terminus* from the Latin and λογος from the Greek. There are too many such hybrid words that have crept into general medical usage for us to hope to eliminate them all. Dr. Jacobi himself has always insisted on using the term amygdalitis in preference to the hybrid formation tonsillitis, but the looks on his hearers' faces have often compelled him to explain what he meant. We cannot hope to utterly replace by other more correct terms such commonly known expressions as vulvitis, ovaritis, vaginitis, strumitis, conjunctivitis, mediastinitis, and the like, however, incorrect

they might seem to be, and how much so ever they might make the utter purists in language shudder. There is just as important a series of errors committed in the pronunciation of medical terms, yet there is not so much protest in the matter. If we are to follow the genius of the Latin language we should say abdomen (long o), not abdomen (short o); vertigo, *ee*go, not vertigo (short i); tinnitus, long i, not short i. While, if we follow the Greek in the same way we should say, diágnosis (accent on the ag and short o), not diagnosis (with long accented o); diapedesis, not diapedésis; diaphóresis, long *e*, not diaphresis, long *e*.

Even the Latins themselves had not been what might be called perfectly consistent in the formation of words in their own language; from dens, for instance, they derived the objective dentatus; from mens, mind, mentalis; from menses, months, menstruus and menstrualis; from mons, montanus; from pons, pontilis, and so on. Too much in the matter of word-consistency should not be demanded then of the moderns. Usage is more powerful than any set of iron rules and will prevail in the end. As for himself Dr. Jacobi finds pathology and pathogeny quite as good as nosology and nosogeny, and thinks it is hypercritical to find fault with them.

DR. R. STEIN then read a paper on

SOME EXPERIENCES WITH APPENDICITIS.

It contained a very exhaustive review of the whole subject, notable, especially, for its excellent division of the various forms of appendicitis that occur, and pointing out that the indications for treatment depend not so much upon the recognition of the patient's condition as appendicitis as upon the form of the affection that he is suffering from. The advance to be made with regard to the disease lies in the clinical differentiation of the limits of various types of the disease, and consequently the method of treatment suited to a given case. Dr. Stein pointed out, however, that by universal agreement of all the authorities appendicitis is to be considered as much a surgical as a medical affection, and that from the very beginning the possibility of surgical intervention without undue delay should be considered.

DR. HENRY J. WOLF'S paper on "Experiences with Appendicitis," and the discussion of the subject was left till the next meeting, which will take place not on the first Monday of May because many members will be absent in Washington at the meeting of the Association of American Physicians, but on the second Monday, May 8th.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 6, 1899.

THE President, DR. W. H. THOMSON, in the Chair.

The first paper of the evening was read by DR. FRANCKE H. BOSWORTH on

SYPHILIS OF THE RESPIRATORY PASSAGES.

He said that so much has been written on syphilis of the respiratory passages of late years that he felt that his communication should be limited to his personal experience. The most striking thing about syphilis is its absolute latency for long periods of time, and then its sudden manifestation like a bolt from a clear sky. Sometimes hopeless damage is done before the significance of symptom is clear. In no part of the body is this more true than in the nose.

The ordinary syphilitic lesion of the nose is familiar to every practitioner. It is the gummatous infiltration of the tissues, including the periosteum, and the breaking down of the exudate, with necrosis of bone. It is recognized extremely rarely while as yet only in the gumma stage. Dr. Bosworth has seen it in a large practice only a few times. It is as an ulcer it is presented for treatment, and as a rule the bone is affected before treatment is begun. Syphilitic processes in the nose without necrosis of bone are very rare, almost as rare as necrosis of bone in the nose which can be traced to another than a syphilitic origin. The necrosing ethmoiditis of Wolfe should not be classed, as Dr. Bosworth has shown very clearly, as a true necrosis. Only recently in consultation he had been asked to see a case in which gonorrhea of the nose was supposed to have been the cause of necrosis, but it proved to be syphilitic, and it is extremely doubtful if the gonococcus can ever cause in any part of the body necrosis of bone.

In the mouth and pharynx and throat we see some of the most typical lesions of syphilis, lesions that enable us to recognize the disease at all stages. There is especially a tendency to infiltration of the upper layer of the mucous membrane. The mucous patch, the most frequent lesion, consists of degeneration of the epithelial layer. There is no occlusion of blood-vessels, hence no necrosis of tissue, only epithelial degeneration, but the lesion is very obstinate to treatment. As it is very contagious and very bothersome to the patient, the indications for prompt, vigorous treatment are manifest. It should be touched with nitrate of silver frequently and persistently until it disappears. One of the most curious things about the mucous patch is its well-known tendency to reproduce itself in exact outline, to imprint itself, as it were, wherever it comes in contact with another mucous surface. Quaint symmetrical lesions result from this tendency.

Besides the mucous patch, syphilitic ulcers occur in the pharynx and fauces. The characteristics of this lesion are very marked, and it is not difficult as a rule to recognize it. It is deep and angry-looking, with punched-out edges, its base covered with yellow pus and with a dusky-red areola. There is a noticeable feature of it in its hesitancy at crossing anatomical boundaries. If originally on the velum palati, for instance, it limits itself to that structure, though it may produce serious and extensive destruction in it.

There are only three possible causes for ulcer in this region: syphilis, tuberculosis, and the breaking down of neoplastic tissue. Other forms of ulcer are often mentioned as occurring in this region, but that is due to a misconception of the meaning of the term ulcer. Any abrasion in the mouth becomes covered with a whitish coating, and is spoken of as an ulcer; slight erosions of

the mucous membrane are sometimes erroneously called ulcers. It is well to bear in mind the classic definition of Erichsen and apply it strictly. An ulcer Erichsen defined as "a solution of continuity with a progressive waste of tissue." With this as a test ulcers are not so frequent. So-called scrofulous ulcers Dr. Bosworth has invariably found to be syphilitic, due to hereditary syphilis or to the disease acquired very early in life.

In children syphilitic ulcers of the respiratory passages may be fulminant in character. Dr. Bosworth has seen necrosis of the bones of the nose in a child six weeks old. In a child of eight years suffering from acquired syphilis he has known bony necrosis to occur in the nose within six months after infection. Despite the serious character of syphilitic lesions of the respiratory passages, they are very amenable to treatment. It is one of the greatest pleasures a medical man can have to see such serious conditions clear up promptly under specific treatment.

The disease is essentially localized in its manifestations. Only those tissues break down that have been the seat of gummatous infiltration. Any true progressive character is not present. The explosive action of the disease is its marked characteristic, but the syphilitic virus seems to exhaust itself in this purely localized gummatous explosion. We are accustomed to think too much of nasal syphilis, especially as progressive, but it is only an apparent progress due to the fact that from the very beginning there was a widely diffused gummatous infiltration of the nasal tissues. For the essentially local disease local treatment is the capital indication. Dead bone should be removed as soon as possible, because like a sequestrum anywhere else it acts as a local irritant, and with the syphilitic virus in the system chronic inflammatory processes are apt to be especially active.

In the pharynx syphilitic ulcers, if at all deep, are apt to be followed by vigorously contractile cicatrization. The whitish bands of the scar tissue pull surrounding soft tissues out of shape. Treatment is powerless to prevent this result. This special inconvenience from cicatrization occurs only in the food tract, the mouth, the pharynx, and the esophagus. It is much less marked in the larynx. It is extremely rare to see extensive cicatrization of the larynx except in old, neglected hospital cases where there has been very deep and extensive ulceration. Ulcers on the larynx, especially as soon as they affect the voice, are the subject of a great deal of anxiety on the part of the patient. This disquietude should be allayed by confident assurances of good results, for laryngeal syphilis, under anything like favorable circumstances, runs a comparatively mild course. Constitutional treatment is of much more importance for laryngeal syphilis than it is for syphilitic lesions of the nose and pharynx. Local treatment should not be neglected, but it is not the absolutely primal indication that it is in specific nasal affections.

Then followed the

DISCUSSION ON MALARIA,

which was to occupy the attention of the Academy for two meetings. The opening paper was read by Dr. Theobald Smith of Harvard University, and was entitled

RESEARCHES ON THE ETIOLOGY OF THE TEXAS CATTLE FEVER AND ITS BEARING UPON MALARIA.

Dr. Smith said in brief: Since Koch last summer in his talk before the German Colonial Society of Berlin on his researches into malaria in South Africa, had spoken of the probable analogy between Texas fever and malaria, the subject had attracted a great deal of attention. It did seem that what we knew of Texas fever and the life-history of its parasite could be assumed to throw light upon malaria and its parasite. We had known in this country for years that south of a certain line there existed an endemic cattle-disease which Northern cattle driven South often caught, and Southern cattle shipped North brought with them to infect healthy herds at the North. The infected territory practically included parts at least of all of the Southern States, though the northern boundary line, beyond which it did not retain its endemic character, meandered irregularly across the country. The line, as drawn by the United States Agricultural Department, wandered from the 29th to 42d degree of north latitude.

There had long been a widespread popular opinion that this disease, known as Texas fever, was somehow connected with certain ticks, a species of aranea that infest cattle in that region. Scientific men generally had pooh-poohed this idea. A scientist sent over by the English Government to investigate the disease had said that a little consideration sufficed to show the absurdity of this view.

During the speaker's first studies for the Department of Agriculture, it became clear that a corpuscle-destroying parasite was at work, and that it was the cause of the intense anemia with progressive oligocythemia which develops during the disease and finally causes death. In the summer of 1889 he found the parasites in the red blood-corpuscles. The life-history of the parasite has never been completely made out because the reduplication stage has always eluded observation. The organism would seem to have at first a motile, rod-like form which later develops and finally comes to a resting stage. Theory would seem to demand a double form of reduplication; one rapid, the other slow. The first occurs in animals which suffer from the disease acutely, when it is evident that the parasite multiplies very rapidly in the animal's blood. The second form of reduplication occurs in animals which have become practically immune to the disease, though still carrying around in them the germs of the disease, or which suffer from it in a chronic form. In them the unfavorable circumstances, some substances in the blood that hinders their rapid multiplication allows them to increase only fast enough to perpetuate the race, but not to produce the ordinary symptoms of the disease.

How long the parasites may live in animals which have become immune to their effects is not definitely known, but it is concluded from observation to be at least five

years. For the blood of animals from infected districts, though themselves not suffering from any symptoms of the disease. has been known after this length of time has elapsed to produce in healthy animals acute symptoms of the disease. A sort of symbiosis of host and parasite seems to be established in the course of time, and this may last indefinitely.

The disease, though endemic only in the Southern States, may be carried outside of its ordinary limits with fatal results to cattle. Not long ago an outbreak of the disease occurred not far from Boston, the infection having come through the Albany cattle-yards. Though called Texas fever, it is now known to occur in Finland, in Australia, in various parts of Africa, in Roumania, where Babes thought at first that he had found a cause for the fever in cattle there in the shape of a coccus. This proved to be due to a failure in bacteriologic technic, however, and he has since seen and described the parasite of Texas fever as occurring there. The disease is now known to exist in Italy, as Koch found examples of it there recently while studying malaria in the Campagna.

Koch's observations on it in German East Africa, especially the fact of its communication by means of the ticks that infect the animals there also, made him look very favorably upon the analogous theory as to the origin of malaria—that, namely, which makes it a mosquito-borne disease. Koch's practical sagacity led him at once to the crux in the matter of the tick theory of the communication of the disease, *viz.*, the spread of it through parasites never in contact with diseased animals, but brought up artificially. He substantiated the American discoveries in the matter, and then turned at once to the mosquito theory of malaria.

From the immunity that seems to develop to Texas fever in cattle in infected regions, Koch has found the confirmation of his views as to the immunity produced by malaria. Immunity to malaria is not produced, however, as easily as Koch seems to think. Cases of untreated malaria are very infrequent in our day, with quinin so easy to procure, and the subject is a deceptive one. Dr. Smith himself has seen a woman who confessed to having had thirty-six malarial paroxysms in as many days. She had the double tertian form of the disease, and it seemed as though in her case very little progress had been made by the organization toward immunization.

Relapses of the disease after long intervals of freedom from symptoms do not argue so much against the natural tendency to immunization as is sometimes claimed. They merely mean an unwonted invasion into the system of germs before kept out of the general circulation, or a lowering for the time being of certain resistive forces. The phenomena have been very suggestively studied in cattle with Texan fever. During relapses, in cattle that have become somewhat immunized to the disease, the parasites are unable to penetrate far into the interior of the red blood-corpuscle, and are found on its periphery alone.

For the tropics the mosquito theory of the dissemination of malaria may not promise much practical relief, since it may prove impossible to prevent the presence of these insect pests; but in temperate climes the draining of marshes, the taking of measures to prevent the multiplication of mosquitoes as, for instance, the covering of the surface of ponds where they are known to exist with petroleum, which is said to effectually prevent their eggs from developing, and other measures will eventually rid us of the malaria that we still have.

DR. WALTER B. JAMES then read a paper, entitled

PRESENT STATUS OF THE INOCULATION THEORY OF MALARIA.

He said in brief: While Koch's recent public announcement of his belief in the theory that malaria was carried by mosquitos had made the subject of very widespread interest just at present, it must be remembered that the theory was by no means a new one. It was not even modern, but had been originally broached by the ancient Romans, perhaps not even having been original with them, but adopted, as they adopted so many other things, from the ingenious Greeks. The theory has been a popular one in tropical climates for some time, and was suggested as a contribution to the etiology of malaria many years ago here in America.

We have known for a long time that malaria was infectious, *i. e.*, at least that if the blood of a patient suffering from malaria were injected into one who had never had the disease, the affection was reproduced characteristically in the second individual. The injection, therefore, of the disease by a mosquito seemed by no means impossible or even improbable. It was noted besides that the mosquito season corresponded to the season of greatest incidence of malaria, that wherever there was malaria there there were mosquitoes, though the opposite was not absolutely true. Then the same conditions fostered both. They occurred in the midst of low, damp, swampy ground, where the conditions of heat and moisture favored especially the rapid multiplication of the mosquito. There were stories, too, seemingly authentic and authoritative, of travelers having been protected from the disease in tropical countries by wearing mosquito nets.

But all this is theory. The recent work on the subject was led up to by Patrick Manson's suggestive review of the etiology of malaria in a series of lectures in England four years ago, in which he suggested that the mosquito might form the intermediate host for the malarial parasite, between the water or the damp earth where it originally existed, and man. Direct contagion was not easy to explain.

Manson noted a flagella stage of the parasite outside the body, but was not able to demonstrate its significance or how the parasite gained entrance. Then Ross, working in India, demonstrated the parasite of malaria in the stomach-walls of the mosquito. He noted the similarity of a parasite that occurs in birds to the malarial hematozoon, and studied the former experimentally. He was able to demonstrate in mosquitoes which had been fed on blood from birds affected by this parasite, called a pro-

tesana, forms of the bird parasite. Then McCallum at Johns Hopkins threw light especially on the regenerative and reproductive processes of these parasites. He observed them throw off their flagellæ, and learned the biological significance of the flagellæ. They have an important sexual office, and seem to unite with another parasite for reproductive purposes. McCallum noted also an active motile form of the parasite which enters the cells of the stomach-walls of the mosquito after ingestion, and here enters upon another stage of existence, assuming the coccidium form. Further developments take place, and the parasite is to be found in the cells of the proboscis of the insect from which, as is evident, infection would be easy.

Ross confirmed these observations upon the avian parasites, especially as regards the purpose of the flagellæ thrown off as reproductive elements. He studied the parasite in the sparrow, and demonstrated the analogy of the process set up by it with that of the malarial organism.

Bignami, an Italian observer, performed a remarkable and successful experiment. He shut up a number of mosquitoes captured in the fever-laden swamps of the Campagna near Rome in a small room in which was confined a man who had never had malaria. The subject of the experiment acquired malaria. Italian observers have pointed out that there are various kinds of mosquitoes in Italy, and that only certain kinds seem to be carriers of malaria.

All of these observations on mosquitoes are absolutely trustworthy. They have emanated from men of acknowledged scientific standing, they have been substantiated by others, and besides, as in the case of Ross, well-known authorities as Laveran, Koch, Nuttall, and Bignami and others, have had the opportunity to examine the preparations.

This much of the life-cycle of the malarial parasite in the mosquito seems to be clear: forty-eight hours after the malarial blood has been sucked up by the mosquito, the malarial parasite exists in the stomach and intestinal walls as a coccidium. After six days it has grown larger and projects into the intestinal canal. From here it is either ejected into water and infection takes place through the water, or the young mosquitoes become affected with active forms and communicate the disease. It has been noted that malaria may gradually spread in a neighborhood hitherto immune from the disease after some one affected by malaria has moved in, just as in the corresponding case of Texas fever.

We seem to know enough now to connect the mosquito definitely with the propagation of malaria. Prophylactic measures against the disease will be best put into execution by securing the extirpation of these insect pests. The drainage of swamps takes on a new and practical significance. Methods calculated to lessen the number of mosquitoes not only contribute to human comfort, but are valuable measures for public health. It is probable that in temperate climates, at least, we shall soon be able to limit the spread of the disease effectually.

Dr. F. P. Lynch, late of the Congo Free State, then read a paper, entitled

SOME PERSONAL EXPERIENCES WITH AFRICAN BLACK-WATER FEVER.

Though black-water fever has not been known for very many years, Dr. Lynch found it greatly dreaded when he went to the Congo Free State in 1893. The first case he saw was in a robust Scotchman, who had been in the tropics for twenty-five years without having it, and who was attacked after a period of unusual exertion and exposure to climatic hardships. The disease is not by any means so frequent as might be thought from all that is said of it, and even in South Africa one sees cases of it rarely enough.

It occurs in West Africa along the coast, and in the neighborhood of the Lower Congo. It attacks only whites, never the negroes nor half-breeds, and occurs principally in the rainy season. In this part of Africa there are only a few hundred whites, mainly government officials, scattered over 200 to 300 miles of territory, so that even a medical man in the Lower Congo region does not see many cases. The disease occurs without premonition, the first symptom being usually the dark-colored urine, from which the disease receives its name. This symptom at once arouses the most serious apprehensions on the part of the patient, and so adds to the gravity of the disease by the depression its well-known dangerous character is apt to arouse.

Vomiting usually sets in after a short time, especially of bile in large quantities, and jaundice makes itself noticeable. There is usually constipation, and whatever passages do occur or are brought about medicinally are dark and tar-like. Very soon, in the more serious cases, the urine becomes less in amount, and then scantier from day to day until complete suppression supervenes. These cases, complicated by urinary suppression, are practically always fatal. There are no pains complained of during the course of the disease, only a growing feeling of deep depression that settles down over the patient and soon makes his case seem absolutely hopeless to himself.

The disease attacks the vigorous as well as the delicate, and no special constitution seems to confer immunity. It does not, as a rule, attack newcomers to a tropical climate, but selects its victims among those who have been in the country two or three years. It comes on after a vacation in a temperate climate, especially if the vacation has been associated with a good deal of physical exertion, or if after their return individuals presume too much on their former residence in the tropics to do much work at once after their arrival. It does not occur among women as a rule, probably because they are not so liable to these indiscretions in the matter of exposure to the heat and overexertion. It attacks particularly people who, sure of their native health, have been negligent of drugs, and especially those who have not used quinin for prophylaxis or for mild malarial symptoms.

Recovery from the disease is usually rapid once it begins. The usual treatment is about as follows: The gastro-intestinal tract is cleared by an emetic, and by the administration of compound cathartic pills, the absorption of which is made more sure by crushing them before taking. Copious sweating is induced by hot bottles and

plentiful wrappings, and diuretics are given to induce plentiful excretion of urine. Quinin is absolutely invaluable, and must be given freely; 15 grains of the drug are given, to be repeated once or oftener during the day, according to the susceptibility of the patient to the influence of quinin. There must be no hesitation about its immediate and liberal administration. Out of eighteen cases of the disease that Dr. Lynch had the opportunity of seeing, only one patient failed to recover under this method of treatment.

(To be continued.)

REVIEWS.

LECTURES ON APPENDICITIS AND NOTES ON OTHER SUBJECTS. By ROBERT T. MORRIS, A.M., M.D., Adjunct Professor of Surgery in the New York Post-Graduate Medical School and Hospital. Third edition. Illustrated. New York: G. P. Putnam's Sons, 1899.

IT is well known that the author of this little work is an earnest advocate of the surgical nature of appendicitis, a view which is, fortunately for the victims of that disease, rapidly becoming general. He is an earnest pleader, too, for a radical operation in all cases in which the appendix is the seat of an inflammatory process. With the 1½-inch incision which the author has adopted, and with the use of the drain which bears his name, it seems impossible for failure to follow any operation for appendicitis. Yet not all surgeons are armed with his skill and good fortune, and we know of many who to this day can not feel every appendix, normal, or abnormal, as the author would have us believe he can. It requires a *tactus eruditis* which it is impossible to teach and which few men can ever hope to attain. Yet despite these extravagant claims, Dr. Morris has given us a very readable book which contains much that is instructive and which should have a good influence in teaching the fact that a so-called medical cure of appendicitis is one of the impossibilities.

The other surgical notes appended to the essay on appendicitis are reports of interesting cases of various surgical natures and of methods of the author's in physical examination. The book is very handsomely illustrated, and the book-making is good.

DISEASES OF THE EYE. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. DE SCHWEINITZ, M.D. Third thoroughly revised edition, 696 pages, with 255 illustrations and two chromolithographic plates. Philadelphia: W. B. Saunders, 1899.

THE author is to be congratulated upon the necessity of a new edition so soon (the second edition came out only two years ago) and upon the success with which he has brought the work up to date. There are about twenty additional pages in the present edition and good judgment has been shown throughout in the selection of new matter. It is deservedly one of our most popular text-books on ophthalmology.

To the bacteriology of the conjunctiva and cornea, in which so much original work has been done in recent years, is devoted a part of the added pages, and here we find a consideration of acute contagious conjunctivitis, and of the ulcer of the cornea produced by the pneumococcus of Fraenkel. A trifling typographical error (which, however, was fortunately discovered before many copies of the new edition were printed) occurs in the copy in the hands of the writer in the lines devoted to the diplobacillus of subacute conjunctivitis (2–3 mm. long instead of 2–3 μ long, page 254).

The different methods of designating the meridians in astigmatism are given, and a much more complete description of the Holmgren test for color blindness, one of the best tests we have, is also furnished.

The revision of the pages upon retrobulbar neuritis are characteristically well done, and a better discussion of this interesting subject in as compact a form it would be difficult to find.

Reference is made to the use of the Röntgen-rays for the detection of foreign bodies in the vitreous, and some lines are devoted to fugacious periodic episcleritis, retinitis striata, and hereditary optic-nerve atrophy. The subject of ethmoidal disease which has interested ophthalmic surgeons of late is treated here more extensively, and there are some additions to the consideration of the treatment of muscular insufficiencies.

In the chapter on operations we note a reference to the use of eucain and holocain as local anesthetics, and of formaldehyd for sterilizing instruments. The description of the operation for extirpation of the contents of the orbit and for muscular advancement (Swanzy's) is more complete, and allusion is made to the method of removal of tumors. Additional operations for ptosis are described, one of which the author says he "has used in several instances with gratifying success."

The above include not all but most of the important changes in the new edition and will serve to show how zealously the author continues to cultivate the the field of ophthalmic science.

THERAPEUTIC HINTS.

For Bronchitis with Copious Expectoration During Grip.—

℞ Terpini hydratis . . . gr. lxxx
Glycerini }
Syr. simpl. } . . . . q. s.

M. Ft. pil. No. XX. Sig. Three to five pills a day. —*Lyon.*

Treatment of Grip at the Time of Onset.—

℞ Pulv. ipecac. et opii . . . gr. x
Hydrarg. chlor. mitis . . . gr. iii
Sodii bicarb. . . . . gr. ii.

M. Ft. pulv. No. I. Sig. One dose.

On the following morning a laxative dose of phosphate of soda is given, and 5 grains of phenacetin are administered every two hours for five doses.

Externally the body may be rubbed with an alcoholic lotion, and if lumbar pain be severe, a sinapism should be applied.—*O'Neill.*

ORIGINAL ARTICLES.

BACILLUS ICTEROIDES AND BACILLUS CHOLERÆ SUIS.—A PRELIMINARY NOTE.

BY WALTER REED, M.D.,
Surgeon United States Army,
AND
JAMES CARROLL, M.D.,
Acting Assistant-Surgeon United States Army.

IN the course of a comparative study of bacillus *x* (Sternberg) and bacillus icteroides (Sanarelli) which has engaged our attention as opportunity would permit during the past eighteen months, we have had occasion to observe the effect produced by the intravenous injection in dogs of other micro-organisms, such as the bacillus coli communis and the bacillus choleræ suis. Without entering into details in this preliminary note we may state that the same clinical symptoms, *viz.*, vomiting, increased action of the bowels, and profound prostration, which are produced in dogs by the intravenous injection of B. icteroides, are also brought about by a like inoculation of the hog-cholera bacillus. When death occurs, the stomach contains a considerable quantiy of fluid blood and extensive hemorrhagic lesions are present in the small intestine. We have not found fatty degeneration of the liver, since our dogs, few in number, injected with the hog-cholera bacillus, have died too early for this change to occur. We have also failed to discover any fatty degeneration in the liver of dogs that have died within a few days after the intravenous injection of B. icteroides. This change has only been met with in two instances, when the animals had survived until the ninth day after inoculation with B. icteroides. In neither of these cases, however, was the degree of fatty degeneration at all comparable with that present in the human liver in yellow fever.

In addition to the experiments upon dogs, we have compared the course of the infection and the lesions produced in guinea-pigs and rabbits inoculated with small quantities of B. icteroides and B. choleræ suis, and have been much impressed with the similarity of the results obtained. The same cyclical course of the infection described by Sanarelli for guinea-pigs inoculated with B. icteroides is seen in these animals when injected with like quantities of B. choleræ suis. The greater susceptibility and shorter course of the infection in rabbits applies equally to both micro-organisms. Theobald Smith has called attention to the extreme susceptibility of these animals to inoculation with minute quantities of the hog-cholera bacillus.[1] We have succeeded in killing rabbits with $\frac{1}{1000000}$ c.c. B. icteroides injected subcutaneously. The lesions produced in rabbits and guinea-pigs inoculated with B. icteroides and the hog-cholera bacillus are practically the same, the most constant change consisting of multiple necroses in the liver. Sanarelli does not appear to have made any mention of this most striking lesion. We have found these punctate necroses of the liver especially prominent in guinea-pigs that have survived the inoculation more than five days.

Observations have shown that pigeons are not very susceptible to inoculation with the hog-cholera bacillus. We have also found these birds to be tolerably resistant to infection with B. icteroides. A fatal result has been produced by injecting 3 c.c. of a bouillon-culture into the breast muscle. Hemorrhage, swelling and extensive necrosis of the muscle are present, under these circumstances, as has been described by Welch and Clement, for the hog-cholera bacillus.[2]

We desire also to record in this preliminary note that bacillus icteroides, when fed to young hogs, produces an acute infection which may be followed by a fatal result, and that the chief lesion is confined to the large intestine. This lesion consists of an inflammation of the mucous membrane accompanied by fibrinous exudate, together with numerous small and large superficial ulcerations affecting the colon and cecum. These ulcerated areas are covered by an abundant, thick, bile-stained exudate. The "cork-lining" appearance mentioned by Smith would apply to the description of the intestinal mucosa. A portion of the viscera of a young hog that had been fed with 25 c.c. of a 24-hour bouillon-culture of Sanarelli's bacillus and which had died on the sixth day of the disease was fed to a second animal. The latter after exhibiting symptoms of sickness, such as fever, shiverings and loss of appetite, for a few days appeared to have fully recovered from the inoculation. It was killed on the 18th day. At autopsy numerous ulcers in various stages of cicatrization were found in the large intestine.

[1] Bulletin No. 6, U. S. Department of Agriculture, 1894.
[2] "Hog Cholera and Swine Plague," Welch and Clement, 1894.

As regards the morphologic and biologic character of B. icteroides and B. choleræ suis we have been unable to observe differences other than may be met with in varieties of the same species. Both are small, quite active, motile, non-liquefying bacilli whose slow rate of growth is the same in bouillon and in gelatin; likewise on agar, potato, and in litmus milk the growth presents the same appearances. Milk is not coagulated by either of these bacilli.

The action of B. icteroides and B. choleræ suis upon the three sugars has been the same in our hands. Both ferment glucose. If the bouillon is free from muscle glucose no fermentation takes place in lactose or saccharose bouillon. Exceptionally we have recorded a very slight fermentation of saccharose with both organisms Both of these bacilli, when cultivated in Dunham's solution, give a faint indol reaction.

We desire further to record the marked agglutinative reaction exhibited toward the hog-cholera bacillus by the serum of an animal immunized with B. icteroides. As long ago as May, 1898, we had observed that the blood-serum of a dog which was being immunized with B. icteroides would in dilutions of 1 to 5000 promptly arrest motility and agglutinate the hog-cholera bacillus. After testing various dilutions of this serum from 1 to 100 to 1 to 5000 we could observe no difference in its agglutinative reaction upon B. icteroides and B. choleræ suis. We have recently obtained, through the kindness of Surgeon General Sternberg, a specimen of icteroides serum, which, in dilutions of 1 to 120,000, promptly arrests the motility and agglutinates bacillus icteroides. In the same dilution this serum immediately arrests the motility of the hog-cholera bacillus, but does not bring about agglutination of the bacilli until at the end of about three hours. In a dilution of 1 to 30,000 agglutination commences within ten minutes and is complete at the end of one hour. The groups of bacilli are smaller than occurs with B. icteroides.

In rejecting B. icteroides as the specific cause of yellow fever Novy emphasizes the extreme resistance of this bacillus to low temperatures[1]. We have found Sanarelli's bacillus to preserve its vitality and virulency after twenty days continuous freezing at 10° C. (14° F.). That the hog-cholera bacillus is also quite resistant to low temperatures has been proven by the observations of Smith, and by the fact of its survival, notwithstanding the extreme severity of winter in our Northwestern States.

Putting together, therefore, the remarkable cultural resemblances of these two bacilli, and the similarity of their pathogenic action as shown in guinea-pigs, rabbits, pigeons, dogs, and hogs, we venture to express the opinion that the bacillus icteroides (Sanarelli) is a variety of the hog-cholera bacillus, and that it should be considered only as a secondary invader in yellow fever. We find that the bacillus *x* (Sternberg) presents marked differences from the foregoing micro-organisms, both as regards its biologic character as well as its pathogenic action toward animals. Reserving for future publication a more detailed description of our observations, it will suffice to here state our opinion that bacillus *x* should be placed with the colon group.

CARDIAPHOBIA, OR HEART FEAR.

By W. T. ENGLISH, M.D.,
OF PITTSBURG, PA.;
PROFESSOR OF PHYSICAL DIAGNOSIS IN THE MEDICAL DEPARTMENT, WESTERN UNIVERSITY OF PENNSYLVANIA; CONSULTANT IN CHEST DISEASES IN SOUTH SIDE HOSPITAL AND KAUFMANN CLINIC.

THE title of this paper is meant to include all cardiaphobias (heart fears, cardiac dreads, and heart frights) that are associated with so-called functional derangements of the heart. In attempting to establish a classification it will be necessary to separate the cardiaphobias into three principal groups, *viz.*: First, those in which the fear elements appear as preliminary to the functional derangements, and are, therefore, to be regarded as results of psychic action. Second, those in which the fear elements succeed upon the cardiac symptoms, and are secondary without preliminary ideation. Third, those in which the psychic elements act in conjunction with the cardiac disorders, producing a mixed condition, and are not in themselves primal.

Much valuable data has been contributed upon the general topic of fear, but the discussions of the fear element as exemplified and modified in disordered conditions of the body have been meager and unsatisfactory. Two centuries ago Descartes claimed that anything originally harmful to the body or closely associated with it would produce a similar passion or emotion upon successive generations, and prompt them to flight or efforts at escape. "There also comes," he says, "into the blood and the impulse imparted to it, a message that increases the passion of fear."[1] Giovanni Lancisi, the celebrated Court physician of Italy, places mental functions in close dependence upon the heart nerves, ganglia, and coronary vessels.[2] There is a disposition upon the part of recent authors to regard the fear element as largely the product of somatic life, rather than the ideational centers. Some, however, place fear among the purely psychical phe-

nomena. Its connection with cell actions, whether of the mind organ, the nerves, or the bodily life, must each influence the living organism and modify metabolic activity. Many have maintained, and still do maintain, that fear is a morbid entity, no matter how produced or expressed. Brown-Séquard once thought that all fears were due to abnormal conditions, and that he could inoculate with the bacilli of fear.[3] Fear is a universal possession, and is essential to every creature, brute or human.

Diseases divested of fears are bereft of one of the most benignant influences, and one that tends to the preservation of life and the promotion of cure. This is negatively evidenced by the fearless lethargy that consumes the victim of phthisis. Like rudimentary or vestigial organs, some fears have fulfilled their mission and become degenerate and useless. The dread of death, and especially from heart disease, is on the increase. We do not know how much of this belongs to the traces of remote experience, or whether hereditary root is demonstrable at all; but scientific research proves conclusively that some of the oldest traces are among the strongest in the fear manifestations of the present time.

In searching for the cause of this fear element in functional heart derangements, we must remember that the structure of the heart has an extremely abundant nervous supply, both intrinsic and extrinsic. From the earliest period of conception the heart is the first organ to develop, and long before the brain or mind has any dominating influence, it controls the bodily supplies, and is indeed the citadel of life. About one month after conception the human heart has very nearly the form which it preserves through life. The fully developed heart is composed of interlacing bundles of striated involuntary muscular fibers, devoid of any sarcolemma, and from the protoplasmic beginning maintains the habit of contractility.

The complicated innervation of the heart includes nearly 400 nerve ganglia, which are as so many little brains or sentinels on the watch for any cause for alarm. If one is injured the others feel its loss, for it still retains the capacity of giving out impressions, which, because of the injury, may frequently be wrong; later, if the process of deterioration is progressive, it habitually gives out wrong interpretations, and ultimately it degenerates into ganglionic insanity. This again may extend from one to another like a contagion, until a community of ganglia is rendered liable to hallucinations and delusions. These ganglia are reinforced by the cardiac plexuses and myriads of nerves distributed to every fiber of its structure. With these intrinsic nerve elements it could conduct, and does continue its contractions and dilatations even when severed from communication with the nerve centers. It often displays the ideo-motor capacity when all communication with the brain or cord are well preserved and normal. Some of the acts of the heart under stress are as independent as if it were invested with intelligence.

The many channels that connect the heart with the centers in the cord and brain and convey the inhibitory, accelerator, and sympathetic impulses, while augmenting the possibilities for utility, greatly increase the probabilities for varied phenomena, shading from the normal to embarrassing abnormalities. The center of the cardiac nerves is the medulla, and here all the paths of the nervous system converge. This multiplicity of origins of the nerve-supply of the heart has been recognized as products of the higher evolutionary processes, and are supposed by Mosso and others to constitute means by which the fear element may be established and maintained.

Again, it is to be remembered that fears do not always express themselves immediately upon the reception of the impression. The aptitude of the nerve-cell to accumulate and preserve external impressions is one of the most important physiologic facts. This capacity is supposed to reside more appropriately in the brain, but such capacity cannot be denied other nerve-cells throughout the body, and especially would it be reasonable to expect it of the highly organized ganglia, plexuses, and nerves of the heart. There is in each organ an unconscious vigilance that will protect, even in the absence of the ideational centers, and when the organ is perfectly adjusted to its needs this inherent capacity is more certain.

As a causative agent in cardiaphobia, age bears some relations that must not be disregarded. As age increases many influences that favor fear outbursts decline, and others increase. There must be a more or less puerile character to all fears that remain throughout life. Some seem to advance in everything but the elevation of their fears which perturb the heart and mind. There is also a point at which the adult heart and mind in their fears, like other capabilities of the body, are decadent. There are periods in which the heart muscle is subject to the greatest expenditure of force in its growth and development, as at puberty, and the fear element is by nature withheld; but, if by abnormal activity it is forced to the front the manifestations are peculiarly distressing. Again, the young are apt to fear death for themselves, the old for others.

Women respond more readily and vigorously for

a time to the fear element exercised upon the circulatory apparatus than men; therefore, it is assumed that women have more tender hearts than men. The female organization is more conservative of archaic influences than the male. An additional strain is placed upon women throughout life, and the periods often touch each other that should demand earnest solicitude and utmost care in observing the demonstrations as occasioned by the fear element: puberty, pregnancy, childbirth, and the climacteric. A self-regarding disposition of mind fosters the fear element. Males are more commonly involved than females in this respect. These cases appear at the most active and most wearying, as well as the most important period of life, from thirty to fifty years. The strain of this period is the greatest mentally, physically, and, to some, sexually.

The age in which we live has its causative influence. There is to-day a greater demand than ever made upon all for the fulfilment of personal tasks, and larger ordinary requirements upon the heart force and nervous system to accord with the pace set for the present generation. There is a growing sentiency in the people [4] so that we feel more than ever, consequently the possibilities of fear are more exalted. Cardiaphobias are, in some individuals, little more than sentient crises. In the highly nervous state there is added cause for sentiency, and the subject listens intently to the heart's frettings with every breath bated, thus adding, however unintentionally, a most potent factor to cardiaphobia and mental unrest. Some cardiaphobiacs are resonators of sensation. The heart engages the most perfect attention during the stillness of the night when the vividness of its impression is augmented by the absence of distracting influences.

It cannot be denied that the etiology of some of the cardiaphobias lies in the hypersensitive condition of the nerves or nerve centers; but, nevertheless, their primal awakening may be in the heart malbehavior which preceded, rather than followed, the nervous irritation. This intermingling of effects must not be overlooked.

For the production of certain characteristics of fear in heart perturbation, there is no need for the participation of will or consciousness [5] All that is most characteristic in the phenomena attending cardiaphobia is due to automatism. Will is restricted, and involuntary movements dominate these fears. It is not the serious that the heart appreciates to excess—as for instance, long continued heart lesion—but the unexpected explosion of emotions occasions intense perturbations. The first moments are the most energetic in their response, as is true of all phenomena in the nervous system. Some reduction of nervous tone brought about by the habits of life will render the subject liable to heart fear. Overwork, worry, mental strain, and psychic processes generally may mingle and contribute as causative in the nervous depressions or exaltations preliminary in the expression of fear. Faulty central impressions may be received upon the heart directly without previous unwholesome condition or malbehavior of the organ, and the psychic expressions find outlet in organic functional malbehavior.

If the heart received no sudden shocks from fear and was not made capable of them, the influences entering the ideational centers through the senses would easily be pushed aside. The more frequently the fear act is performed, the less appeal the heart needs make to the nerve centers, and it is often accomplished by the heart itself and by some less important organs, without such appeal.

Cardiaphobia is not necessarily the result of influences proceeding from ideational centers but is often clearly demonstrated to be immediate and intrinsic. If a loud noise as of an explosion take place near us, even if asleep, the heart begins to beat much faster than before. We betray this fear element without ideation, and when the ideational centers act, there is a tardiness because of their influences. Finally, fears may occur in the most valorous and are beyond the control or suggestion of the will.

In our study of the phenomena of the fear element in functional diseases of the heart, we must keep in view the fact that the nerve-cells may store up the fear elements, and while apparently latent, the fear-charged cells are under tension and thus resemble in their possibilities the Leyden-jar,[6] and contact may secure a more or less violent discharge. This may be accomplished by a slight cause, either extrinsic or intrinsic to the body. Thus sudden fright may precipitate an attack of the most persistent and severe form of cardiaphobia, which primarily has its source in the ideational centers. Cardiac fear of this kind endures for months and even years, and displays itself on occasions in the half-convulsive demeanor that possesses the cardiac plexuses and ganglia. The cardiaphobia may express itself in loudest terms or write its characters very large within the cardiac area, and yet take its primal origin in the brain. Again, there are fears which come into the psychic experience so suddenly and violently that for a time they half hypnotize the psychic element, so that the somatic and cardiac factors are the only ones observed. In these cases, there is an exaggerated anxiety and an excessive apprehension pervading the entire life with corresponding cardiac perturbations. Pseudo-angina pectoris,

tremor, vague thoracic experiences, without proportionate change in heart demeanor, usually indicate the psychic character of this disorder. It is more psychic and less cardiac than the succeeding classes. Beginning in the ideational centers, we would naturally infer that the mind would be prepared with its defense, but experience proves that the cardiaphobia thus induced, acts with such intensity and celerity that the knowledge that should be anticipatory of it, is disassociated.

A case which illustrates this form of heart fear came under my observation in October, 1892. The patient was a man thirty-two years of age, height five feet, nine and one-half inches; weight, 187 pounds, and of good family history. His life had been free from serious illness. Several years prior to his call on me he had feared his heart would cease beating, and while describing his symptoms he was unconsciously feeling his pulse. When his attention was called to the fact, he admitted that it was his habit. At night he was afraid to sleep lest he might not live until morning. He, therefore, suffered from insomnia. He was afraid to be alone, and as he was a traveling man this was very inconvenient. He always walked very slowly, lest an accidental death might result from his exercise. He would suddenly leave the social circle or the card-table to hide his fright, and yield to a vague demand of his heart. This fear of sudden death caused unwarrantable limitations and modifications in his habits, diet, regimen, and usefulness of life.

A physical examination revealed functional derangement of the heart. Tachycardia increased the frequency of the heart beats to 146 per minute. Observations made at short intervals discovered the heart-beat reduced to 98 per minute. There was an irregular intermittence occurring five times during the minute of rapid action, and only twice during the more quiet action. These omitted heart throbs created a corresponding breach in the respiratory action, and a sighing respiratory effort. The countenance at this instant became exceedingly anxious. The lungs presented no evidence of disease. The digestive apparatus was taxed in the performance of its duties because the subject ate freely. This he did without relish, and he indulged in alcoholics to slight excess. His tongue was large, flabby, furred, and somewhat pale. Bowels irregular, but usually one evacuation each day. Complained of visual limitations and headaches which were of evanescent duration. He was disqualified for mental or physical exertion. Urine of normal quantity, high specific gravity, and loaded with urates. Because of his general aspect of health he claimed to have been subjected to unsympathetic treatment by friends and also by physicians.

After the examination and hopeful assurances he departed with apparent satisfaction, promising to follow the treatment suggested. On the next day, however, he returned to have his heart re-examined, fearing that something had escaped detection. This was repeated for months, until there was marked improvement. He then disappeared to return in 1895, after a lapse of nearly three years. He reported that he had been comparatively free from any cardiac malbehavior, although vague apprehensions would suddenly seize him that the heart perturbation might return. His visits have been repeated frequently, and at each departure he asks the question, "Are you sure, Doctor, that I will not die suddenly?" The psychologic source of fear in this patient still remains active to haunt his life, and at such times to perturb his heart. He admits that on several occasions since his departure he has arrived at the diagnosis in his own case of incurable heart lesion.

In the second group the fear elements succeed upon the cardiac malbehavior, and are secondary, without preliminary ideation. The functional disorder in the heart may exist for an indefinite period, without any manifestations of a psychic fear element. The depression in the precordial region and the startling terror-laden heart throbs are sufficient in themselves to reproduce the most fossilized neural tweaks and shudders of Arcadian times. There are circumstances when nothing appears but the intrinsic manifestations, and a fear uprises that is thrust upon the consciousness by a missing heart-throb or some other perversion of the cardiac action. This is the form of fear that seems to rest on experience. It is not psychical, but is located in the somatic life. This is the most closely associated cardiaphobia. When alarm is given to the heart directly through its intrinsic nerve cells, it is attended by cardiac distress peculiarly its own, and that is separate and distinct from the object feared. No more real symptoms can appear than these that are so closely associated with and abiding in the heart. Moreover, they may be forced upon the attention of the psyche through any or all the nervous channels in sympathy with the cardiac anxiety. When the precordial symptoms subside, there is, as a rule, a complete hiatus in the distress for some time. Rarely in the intervals of cardiac calm the subject anticipates with dread the recurrence of the distress, and each ache or pain in the vicinity of the heart is magnified into a possible fatal return. This fear of its return in this and other groups of cases has somewhat to do with its return. No emotion or pronounced impression takes place without immediately acting upon the heart and blood-vessels. In the absence of heart malbehavior the patient is ashamed of his alarm, but resumes it immediately on the return of the palpitation.

Among the cases recorded of those belonging to the second group, I refer to one very characteristic. A physician who had suffered from several

paroxysms of palpitation with accompanying arrhythmia was prompted to repair to my office, a distance of five squares. The exercise incident upon the more or less hasty walk seemed to aggravate his symptoms. At each step his anxiety seemed to augment. Upon arriving at my office and finding me temporarily engaged, he unceremoniously rapped upon my private door and called loudly for me. He explained by assuring me that he did not think he could live another minute. An immediate examination and some temporary medication served to calm him somewhat, and the paroxysm gradually faded away. During the succeeding six months he reported three lesser attacks, but at the expiration of one year and three days from the first appearance at my office he returned in a like frame of mind, and after similar treatment he retired, since which time he reports entire freedom from such experiences.

In the third and last form of the expression of the fear element, there is an evidence of the psychic and cardiac activities combining. The clinical picture in these cases is a changeable one. There are varied and kaleidoscopic diversifications that are not always traceable to their true cause. This is due to the mutability as well as the multiplicity of the disturbances and their factors. Whether or not the fear influence begins simultaneously at both ends of the chain, the expressions appear at each extremity of the circuit at the same instant. By the manifestations in some cases it is to be inferred that the fear element is hidden deeper in the psyche than in the soma, and they can more readily be appreciated by the sphygmograph, the educated finger-tips, and other physical means than by an analysis of the psychic phenomena. On the other hand, these subjects are often found without heart perturbation, but the ideational freedom is accompanied by the subjective sense of something wrong in the precordial region. Cardiaphobias of this class often arise with no pronounced demonstration of either the somatic or psychic life, but these factors naturally develop into prominence. When thus developed, with both extremities of the nervous chain active, they are not easily differentiated as to their cause or primal origin. The degree of cardiac self-consciousness is more marked than cases observed in the first group. The functional malbehavior of the heart is placed under closer observation, and this increases its activity and retards intrinsic repair. Moreover, by the greater activity of the heart the brain is more generously supplied with blood, and the ideational centers thereby acquire unusual energy. The intermediate nerve-links, including the vagi, sympathetic, medullary center, as well as the vasomotor system may act as mediators between the cardiac and psychic tumults. It is in this mixed group that we most commonly find those subjects who are accompanied by a weakness that prompts them to hide their fears. Like pent-up grief, this fear element when hidden is more dangerous and disqualifying than when open From very fear of finding out the cause of his distress the sufferer hides the cardiaphobia from his physician.

A man, thirty years of age, weight 143 pounds, height five feet, eight inches, manager of a dry-goods house, and of previous good health, had felt uneasiness in the precordial region with a sense of respiratory limitation. The paroxysms grew more and more unbearable as he thought upon the necessity for medical counsel. His pulse reached 126 per minute. During two or three successive minutes intermissions would occur. A varied period of freedom from irregularity would succeed. Any reference to the perturbed or irregular action would have the effect of augmenting the perturbation. The psychic and somatic influences were interactive, and ran the gamut of discomfort so that moral expedients were deemed imperative, but they were without avail. As long as the patient's disorder was the subject of his thought or the topic of conversation the irregularity and anxiety were increased. An attempt to secure a sphygmographic tracing of the pulse at our first interview was abandoned because of its awe-inspiring results. Treatment, aided by time and experience, have rendered subsequent attacks less appalling, and during the eight months he has been under observation they have been separated by wider intervals and reduced in severity.

To enable us to approach an unbiased judgment we must rid our minds of the fallacious belief that the fear products are the results of imagination. The fear element, when properly educated, drilled, and disciplined,and manifesting itself through wholesome life, must be regarded as distinct from those expressed under excitement and through functionally deranged organs.

To describe these symptoms or conditions as nervous is equivalent to saying that they are fanciful or fictitious. Constancy in any symptom must be regarded as evidence of its reality, and it enables a diagnostician fully to determine the underlying conditions. When we approach a patient who is insane from terror it is no fit time or occasion to attempt to calm him by telling him he has a diseased imagination. No patients are more to be pitied than those under the thralldom of cardiaphobia. I am convinced from their point of view they are the victims of misery to which actual pain would bear no comparison; which the physician, try as he may, cannot comprehend. Whether this fear element is worthy of the physician's recognition as a symptom and a guide to the diagnosis and treatment, is, to

my mind, answered affirmatively. No longer should we call it hysteria, hypochondriasis, dyspepsia, imagination, and neurasthenia. It should be denominated cardiaphobia, and regarded as a reality with its roots imbedded in the somatic as well as psychic life. It is well also to remember that these conditions do not uprise only in the half-foolish, crochety individuals with weak nerves and small mental endowments, but they are oftentimes the unfortunate belongings of the best.

The diagnosis of these cases is not always as simple a procedure as might, on first thought, appear. When a heart is greatly perturbed it is difficult to make a satisfactory physical examination, and it will be found necessary to defer this portion of the analysis until a more quiescent period True cardiac lesions must never escape detection, and these special conditions of heart fear must be placed in the right category. A due amount of importance must be accorded each symptom and group. The gravity associated with them must not be disassociated. In the first group the discrimination is quite easy, at least it is readily separated from the second and third by its primary expression in the ideational centers. It is often attributed to the imagination in its first outbreak, especially by those who believe the imagination is nothing, and proceeds from nothing. There is something too real in the symptoms attending to be thus interpreted by the observing physician. In each class the symptoms must be carefully reviewed. In the mixed group there will be a division of the fear manifestations between the heart and the ideational centers. Now one will preponderate, and, anon, the other gain the ascendancy. This will involve instability as to the character and position of the fear element. The precedence or early preponderance of the intrinsic cardiac element will usually suffice to prove that the heart enervation is the primal cause. Hysteria should be separated without difficulty because of the absence of the most fundamental symptoms that constitute the heart fear an entity.

Hypochondriasis is, as a rule, a product of the ideational centers, but is rarely, if ever, associated with cardiac malbehavior. There are some symptoms that stand out very evident which belong to dyspeptic conditions, and which are very commonly associated with malbehavior of the heart. These are not the necessary concomitants of the fear element as exemplified in functional heart derangement, but they often add to the fury of the nerve storm when they are present. To class these sympathetic influences with the phenomena of cardiaphobias would be widely remiss, because the latter originate in heart and brain and the former are reflex. Some have intimated that these fears are the results of neurasthenia. The phenomena under consideration are specifically local products of the heart, the brain, or both, but not of a general irritability of the entire nervous system, as is neurasthenia. Finally, we will be aided in diagnosis by remembering that the fear element is more commonly associated with functional derangement of the heart than with any other disorder. Very rarely are they found in the insidious quiet forms of organic heart disease, and it is only when there arises some associated functional disturbance that fear comes to the front.

The prognosis may usually be regarded as favorable. The personal equation must be taken into consideration in each case. Fears that might be very injurious to one would act as a tonic to another. Especially will this hold good when they are results of perfect functions.

Age constitutes an important factor in our estimates of the prospects. The sudden vascular tension incident upon some of the more severe cardiaphobias must be regarded as serious if occurring after middle life, and may prove to be the weapon by which the last fatal stroke is inflicted. There comes a stage of fear change that belongs usually to advanced life which we may call the stage of forgeting or failure to reproduce the protecting fear. When the heart or brain fails to be impressed with fears that once were occasions for the uprising of nerve storms there is something seriously wrong. The persistence, as also the severity, may intimate the probable outcome. If heart fears continue with cardiac perturbation throughout a period of years, even with the ordinary intervals of relief, there will be found some myocardial changes. If nothing more than hypertrophy of the most benignant nature, it is to be estimated as a step toward other changes. The blood-forming functions associated with respiration and digestion, as well as general trophic metabolism, will each yield up some capacity as sequelæ to protracted cardiaphobia. It should be looked upon as evidence of nerve weakness when the subject is prompted by fear to shrink from the verdict of the diagnostician. The effect of such secrecy is the useless expenditure of nerve fluid. In all low states of vitality the sudden uprising of the fear element will be more influential than in normal conditions.

In treating these patients we must bear in mind that we cannot hope to eliminate fear, but it should be our purpose so to manage it that it may have the power of proper reaction. This may be achieved through medico-moral therapeutics. The treatment by moral suasion alone has little to commend it empirically, but there are patients who, if once made to

realize that their fears are beneficent in design, and are but timely warnings which they should eagerly heed, will experience an intellectual gratification and somatic freedom that is worth the price of rubies. No one, however intellectual, but will experience a charm when he feels this advance in the character of his fears and his relations to them. Excessive fears, however, must be controlled by other means than those appealing through moral influences. It is the disposition of most of the subjects to seek temporary relief by indulgence in alcoholics. Unless the patient be anemic, or weakened by previous drain, the use of stimulants or heart goads is contraindicated. Bromids have held a popular place in the treatment of all undue nerve uprising or irritability; I mention them to condemn them as inefficient. A remedy is needed that will act with celerity and potency in securing desirable quiescence. If in our investigation we have carefully eliminated serious heart lesion, chloral hydrate may be boldly employed, and the dosage in quantity and frequency pushed until our patient has secured a dreamless sleep extending over a period of at least four or five hours. This will be found to give much relief to the symptoms, no matter whether intrinsic to the heart or belonging to the ideational centers. Trional, usually administered in 10-grain doses, is well borne under these circumstances in 30-grain doses, repeated in three or four hours until sleep is produced. This drug has the advantage of being free from depressing effects upon the heart, and can be employed even in the presence of heart lesions. The doses selected should be given in a glass of hot milk. Acetanilid and phenacetin will emancipate the nerves from their irritability, but will not relieve with certainty the cardiac arrhythmia. Tonics must be administered to replace the nerve outlay. The physician should have constant oversight and often reassure himself by repeated examination so that he may rationally assure his patient of the hopeful prospects for relief.

Rectal Specialists.—During the meeting of the American Medical Association at Columbus, June 6th to 9th, there will be a meeting of the medical men engaged in the practice of proctology, for the purpose of effecting a permanent society for the study of their specialty. Physicians interested in the project are requested to address Dr. William M. Beach, 515 Penn Avenue, Pittsburg, Pennsylvania.

A BACILLUS RESEMBLING THE DIPHTHERIA BACILLUS IN ALL CULTURAL CHARACTERISTICS, BUT NOT PRODUCING DIPHTHERIA TOXIN.

BY LOUISE DUDLEY DAVIS, A.B.,
OF NEW YORK;
ASSISTANT BACTERIOLOGIST IN THE NEW YORK CITY HEALTH DEPARTMENT.

THE occasional development of a case of diphtheria among the cases of scarlet fever in the Willard Parker Hospital caused an examination to be made from time to time of the throat secretions of patients on their admission or during their stay. It was discovered that at certain times the secretions from fully ten per cent. of those admitted from the tenement district with scarlet fever contained bacilli which microscopically and culturally were characteristic of B. diphtheriæ.

During a portion of the winter of 1897–98 nearly fifty per cent. of the scarlet-fever patients developed otitis media, and as this was a quite exceptional occurrence, Dr. William H. Park made cultures from the ear abscesses of two patients. Smears from the growth on the serum tubes from the first patient revealed an almost pure culture of a short bacillus with considerable differential staining, and with most of the individual bacilli lying parallel to one another, and these bacilli resemble the shorter form of the diphtheria bacillus. From the second case an agar-plate had also been made; this showed a variety of colonies. Upon careful examination of these a few were found with the following characteristics: Dark centers, light uneven edges, various tones of shading and granulation, and colonies which microscopically resemble those of B. diphtheriæ.

Serum tubes were made from these colonies, and, after twenty-four-hours' growth, smears from these showed bacilli extremely characteristic of that of Löffler. They were polymorphic, some long, irregularly staining, others short and evenly staining. Agar-plates made from bouillon-cultures showed spreading colonies with light uneven edges and dark centers. The colonies were creamy white, and, as a rule, the growth was a little heavier than one expects to see in true B. diphtheriæ.

The presence of this bacillus in these two cases led us to obtain cultures from other cases of scarlet fever in which otitis media was present. Cultures were also taken from the throat of most of these patients, as it was supposed that the bacilli might have migrated through the Eustachian tube. Cultures and smears were examined from twelve of these patients, and short bacilli, staining irregularly, were found in all. The bacillus was isolated from ten cases. In all of this series the bacilli were isolated from the cultures made from the ear abscess, but in

three of the same patients the cultures from the throat gave negative results. Unfortunately, in these three instances the cultures were not taken from the throat until five days after cultures had been taken from the ear, and no controls were made from the ear at the time the throat cultures were taken. The throats were fairly clean when the cultures were made, and so it may have been that the bacilli, though originally present, had disappeared, as was sometimes found to be the case when second cultures were taken from the ear. Once the bacillus was also isolated from an abscess in a cervical lymph-node of one of the patients. In another similar case it was not present, though found in the throat and ear of the same patient. In both of these cases the chief infection seems to have been staphylococcus aureus.

No diphtheritic symptoms were noticed in any of the patients, but the unusually large number complicated by otitis media is interesting, and was perhaps due to the presence of this bacillus. Most of these patients at some time had rhinitis; otherwise the cases presented nothing of especial interest, with the exception of one patient, again to be referred to. One case of the twelve proved fatal, the patient dying of gangrenous cervical cellulitis of the neck and bronchopneumonia. These conditions had developed before the child's admission to the hospital. None of these patients had unusual throats for scarlet fever, but cultures were made merely to prove or disprove the presence of this bacillus.

In the case already alluded to, cultures were taken from both ear and throat of the patient, though at the time there were no throat symptoms. Smears from these tubes showed bacilli very typical of B. diphtheriæ, from the throat as well as the ear, and the colonies on agar-plates were very light and spreading. The cultures in every way looked characteristic of a virulent diphtheria bacillus, but when inoculated into guinea-pigs 2 c.c. of a bouillon culture failed to produce any reaction. Five days after these cultures had been taken a membrane developed in the patient's throat, and an examination made at the Hospital showed what was considered to be diphtheria bacilli. The patient was isolated, but the membrane disappeared after five days, and the patient recovered.

Cultures were made from the throats of two scarlet-fever patients who did not develop otitis media, and this bacillus was not found either in the smears or the cultures. The possible relation to otitis media and the necessity of knowing whether the cases in which this bacillus occurred were dangerous, led to a careful study as to its relation to virulent diphtheria bacilli.

The bacilli isolated in the twelve cases vary somewhat in appearance, both as individuals and also as to the shape and color of the colonies on agar-plates. Some grow in rather heavy dark colonies, while others are light and spreading; some give pellicles on the bouillon and leave the fluid clear, while others do not give as heavy a pellicle, but cloud the entire media. However, in all cases the general appearance of the bacilli and of the cultures is the same, and they differ among themselves no more than do diphtheria bacilli from different sources. When stained with the Neisser stain, which C. Fraenkel especially recommends to differentiate the true bacillus from the pseudo, all show the end stain and decolorized body.

With the exception of Case II., none of the bacilli proved virulent to guinea-pigs in doses of 2 c.c. bouillon culture. Some of the pigs lost weight rapidly, and appeared sick and then gained again. Little or no edema was noticed even at the point of inoculation. A pig inoculated in the abdominal wall with 2 c.c. bouillon culture from Case II. died within twenty-four hours after inoculation. At autopsy the pig did not show edema or congestion at the point of inoculation, but there was a general serous peritonitis, and the kidneys, liver, and spleen were all much congested. The plates and cultures made from the heart-blood, liver, and tissue about the point of inoculation showed pure and abundant cultures of the bacillus. The absence of characteristic diphtheria lesions and the presence of general blood infection made it seem of sufficient interest to follow this organism further.

Morphologically, it bears a most striking resemblance to the bacillus diphtheriæ. It is polymorphic, sometimes short, rather evenly stained, while the individuals lie in parallel lines; at other times it is long, lies irregularly, and gives the broken stain typical of B. diphtheriæ. It also shows the characteristic reaction when stained by the Neisser stain. It is non-motile, positive to Gram, produces acid by its growth in glucose bouillon, and does not form gas in fermentation-tubes. In cultures, careful comparison has been made with cultures of several diphtheria bacilli, and although there is a constant difference, in most instances it is so slight that it is only noticeable when the cultures are carefully compared, and it is no more than occurs between any two cultures of diphtheria bacilli.

The diphtheria bacilli tested form a heavy granular pellicle in bouillon, but the pellicle formed by growth from Case II. is thin, gray, and smooth, together with a heavy precipitate at the bottom of the tube, while the broth itself is left clear.

On agar-tubes the growth of diphtheria is decid-

edly granular and very white, while Case II. shows an even, almost transparent growth. This same variation is seen on glycerin-agar, the colonies of diphtheria inclined to be granular and flaky, while Case II., on this media, is more of a gray-white, much dryer in appearance, and more inclined to grow in small colonies. On potato neither show a visible growth. On blood-serum the macroscopic appearance is much the same. Both grow very poorly on gelatin. The same characteristic differences in the growth of these two organisms are seen in the cultures, whether grown at room temperature or in the incubator.

Although the cultural variations between this bacillus and B. diphtheriæ have been of interest, the most characteristic and significant difference between the two has been found in pathogenic properties of this organism. Though the animal experiments thus far have been somewhat unsatisfactory, still they have shown important reactions which the true B. diphtheriæ never presents. After the first experiment had been performed, in which the pig was killed with 2 c.c. culture, some time elapsed before another inoculation was made, and the culture had lost its virulence, for neither the original culture nor the pure culture derived from the heart-blood of the first pig would kill with 2 c.c. of the growth. Five cubic centimeters were tried, with no apparent ill effect, and finally 11 c.c. of a twenty-four-hour culture were inoculated subcutaneously, with the result that the pig was dead the next morning. No edema was seen at autopsy, but the subcutaneous and muscular tissues were much congested. There was extensive peritonitis, and slight congestion of the kidneys, liver, and spleen. The latter was slightly enlarged. Lungs normal. Cultures from the organs showed very heavy growth of pure cultures of the bacillus; even the plates and tubes from the heart-blood showed a fairly large number of colonies. Smears made at autopsy, especially from the spleen, show very beautiful pictures of phagocytosis. There are a large number of bacilli which show the end stain and many groups of leucocytes massed together, all well filled with bacilli. The cell outline of these leucocytes is broken away, and throughout the smear are fragments of nuclei from broken-down phagocytes. Apparently, as judged from the smears of liver and other tissues, the bacilli have not invaded the tissue-cells themselves, but as yet no sections have been made.

A pig was inoculated, subcutaneously, with 9 c.c. of culture mixed with ¼ c.c. 750-unit antitoxin. At the same time a control was inoculated with 9 c.c. of the culture. The last animal lived, while the former was dead the next morning, and the autopsy showed much the same condition as that of the previous pig (which had not received antitoxin), except, in this instance, the lungs were greatly congested, and there was fluid in the pleural cavity; the peritonitis, also, was of a purulent type. The smears and cultures showed relatively the same number of bacilli as in the previous case.

The variations in the animal experiments have been very great, as a pig may die from a certain amount of culture, and another, inoculated at the same time with the same amount, may live. In general, it can be said that the pigs which have received antitoxin have died more quickly than those which have not. As much as 5 c.c. of antitoxin, containing 850 units per c.c. have been tried, when 10 c.c. of culture was inoculated, and still the pig died within twenty-four hours, while a pig inoculated at the same time with 10 c.c. of the same culture alone may live a day or so longer. Some of the pigs used in these experiments had previously been used to test antitoxin, but the fact has not seemed to appreciably effect the virulence of the bacillus.

From these experiments it is found that the bacillus produces a general septicemia, or, at least, it is found abundantly in the blood, after the infection of large numbers of bacilli, and that it does not form a diphtheria toxin, nor does it form any strong toxin of its own, for 8 c.c. of a seven-day culture sterilized with carbolic acid did not produce a reaction.

Experiments have been made to determine whether this bacillus is more virulent intraperitoneally than subcutaneously, but nothing very satisfactory has yet been found, as the pigs seem to die after about the same number of hours and peritonitis is always found at autopsy, although in those inoculated intraperitoneally the peritonitis is of a more extreme degree.

Here it is of interest to note that Spronck endeavored to differentiate the true B. diphtheriæ from the pseudo by means of inoculation with antitoxic serum. For the most part his cultures of pseudo, in doses of 1 to 3 c.c., produced edema, ruffling of fur, loss of appetite, and loss of weight. After a few days these symptoms disappeared and the pigs were apparently normal again. The same results were obtained when the protective serum was injected six to thirteen hours before the culture, only the pathogenic symptoms were exaggerated; however, no fatal results were obtained in any case. When the pseudo is of sufficient virulence to produce edema Spronck thinks the serum an accurate means of diagnosis.

This series of experiments was afterward repeated by C. Fraenkel. He worked with seven pseudos from the nose and eyelids of sick and well, also one from a conjunctiva crouposa. When 5 to 10 c.c.

were put into the body he noticed more or less extended swelling and infiltration which disappeared after a few days, but none of the changes of the general nature which Spronck had mentioned. This was the same even when he injected 56 c.c. of a young or old culture. But the injection of the antitoxic serum either before, at the same time, or after the injection of the culture failed to prevent the slight local changes, which took place much the same as if the serum had not been injected. This fact rather shakes the belief of Fraenkel that the diphtheria and the pseudo belong together.

Fraenkel also noticed much uncertainty in regard to the results obtained from the inoculations, into pigs, of the same cultures, in either the same or varying amounts, though he never obtained fatal results. He thinks that these variations are probably due to the "individual disposition" of the guinea-pig, and also somewhat dependent upon the location and manner in which the inoculation is made. This variation in the animal experiments, not only in different, but also in the same cultures of pseudo, make the differentiation between it and the true B. diphtheriæ, doubly hard. But both Spronck and Fraenkel agree that the bacillus which gives a *clear* acid reaction in glucose bouillon is *usually* virulent.

Much assistance in regard to the relative number of bacilli actually present in the throat and ear has been given by the practice of taking smears at the same time as the cultures. This seems a much more accurate method of determining the proportion of the bacilli to other bacteria, for if some spreading organism be present, as pyocyaneus, a few colonies of the bacillus would be overrun, while the bacilli would be evident in the original smear. On the other hand, from blood-serum tubes, one might think that there were relatively a larger number of bacilli present than is actually the case, for the diphtheria bacilli outgrow, for instance, streptococci which ought to be found with them. Probably bacilli of this kind are frequent, for several bacilli which came from quite different sources have been worked out by Drs. Park and Williams along the same lines. They, also, have proven virulent in doses of from 3 to 10 c.c. and been unaffected by diphtheria antitoxin.

Although this work has not been carried sufficiently far to obtain very important results, still it has suggested many points of interest. The fatal results obtained when the diphtheria antitoxin was injected with the culture seem to be different from anything reported up to this time. Can we say that this is an attenuated diphtheria, a variety of that group, or an entirely different organism? It would seem that there are many points in favor of any one of these conclusions, but it is to be hoped that further work will determine this more definitely. Another point of interest is its connection with otitis media.

AN EXPERIMENT IN TRANSPLANTATION OF THE ENTIRE HUMAN OVARY.[1]

By James H. Glass, M.D.,
of Utica, N. Y.;
Surgeon in Charge of the Faxton Hospital.

Miss S. C. (indicated for convenience as Case No. 1), by occupation a housemaid, aged thirty-nine years, applied for treatment May 9, 1898, two years before having had a double oophorectomy for a somewhat indefinite condition. The menopause, supervened promptly, sexual instinct being diminished, and soon lapsing completely. The nervous symptoms so frequently following the menopause, natural or artificial, were present and characterized by marked mental depression, insomnia, giddiness, palpitations, heat flushes, perspirations, pelvic pains, and constipation. Nutrition was impaired; she was chloranemic, and incapable of the exertion incident to her usual occupation.

Examination demonstrated a uterus somewhat smaller than normal, flexed, and fixed posteriorly. A cautious prognosis was given, the patient being advised that she might expect some good effect from general treatment including the use of ovarian extract, and that improvement of the pelvic pain might possibly follow release and ventrofixation or suspension of the flexed and adherent uterus. Having been under general treatment almost constantly since her operation without benefit, she naturally lacked confidence in medical measures and was impatient of delay of any procedure offering a remote probability of relief from her distressing condition. She urged immediate operation, and this was performed May 11, 1898. The uterus, having been disengaged, was suspended to the abdominal wall in front, all raw surfaces being carefully covered with peritoneum.

A brief history of Case No. 2 is interposed for the purpose of establishing the juxtaposition necessary in the conduct of the experiment: Mrs. A., aged seventeen years, married, no children living, was delivered of a dead child one year ago, the head having remained in the inferior strait several days. Extensive sloughing followed, leaving after cicatrization a canal at its narrow point five millimeters in diameter. The patient had been referred to me for such reconstruction of the vagina as might be possible through plastic operation, her physician believing that patency of the vagina was more or less es-

[1] Read at the Ninety-third Annual Meeting of the New York State Medical Society, held at Albany, January 31 and February 1 and 2, 1899.

sential to the preservation of the conjugal relation. The result following operation was good, the vaginal diameter without painful dilatation having been increased to twenty-five millimeters. The inadequacy of the canal, however, for possible future child-bearing was apparent, the necessity for the Cæsarian operation in her case explained should pregnancy supervene, and the patient recommended to have excision of both tubes or perhaps of one tube, and one ovary, for the prevention of conception. The latter alternative was accepted, the patient readily consenting to the employment of the amputated ovary in the transplantation-experiment proposed.

May 14th, three days after the abdominal section for the suspension operation in Case No. 1, both patients were anesthetized and brought to the surgery together, the most scrupulous care having been taken in the vaginal sterilization of Case No. 1. Resection of the tube and amputation of the ovary in Case No. 2 were rapidly performed, the healthy ovary being placed in gauze kept moist with warm normal salt solution in the interval of time between its amputation and implantation in Case No. 1, which was accomplished by incising the vagina and connective tissue down to the cervix, which was stripped up to the peritoneum with the finger, which membrane was carefully raised from its attachments to a point approximating the normal position of the ovary. All oozing was controlled by compresses wet in hot salt solution, and the amputated ovary anchored in position by closing the canal through which it was introduced by two tiers of fine cumol catgut, and the vagina lightly packed with silver gauze. Two days later I left the country for six weeks, instructing my assistant, who had followed the steps of the operation critically, that should there be the least evidence of non-viability of the ovary it was to be removed promptly. The recovery, however, was reported as uninterrupted. After my return I was informed by the patient with evident embarrassment that six days after the transplantation she had a condition of sexual erethism continuing for several days, during the period having had two erotic dreams. From this time she says she has continued to have a positive sexual impulse. Sixteen days after transplantation menstruation occurred, and lasted two full days. No recurrence of the menses followed, however, until December 22d last, when she again menstruated,[1] the flow continuing three days, being natural in color and consistence, and accompanied by a little pain. At this time, nearly eight months after transplantation, the patient has apparently regained her mental and nutritive equilibrium and says she is well, a statement borne out by her deportment, good color, and general healthful appearance.

Normal ovariotomy is followed so constantly by certain phases of denutrition and neurasthenia that there remains no reasonable doubt that the ovary has a function besides that of its external secretion or ovulation, which plays an important part in metabolism. Whether this is an internal secretion of unknown chemical composition which has the faculty of oxidizing organic phosphorized substances, carbohydrates, and fats, as maintained by Curatulo, or whether the ovary influences the elimination of organic toxins through the menstrual flow, as suggested by Spillman and Etienne, will perhaps be shown by the physiologist who now is actively engaged in an investigation of the phenomena presented by certain special organs of the body, and the effect of their secretions upon general and special nutrition.

Fehling's theory, that osteomalacia is a trophic neurosis due to excessive pathological activity of the ovary, with the well-known fact that the disease receives a fresh impetus after conception, has a new significance since Consentino has shown that ovulation continues during reproduction and is important negative evidence of the influence of the ovary and its secretion on nutrition. If further argument were necessary to demonstrate the modifying effects upon nutrition of the ovary, or its essential principles, we may refer to the experiments with ovarian extracts procured from the lower animals, original with Professor Werth of Kiel, which have been substantiated by Landau, Stouffs, Stehman, Jayle, Jacobs, Dunn, and many other eminent authorities who have conclusively shown that the administration of the extracts (which appear to preserve, their integrity in the presence of the digestive fluids or reach the circulation so little changed that their physiologic action is not materially interfered with), generally mitigates or completely relieves the train of disagreeable and distressing symptoms usually following the appearance of the menopause, natural or artificial, so long as the subject remains under the influence of the extract.

However feasible or desirable the operation may become, transplantation of the human ovary must always remain an uncommon operation by reason of infrequent opportunity to establish the juxtaposition necessary; but we see no reason why it should not become a recognized and successful procedure, notwithstanding the probable limited field offered for its execution.

At the suggestion of Professor Chrobak, Dr. Emil Knauer, whose experimentation began in 1895, has shown[1] (1) that in rabbits the ovaries may be transplanted from their normal to other positions; (2) that they may heal in as well on the peritoneum as between the muscular structure; and (3) that the ovaries thus healed in can not only be nourished but they are able to perform their functions, *viz.*, generate and ripen the ova, and possibly under certain circumstances attain their discharge. In a later

[1] Since the presentation of this paper the patient writes me that she again menstruated in February, 1899.

[1] *Centralblatt für Gynäkologie*, No. 20, 1896.

paper[1] Dr. Knauer reports births at the normal end of pregnancy after transplantation of ovaries in rabbits, which he succeeded in attaining with a rabbit which he had operated upon sixteen months before.

In this case he was able to show, thirteen months after the operation, the successful transplantation of ovaries by means of laparotomy. The perfect ability of function of transplanted ovaries was thus proven beyond a doubt. He has since continued his experimentation, trying the transplantation of ovaries from one animal to another. During the year a paper referring to these experiments[2] will be published.

That the range of usefulness of ovarian therapy, immediate through its introduction directly into the circulation by transplantation, or otherwise, or intermediate through the use of extracts by the mouth, is being rapidly narrowed down, there can be no doubt. Since Polk, ably seconded by other great specialists, early in the present decade inaugurated and urged a greater conservatism in operations upon the uterine appendages with a view to the preservation of the functions of ovulation and menstruation, and so consistently and practically demonstrated the tenability of his conclusions in his work, there has come a revolution of feeling as to our responsibility to this class of cases and a better conception of the necessity for the preservation of these organs, until now the better element of the profession would brand as criminal the individual who, with ruthlessness or upon a flimsy pretext, would deprive the patient intrusted to his care of these organs of the usefulness of which, *aside from the marital and reproductive aspects*, there remains so little doubt.

Christopher Martin in a recent article tells us that none of the nervous and nutritive symptoms supervene in operations upon the adnexa in which an ovary or a part of one has been left; that there is physiologically *no difference* in the woman who has *two ovaries*, *one ovary* or a *fraction of that organ.* This proposition tallies with that of the writer who, for the past two years, has made a consistent effort to save an ovary or a part of one in a great variety of pelvic operations, from Cæsarian hysterectomy for cancer down the list of procedures to the most simple, having many times curetted, cauterized, resected, amputated, on one, sometimes on both, sides with no more serious result than two abscesses and a single hyperplasia of the ovary (it having quadrupled in size in three weeks from the time of the original operation for pyosalpinx of the opposite side)—conditions easily controlled by vaginal sections and a trifling delay in convalescence, an insignificant sacrifice, we think, for the stake involved. In my personal experience with the convalescent after abdominal operations since adopting a definite plan of ovarian conservatism I am certainly less frequently confronted by those profound nervous disturbances and malnutritions formerly ascribed to prolonged shock and exhaustion. May not the smoother convalescence in these cases be reasonably attributed to the continued influence of the ovarian secretion? I trust the time is not far distant when a greater conservatism aided by an improving technic and dexterity shall make it rarely necessary to consider organo-ovarian therapy and surgery except in their several relations to the menopause of nature.

THE SERUM TREATMENT OF DIPHTHERIA IN THE NEW YORK FOUNDLING HOSPITAL DURING 1898.[1]

By W. P. NORTHRUP, M.D.,
of New York.

During 1898, 103 patients with diphtheria were treated with antitoxin at the New York Foundling Hospital, with 13 deaths, a mortality of 12½ per cent. The diagnosis was confirmed by bacteriologic cultivation in pharyngeal cases. Laryngeal cases to the number of 12 have been included, in which on one cultivation the bacteriologic report was negative. It is stated by Health Board experts that frequently such cultures taken from the pharynx are negative, while at the same time the lesion has been proved to be laryngeal diphtheria. Two of these patients required intubation, but all recovered. Experience at the Foundling Hospital leads the writer to believe that that these cases may fairly be considered diphtheritic. Rejecting these twelve cases altogether leaves a mortality of 14 per cent., which figure we may consider very satisfactory.

	CASES.	DEATHS.	PER CENT.
Pharyngeal	67	4	.06
Laryngeal	36	9	.25
Total	103.	13.	.12½.

Statistics of immunity are not easily compiled. The strongest statement that can be made from the Foundling Hospital is that there have been so few cases as 103 (most of these patients even being brought in from the out-patient department) and that we have within two years (see Medical News, December 25, 1897) passed through an epidemic of measles without having a single fatal complication of diphtheria.

The antitoxin used in recent years has been that made by the Health Department of the City of New York. There have been no antitoxin joints, no pains, and transient rashes in (estimated) only one-fourth to

[1] Read before the New York Academy of Medicine, February 16, 1899.

one-third of the cases. These have been of so little moment as not to have been recorded in the histories. As an immunizing agent it has attained the highest ideal of therapy; it has preserved most lives, and preserved them intact.

In many ways the Foundling Hospital is a favorable place in which to test antitoxin. Greater New York thrusts into our care a large proportion of poorly developed new-born infants. Five of the thirteen fatal cases occurred in children under one year of age, and ten in those under two years; five patients that died were under one year of age; five were between one and two years, and three were between two and three years.

It has been assumed that it requires high intellectual attainments to employ logic and to eliminate at the same time. This audience has been warned against "eliminations" as not for them. Note that Case I. has not been eliminated, and that several more, hopeless at the time of injection, are included.

CASE I.—H. L., aged eight days. Intubated. Tube extracted on third day. Died fourteen days after entrance to hospital. *Autopsy:* Bronchopneumonia.

CASE II.—A. K., aged one year, seven months, and eleven days. Returned from out-patient department with intubation-tube in larynx. Antitoxin three times. Intubated four times in all. Died in convulsions nine days after admission. *Autopsy:* Erosion and inflammation of epiglottis and larynx; bronchopneumonia.

CASE III.—C. S., aged one year and eighteen days. Treated in St. John's Hospital for one month for bronchopneumonia and enteritis. Admitted to quarantine. Condition: croupy, marasmic, bronchopneumonia. Intubated. Antitoxin. Tube extracted on seventh day. Croupy condition cured. Signs of pneumonia. Died seventeen days after intubation. *Autopsy:* Chronic bronchopneumonia; markedly emaciated.

CASE IV.—W. W., aged one year, one month, and nineteen days. Markedly croupy. Dyspnea. Intubated. Child restless. Respiration very rapid. Died thirty-six hours after admission to quarantine *Autopsy:* Rickets, extensive bronchopneumonia.

CASE V.—J. McM., aged one year and three months. Within an hour after admission was intubated. Colitis. Died in a convulsion twenty-six hours after admission. Bronchopneumonia.

CASE VI.—M. T., aged one year, four months, and twenty-one days. Very poorly nourished. Not seen by a physician until had had diphtheria for (about) four days Very croupy. Intubated. Died about thirteen hours after admission to the hospital. Diffuse bronchopneumonia; chronic colitis.

CASE VII.—J. V., aged two years, nine months, and seven days. Dyspnea. Intubated twelve hours after admission. Died seven days after extraction of tube, and fourteen days after croupy condition began. Bronchopneumonia; diphtheria.

CASE VIII.—A. S., aged nine months and twelve days. Intubated. Diagnosis: subglottic stenosis. Antitoxin. Died seventeen hours after intubation. Under treatment about twenty-four hours. Diphtheria-nasal, pharyngeal, laryngeal; subglottic stenosis; malnutrition; rickets.

CASE IX.—H. S., aged one month and three days. Died about forty-eight hours after admission. Disease probably had existed three or four days before patient was seen by a doctor. Tonsillar and pharyngeal diphtheria.

CASE X.—H. S., aged four months and twenty-nine days. On seventh day lung involvement. Died twenty-four days after admission. Under treatment twenty four days. Pharyngeal diphtheria; bronchopneumonia.

CASE XI.—E. B., aged eight months and eleven days. Rachitis. Râles in chest. Bronchopneumonia diagnosed on fifth day. Died one month after admission to quarantine. Extensive bronchopneumonia; rachitis; pharyngeal diphtheria.

CASE XII.—J. T., aged two years, nine months, and nineteen days. Markedly croupy. On seventh day after admission signs of pneumonia. Died one month after admission to quarantine. *Autopsy:* Lobar pneumonia, right side, complete. Not intubated.

CASE XIII.—C. D., aged two years and seven months. Tonsils neurotic; sloughed away. On eighteenth day otitis media and double mastoiditis. Died after a convulsion seven weeks after beginning of diphtheritic attack. Had been in coma about six hours. Mixed infection.

Finally, I submit that 12½ per cent. fatality in infant foundlings is an extremely good result; that in immunizing, antitoxin has attained even higher, almost ideal results.

CLINICAL MEMORANDUM.

A CASE OF CHOLECYSTITIS, WITH STRICTURE OF THE DUCTUS CHOLEDOCHUS.[1]

BY FREDERICK E. EASTON, M.D.,
OF SYRACUSE, N. Y.

ON August 9, 1897, I was called to attend Miss B. W., aged twenty years, a resident of Chicago, but visiting in this city. I found her suffering from acute pain in the epigastrium, with nausea and frequent vomiting. Her pulse was normal, temperature 99° F., tongue heavily coated, bowels constipated, and skin slightly jaundiced. Her urine was dark, chocolate-colored, but nearly normal in quantity.

About a week previously she had had an attack of acute pain in the epigastrium, with indigestion, which was easily relieved. During the month of March preceding she had had an illness which was called malarial fever, during which she had had pain and vomiting, but no jaundice. She had not been in perfect health since this illness, having been troubled frequently with indigestion.

[1] Read before the Syracuse Academy of Medicine, April 4, 1899.

The present attack differed from the preceding ones, in that the vomiting and pain were more severe, and she was jaundiced. A diagnosis of biliary colic, possibly due to gall-stones, was made. The pain was relieved by morphin, hypodermically, and the vomiting controlled by subnitrate of bismuth, oxalate of cerium, and muriate of cocain. The obstinate constipation was overcome by means of calomel, salines, and copious enemas. The stools, which were putty-colored, were watched for calculi, but none was discovered. The diet was restricted to liquids in small quantities. After the acute symptoms had subsided compound ox-gall tablets were also used.

The patient improved rapidly, although the jaundice increased, but at the end of five days she was about the house apparently convalescent, and I was congratulating myself that the obstruction had been relieved; but on August 25th I was again summoned in haste, and found the same condition of affairs as in the preceding attack, but in a more aggravated form. The pain was referred more to the right hypochondriac region, and was more severe in character. Her temperature was 100° F., and pulse 99. At the end of five days she was entirely free from pain, although some tenderness was still present. She was weaker, more emaciated, and more jaundiced, and gave the appearance of one having passed through a prolonged illness. The urine was examined and found to be charged with bile, but no albumin was present, and it was negative in other respects. Early in September another and more severe attack occurred. Her temperature reached a higher point, her pulse was rapid, at times 120 per minute, her abdomen was tender, and she was extremely emaciated. On palpation the distended gall-bladder could be distinctly felt, which rose and fell with each deep respiration.

Dr. W. C. Kellogg, whom I called in, agreed with me that we had to deal with a case of cholecystitis, cholangitis, associated with gall-stones, which demanded surgical interference. Dr. Elsner was asked to see the case with us, which he did September 12th, and his views of the condition being similar, immediate operation was advised. The patient was taken to New York, and on September 20th Dr. Longe operated.

An incision, two inches long, was made in the right hypochondriac region, parallel to the free border of the ribs. The gall-bladder was found to be thickened and distended, and contained a calculus. The common duct was thickened, but free from impacted calculi. The cystic duct was occluded. The gall-bladder was drawn up against the opening in the peritoneum and stitched firmly to it, effectually closing the opening into the abdominal cavity. This line of stitches was then protected by a narrow strip of iodoform tape. An aspirating-needle was then plunged into the gall-bladder, and a quantity of bile-stained pus removed. The opening made by the needle was then enlarged by the thermocautery, and the calculus seized with forceps and removed. It was the size and shape of a nasturtium seed. The gall-bladder was then cleansed, a long rubber drainage-tube was inserted and fastened in place, the wound was loosely packed with iodoform gauze, and the patient was placed in bed. Following this operation there was a slight improvement; her temperature fell, her pulse improved, and the jaundice lessened, but the stools remained putty-colored, and there was no evidence of bile having passed through the common duct. On October 1st she had another attack of biliary colic, accompanied by rapid pulse, high temperature, etc. This led Dr. Longe to believe that the patient had an obstruction in the common duct, and prompted him, October 6th, notwithstanding that at this time the condition of the patient was nearly hopeless, to attempt another operation.

On opening the common duct no stone was found, in spite of most careful search, but a cicatricial contraction was felt at the point of entrance into the duodenum. A new opening was made into the gut, and the common duct was opened and stitched to it. The patient rallied from the operation much better than was anticipated, and during five days everything went well, when, upon removing the tampon, the suture line was found to leak, and the duodenal contents to escape through the wound. This was overcome by persistently keeping the patient on her left side, and skilful tamponing. Under this treatment the patient improved rapidly and made an uneventful recovery, returning to Syracuse in December with but a small fistula into the gall-bladder, which soon healed.

This case presents some very unusual and interesting features: first, the history of febrile disturbance, with pain, five months prior to the obstruction of the common duct in August, at which time I believe there was duodenal ulceration near the opening of the common duct, with accompanying cholangitis. This terminated in recovery, but left a cicitricial contraction of the common duct; second, the small calculus which doubtless would have passed through the common duct during one of the attacks mentioned had it not been for the cicatricial contraction at its outlet. The stone acted as an irritating foreign body and caused empyema of the gall-bladder. This would have continued no doubt until perforation or until the patient died from exhaustion.

MEDICAL PROGRESS.

Hernia in Hebrew Soldiers.—Ssolomka (*Centralbl. f. Chir.*, February 25, 1899) quotes the statistics which were gathered in the Russian army in order to determine whether hernia occurred more frequently in one race than another. It had been said that the Hebrews brought on hernia oftentimes in order to avoid military duty. The statistics showed that among the Russians 1 man in every 250 had to be rejected on account of hernia; 1 in 200 among the Poles; 1 in 175 among the Germans, while among the Hebrews 1 in every 35 had to be rejected on this account. The writer admits that the Hebrews were of slighter build than the others, but he does not attempt to explain the great discrepancy between the figures as given.

The Etiology of Seasickness.—Darnall (*Jour. Amer. Med. Asso.*, March 11, 1899) explains seasickness as the overstimulation of some portion of the sensitive mu-

cous membrane lining the semicircular canals. Most of the disagreeable sensations in the body are produced by overstimulation of some one of the special senses. Too much light hurts the eye; too loud noise the ear; too rough handling the nerves of touch, etc. Hence too strong, or too-long-continued motion in a given direction hurts the membrane of some part of the semicircular canals, and by well-known reflex action, headache or nausea results. Naturally but little relief from seasickness may be expected as long as treatment is directed toward the stomach. Attention should be turned to the nervous condition of excitability.

The Carcinomatous Nature of Malignant Growths Arising from Pigmented Moles.—GILCHRIST (*Jour. Cutan. and Genito-Ur. Dis.*, March, 1899) contributes from the pathological laboratory of the Johns Hopkins University a study of the histogenesis of pigmented moles, with a report of two cases of malignant new growth arising from them. Such tumors have long been regarded as sarcomatous, but Gilchrist's study confirms the view of Unna, that these growths are epithelial and should be properly placed among the carcinomata. One of the two cases of melanocarcinoma described occurred in a negro. The patient was a man fifty-eight years of age, who presented eighty-seven metastatic tumors, scattered over the entire body surface. The primary growth was a pigmented nodule in the sole of the right foot, which had appeared four years before, and recurred after excision. The smaller nodules were freely movable beneath the skin. There was no enlargement of the lymphatic glands. The patient was put on hypodermic injections of Fowler's solution in increasing doses, but death occurred eight months later. The second case was one of single primary pigmented new-growth of the face, originating in a small pigmented mole. Thorough excision was performed. Microscopic examination of prepared sections showed all stages of commencing malignant downward growth of the cells of the epidermis, with accompanying excessive increase in the production of pigment, demonstrating beyond a doubt that the growth was of epidermal origin, and properly a melanotic carcinoma.

A study of pigmented moles excised from five other individuals showed that masses of epithelial cells becoming detached from the epidermis, go to form the structure of the mole itself. Since the cells which make the structure of the mole are of epidermal origin, any malignant growth springing from the cells should be regarded as carcinoma and not sarcoma.

Splenic Anemia.—ALFRED COLES (*The Blood*, London, 1898) gives splenic anemia a definite position among diseases of the blood. The disease has hitherto received indifferent recognition, and its literature is scant. Coles describes splenic anemia as characterized by marked increase in the size of the spleen, progressive anemia, an absence of leucocytosis, and a similar absence of enlargement of the lymphatic glands. Such a definition excludes leucemia on the one hand, and the ordinary forms of Hodgkin's disease on the other. The disease may be characterized in addition by attacks of colic-like pain in the left hypochondrium, nausea, vomiting, and diarrhea. These occur in paroxysms, and are generally followed by a shorter or longer interval in which the patient feels comparatively well. The spleen is invariably enlarged, and may reach the level of the iliac crests. It is uniformly increased in size, and its shape is unaltered. The liver may be normal or may be enlarged. There may be jaundice. Epistaxis may be an early and prominent symptom. Splenic anemia is distinguished from Hodgkin's disease by the entire absence of any enlargement of the lymphatic glands. The examination of the blood is not pathognomonic. The changes in the blood may be similar to those in Hodgkin's disease. On the other hand, the blood examination is important, as the disease cannot be differentiated from leucemia without it. The red blood-corpuscles frequently fall to two and one-half million per c.mm., and may be further reduced. Microcytes may be present. Hemoglobin is reduced to a much greater degree relatively, and accordingly the color-index of the individual corpuscles is very low, even as low as thirteen per cent. The leucocytes are usually normal in number, and no characteristic changes in the differential count are described. Splenic anemia progresses to a fatal termination in from six months to two years. Its early differentiation from other pathological blood conditions is important in view of treatment. Splenectomy has resulted in cure in three cases of splenic anemia. This operation is almost invariably followed by death in leucemia.

Artificial Eyeballs.—SNELLEN, Professor of Ophthalmology in the University of Utrecht (*Ophthalmic Rev.*, December, 1898) reports his modification of the shell-shaped artificial eyeball, which he considers of advantage, in that the cavity behind the shell is done away with, and the mobility of the artificial eye increased. His device is a double shell of hollow glass, especially designed, where simple enucleation has been performed, to obliterate the cavity and prevent the wounding of the soft tissues behind by the thin edges of the single glass shell. This double-walled shell is fitted to the small stump remaining after evisceration by a concave posterior surface. When the conjunctival sac is emptied an artificial eye-globe with a plane posterior surface is used. The original hollow eye-shell is retained for cases of atrophic eyeball.

Rupture of the Uterus; Child Saved by Post-Mortem Section.—KENDALL (*Ann. of Gynec. and Pediat.*, March, 1899) reports two cases of rupture of the uterus in which after the death of the mother the life of the child was evident from its motions in the abdominal cavity. The abdominal wall was, therefore, slit up, and the child extracted. One of the children died in a few minutes, but the other was saved, a finely formed boy, weighing ten and one-half pounds. The mother was a primipara, only eighteen years of age.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 29, 1899.

IS SANARELLI'S BACILLUS ICTEROIDES THE CAUSE OF YELLOW FEVER?

As the warm weather and rainy season of the first year of our possession of Cuba and Puerto Rico approach, interest in everything that concerns yellow fever is redoubled. In our department of "Scientific Jottings from Tropical Countries" we recently published an abstract of some recent opinions advanced by Sanarelli himself. Further study has only convinced him more surely that his bacillus icteroides is the true and only cause of yellow fever. He has found that it has a special symbiotic favoritism for molds, that it grows by preference and more luxuriantly in the presence of molds than when alone. This symbiosis of micro-organisms, analogous somewhat to parasitism in larger organisms, is not a new biological fact. It is of extreme interest in this case, however, as it seems to explain the preference yellow fever has for the sea-shore and vessels and docks where the constant dampness causes molds to grow with special luxuriance.

We publish this week a preliminary note from Drs. Reed and Carroll, who have been investigating, in the laboratories at Washington, the specificity of the bacillus icteroides (Sanarelli) and especially its relations to the bacillus *x* described by Sternberg some years ago in his investigations of yellow fever in Cuba. Sternberg, however, did not pronounce the bacillus *x* the cause of the disease.

Drs. Reed and Carroll do not consider Sanarelli's bacillus to be the specific germ of yellow fever. It is not the same as Sternberg's bacillus *x* which is probably a form of the colon bacillus but it has so many points of similarity with the bacillus of hog cholera that these observers think it to be only a variety of that micro-organism.

There the question must remain awaiting further investigation. Certainly these last observers seem to have studied the question very carefully before announcing their conclusion. The impression has, we think, been gaining ground generally in bacteriological circles that Sanarelli's bacillus icteroides has been accepted too hastily, especially in certain European countries, as specifically pathogenic of yellow fever. The enthusiasm was not so marked in this country, while in Germany the supposed discovery attracted very little attention. The Germans are, to be sure, not much interested in yellow fever but, even after careful consideration, Sanarelli's investigations were not considered so definitely conclusive as to put the question of specific pathogenesis beyond reasonable doubt. There remains open for ambitious American bacteriologists a very interesting problem of etiology whose study the United States' possession of Cuba and Puerto Rico will greatly facilitate and whose importance can scarcely be overestimated. Any discoveries in this matter will confer lasting fame upon the investigators.

THE NEW DISPENSARY LAW OF NEW YORK.

After having passed the Senate and Assembly almost without a dissenting vote, the bill, amending the State Charities law, relative to the licensing and regulating of dispensaries by the State Board of Charities was signed by Governor Roosevelt on April 18th and will go into effect on the first day of next October. The text of the bill will be found elsewhere in this issue.

The enactment of this law marks the culmination of years of conscientious effort, and too much praise for this successful issue cannot be bestowed on those having the matter in charge. The gross mismanage-

ment of dispensaries in this city has been a public scandal for a generation or more, the apparent object of many of them being to treat annually as many applicants as possible without regard to their worthiness. Carefully compiled statistics have shown that during the year 1897 one-fourth of the population of the City of New York received free treatment at the dispensaries. It is more than probable that this total could have been divided by six if proper investigation had been made of the claims of the applicants and measures taken in accordance with the findings. Unwillingness on the part of managers to institute reforms, of their own accord, and thus harmonize their work with the growing public conscience and trend of opinion made legislative enactment imperative.

The bill which has just become a law is the same, with a few unimportant modifications, as that which was introduced during last year's session of the Legislature, and which failed to be reported back from the committee to which it was referred. The State Board of Charities, while possessing the power to issue licenses and nominally to regulate the management of dispensaries of the State, has never, until now, had conferred on it authority to discipline any institution which failed to conduct its operations in accordance with the board's requirements. The re-result has been that its suggestions or recommendations in this connection have uniformly been ignored. It has repeatedly urged legislation looking toward the correction of this defect, but without satisfactory result. The new law confers upon the board the desired power, subject to certain restrictions, and there is every reason to suppose that it will be exercised along such lines as will prove fairest and to the best interests of all concerned.

Unless we mistake not this is the first instance in which it has been declared, by any law making body, to be a misdemeanor, punishable by a fine, for any person to obtain free medical or surgical treatment at a dispensary under false representations. While the law will in no wise limit or prevent deserving persons from receiving such treatment, but, on the contrary, will increase the facility with which they may obtain it, it will serve to effectually bar all unworthy applicants from participating in the benefits to which they have neither moral nor legal right. The crowds of well-dressed people which are accustomed to throng the waiting rooms of the dispensaries to the exclusion of the needy poor will be greatly diminished or will disappear and the young dispensary doctor will have less to do, but the direct result will be the withdrawal of tacit encouragement toward pauperism, the inculcation of a proper spirit of self-respect in the worthy other half whose necessities compel recourse to charitable aid, and finally, will redound both to the welfare of the community at large and of the profession.

SECOND ATTACKS OF THE INFECTIOUS FEVERS.

IT is becoming more and more certain, now that medical statistics are being kept with greater exactness, that second attacks of the infectious fevers are not so rare as was formerly thought. It is especially worth noting because the old idea, that one attack of a specific disease gave almost assured immunity from a second attack, sometimes led people to take insufficient prophylactic precautions when exposed to the disease for a second time. Even physicians permitted such exposure or protested but slightly against it. In the ordinary infectious diseases of childhood, it is now definitely known that second attacks are by no means rare, in fact are so common that no assurance of the existence of immunity in any given case is justifiable.

The subject has recently interested Professor Gerhardt of Berlin, who, besides being a distinguished general clinician, is the well-known editor of a standard German work on children's diseases. He has carefully collated the personal experience of his own medical students in scarlet fever and measles during a number of years. Taking their statements in connection with the statistics gathered from his hospital and private patients he is able to announce the following opinion: Of ordinary healthy young men about 20 per cent. have not had scarlet fever; about 1 per cent. of them have had two attacks and 10 per cent. of scarlet-fever patients, who have passed the period of youth, are experiencing their second attacks of the disease. As regards measles, about 6 per cent. of young men in the third decade of life have not had the disease, about 2 per cent. have had repeated attacks, while of the young men of this age who acquire measles about 13.5 per cent.

have had the disease previously. One of Gerhardt's students had had seven distinct attacks of measles.

Gerhardt's experience is not an unusual one. In "Progressive Medicine" Dr. Blackader quotes Feltz, who reported from Vienna certain undoubted cases of relapse of measles within a month after the first attack. He also cites Emmet, who has had a similar experience. He has observed altogether 122 cases of second attacks of measles occurring at varying intervals. There are a number of American authorities on children's diseases who have been calling attention to this feature. The subject is deserving of careful investigation and in this matter the statistics of a large number of general practitioners would be of great value. We should be glad to be able to contribute to the further elucidation of this important question by the publication of the personal experience of men whose large numbers of cases in family practice will undoubtedly throw conclusive light on the subject.

PROPHYLAXIS AND TREATMENT OF INTESTINAL OBSTRUCTION.

The last number of *Schmidt's Jahrbücher* contains a review of some interesting contributions to this important subject. Professor Heidenhain, in discussing the cases that have come under observation in the clinic at Greifswald during the past few years, maintains that clinical experience absolutely demonstrates that intestinal obstruction may be in some cases the result of a purely functional disturbance of intestinal peristalsis. In three cases a spastically contracted portion of small intestine was found at operation as the cause of the acute symptoms. The serious disturbance of peristalsis had been brought about in one case by a stricture of the rectum high up, in a second by a volvulus involving the large intestine at the sigmoid flexure, in the third by the presence of a roundworm.

In cases in which any chronic disease of the intestine exists every possible precaution should be taken to avoid disturbing the already irritated peristalsis by anything calculated to produce additional reflex excitation. Only the most bland food should be permitted and every excess strenuously prohibited. Acute intestinal obstruction from bunches of roundworms knotted together have been noted before but now for the first time the direct irritation, due to the presence of a single worm, has been reported as causing sufficient spastic interference with peristalsis to set up acute obstructive symptoms.

Three patients in whom complete intestinal obstruction was diagnosed were relieved by high injections. Under these circumstances doubt still remains whether the condition was due to any of the ordinary serious causes of true obstruction or was occasioned by an extreme degree of coprostasis. Heidenhain thinks that obstruction due to ileus at the sigmoid flexure, a not infrequent condition, may be relieved by injections. Not, however, if the twist of the gut is more than 270°. Operation for this condition, followed by fixation of the intestine has given excellent results in Heidenhain's hands.

An interesting commentary on Professor Heidenhain's success with high injections in certain cases of acute obstruction is found in the report of Dr. Barker's experience with fifteen such cases. In six cases he succeeded in reducing the intussusception by water or air injections. The tumor so changed its character on palpation that no doubt of the reduction seemed possible. In every case, however, it recurred, in a few hours could be felt as before, and necessitated operative interference. Of the fifteen patients ten recovered. Eleven of the patients were children under sixteen months of age, one was an adult, aged thirty-two; the others were children, aged respectively, four, five, and twelve years.

While injections of air and water still have a place in the therapeusis of obstruction they must evidently not be allowed seriously to delay surgical procedures which are always to be thought of at once. In intussusception in children where it was hoped injections would be effectual they have proved of doubtful utility and may only make the eventual prognosis worse by delay. It is clear, however, that as diagnosis becomes more exact operations are undertaken earlier, and the percentage mortality from acute intestinal obstruction is ceasing to be the opprobrium to modern surgery that it formerly was.

SUGGESTIVE DISCUSSION ON MALARIA.

The recent discussion on malaria at the New York Academy of Medicine, the last instalment of which we publish this week, brings out very well the last and best medical opinions on this interesting

subject. So much convincing material with regard to the mosquito-borne theory of the disease has accumulated during the last year or two that even the most conservative medical men must be ready to adopt opinions not unfavorable to it at least. The observations made by English and American investigators regarding hematozoic parasites, in general, have been confirmed by Italian students in respect to the parasite of human malaria, in particular.

Hereafter, practical prophylaxis of the disease and the problem of public health in malarious districts must include the study of the mosquitoes of the neighborhood and the adoption of means for the prevention of their multiplication. A very interesting set of observations that should occupy attention all over the country will have reference to the possibility of the introduction of malaria, by returning soldiers, into parts of the country hitherto unaffected by the disease. Many of them have acquired in their Southern and Cuban experiences chronic forms of malaria which may run an almost latent course, though their blood still contains at times some of the malarial parasites. Malaria has been known to develop *de novo* in a hitherto virgin vicinity under such circumstances, so that careful observation may be rewarded by some facts of great value to the present theories of the etiology of the disease.

Dr. Ewing's announcement that he had seen in one case, and had good grounds for suspecting in others, the transformation of the estivo-autumnal type of malaria into the tertian, is somewhat startling just now when most of us had settled down to the views promulgated by Italian observers that malarial parasites are multiple in species. It is in accord with the present trend of thought on the subject, however, and should open some suggestive lines of investigation for those who have many of the returned soldiers under observation. The careful study of any malarial parasites that may be found in the blood of such patients can serve the very useful purpose of confirming or disproving this opinion of the occurrence of transitional forms, or of an absolute transformation of one form of parasite into another. The idea of such a metamorphosis is not absolutely new. Its possibility under the very different conditions that prevail in the tropical climate where the disease was acquired and the temperate climate in which the men have since lived seems very plausible. Painstaking American medical men have an excellent opportunity under the circumstances to add some very pregnant facts to the scientific as well as the clinical aspects of malaria.

ECHOES AND NEWS.

Health Department to Move.—The New York City Health Department will move from its present quarters in the Criminal Court Building to the building formerly occupied by the New York Athletic Club at Fifty-fifth street and Sixth avenue.

Buried Many Fathoms Deep.—Dr. Bachmann, the physician of the German deep-sea expedition, died suddenly on January 14th, and his body was lowered in the deepest place so far sounded by the expedition—5733 meters—near the Kakos Islands.

Non-Alpine Sanatoria for Consumptives. — The results in non-Alpine sanatoria of Germany have been sufficiently good to warrant the insurance companies in the country in paying between three and four million marks in 1898 for the erection and maintenance of such sanatoria for the people.

Publications in the Lay Press by Dr. Schenk. — There seems to be a general feeling of satisfaction in the medical profession of America over the announcement that the Vienna Academy of Medicine has decided to discipline Dr. Schenk for having made known his alleged discovery concerning the production of sex at will through the medium of the lay, in place of the medical, press.

International Congress of Life-Insurance Examiners.— The first International Congress of doctors connected with life insurance will be held at Brussels, September 25 to 30, 1899. Representatives from all the civilized countries of the world are expected to be present. An effort will be made at this Congress to establish universal formulas for the examination of applicants for life insurance.

The Psychic Study Society.—Among the stated objects of the Psychic Study Society, which was organized on April 20th in New York City, are, "the study of hypnotism and mesmerism and an inquiry into the alleged phenomena of clairvoyance, somnambulism, thought transference, and all matters of kindred nature, and the careful investigation of any reports resting on strong testimony of alleged apparitions occurring at the moment of death or otherwise," etc. A number of physicians are members.

Tuberculosis Hospital for the United States Marine Hospital Service. — By order of President McKinley, Fort Stanton, an abandoned military reservation in New Mexico, containing about 10,240 acres of land with the buildings thereon, has been transferred to the Marine Hospital Service for the care and treatment of cases of

tuberculosis coming under its jurisdiction. Preparations will be immediately made for its occupancy by the Service, and the buildings will be put in order for the reception of patients.

Increase of Attendance at the Medical School of the University of Paris.—According to the report of the council of the University of Paris the following is the comparative attendance at intervals of 6 years for the last 15 years. In 1885–86 there were 3696 medical students, in 1891–92, 4111; in 1897–98, 4494. During the same period the number of students in the law department has increased from 3786 in 1885 to 4607 last year. The number of students of pharmacy has remained about stationary, while the number devoting themselves to science has more than tripled, from some 400 to over 1300.

New York City Appropriations for Hospitals.—On April 2d Governor Roosevelt signed a bill empowering the New York City Board of Estimate and Apportionment to appropriate annually sums of money to any charitable, eleemosynary, correctional or reformatory institution, wholly or partly under private control, for the care and maintenance of its inmates. Payments are to be made only for such inmates as are received and retained therein pursuant to rules established by the State Board of Charities. The board may increase or diminish the sum now authorized to be paid annually to any such institution, association, corporation or society.

A Declining Birth-rate—An Increasing Marriage-rate in England.—The *Medical Press and Circular* of London calls attention to the fact that while the birth-rate in England has been steadily decreasing for some years the marriage-rate has been almost as steadily increasing. Our contemporary says that it offers no explanation of the fact, but that it evidently cannot be explained on any ordinary natural grounds. In the jubilee year, 1897, the marriage-rate touched the highest figure ever known in England—namely 16.0 per cent., but while in 1897 more persons entered upon matrimony than had ever been known up to the present time, during the next year, 1898, less births were recorded than during any corresponding period, at least in the last ten years.

Tenth International Congress of Hygiene.—It will be remembered that the last session of this congress was held at Madrid just before the breaking out of the late war with Spain. The next one is to be held at Paris, in August, 1900. The proceedings will be conducted in seven sections: (1) Microbiology and parasitology as applied to hygiene. Of this section Laveran is president and Netter, secretary. This section also will discuss the etiology of intestinal helminthiasis. (2) Chemical and veterinary science as applied to hygiene. (3) Hygienic engineering and architecture. (4) Personal hygiene. (5) Industrial and professional hygiene. (6) Military, naval, and colonial hygiene, and (7) General and international hygiene.

Still Another Medical Martyr.—Dr. Angelo Knorr, privat-docent in the veterinary department of the University of Munich in Bavaria, died last month from acute glanders. The disease occurred as the result of an inoculation during the course of some experimental studies on mallein, the toxin produced by the bacillus of the disease. Glanders is mainly an animal disease, seldom affecting human beings, and the studies on it were undertaken entirely for the purpose of preventing animal-suffering. When the cry goes up from rabid antivivisectors of the awful suffering inflicted upon animals in the laboratories of Europe, do they ever think of the numbers of young men who are ready and willing to risk health and even life itself in the study of the diseases of animals, in order to prevent suffering among them?

Mississippi Valley Medical Association.—The Executive Committee and the Committee of Arrangements of the Association have changed the date of the next meeting in Chicago, from September 12th–15th to October 3d–6th inclusive. The Autumn Fête to be known as the American Festival will be held in Chicago, beginning September 25th and ending October 9th with the laying of the corner-stone of the Federal building, when the President and the Cabinet will be in the city. During this time the railroad fare to Chicago from all points will be a one-fare rate for the round trip, without the necessity of certificates or signatures. The limit of the tickets is so long that a protracted stay can be made in Chicago in order to take advantage of the clinical facilities of the meeting as well as enjoy the added attractions of the Festival.

The First Woman Teacher of Medicine in Paris.—Mlle. Edwardes Pilliet, M.D., has just been appointed by the Department de l'Assistance Publique of Paris an instructor in certain medical branches. She is to lecture on physiology to the nurses at the Hôpital Lariboisiere, and to give instruction in bandaging to the attendants at La Salpétrière. These positions are not in connection with the medical department of the University of Paris, but with the training schools for nurses connected with the Department of Public Charity. Mlle. Edwardes Pilliet is the first woman to be accorded the honor of a teaching position in this department. It is safe to predict, however, that the time is not far distant when in Paris, under the auspices of the University of Paris itself, as in Bologna of yore, women will lecture publicly on medical subjects.

Wire-Pulling Extraordinary over a Dispensary Position.—The following story from the *British Medical Journal* of April 1, 1899, will serve to show that some of the profession across the water can give even American medical politicians points in wire-pulling for positions. The office of medical attendant at a dispensary not far from Dublin was vacant. The vote for the new incumbent it was rumored would be a tie. The evening before the election meeting one of the members of the board received a telegram saying that his country seat in the West of Ireland was on fire and asking him to come at once. He did so by the night express, but found everything safe and peaceful on his estate. When he returned the election was over. The board is now investigating the affair. Of course the elected candidate knows nothing about the telegram. He was of the opinion that the man so sud-

denly called away would have voted for him. All that is wanted now is some lapses of memory when the time for taking testimony arrives, and the whole thing will wear a wonderfully familiar air.

Yale Asks for $2,000,000.—The Bicentennial Committee of the alumni of Yale University has just published an address asking that $2,000,000 be contributed for University purposes in honor of the two hundredth anniversary of the institution, which will be celebrated in 1901. Of this sum $225,000 has been subscribed and without condition. Among the objects for which the money is to be expended we note these items of special interest to medical men: fund for instruction and scholarships in the Sheffield Scientific School, $250,000; biological laboratory, $150,000; instruction and scholarships in the Department of Medicine, $200,000; clinical building and Pathological Institute, $100,000; University Library, $200,000. If the present appeal proves successful and the enthusiasm amid which it has been proposed, the energy and promptness with which the matter has been taken up, and the proverbial willingness of the "Yale spirit" would seem to be an earnest of this, there is every reason to believe that a great medical department worthy of Yale University will flourish within the next ten years amid the classic shades of New Haven.

The Late Dr. W. W. Van Arsdale.—The following memorial notice was adopted by the New York County Medical Association at its stated meeting on April 17th and ordered published in the medical journals: *Resolved*, That in the death of Dr. W. W. Van Arsdale the New York County Medical Association has lost one of its most accomplished members. In addition to a thorough academic education, Dr. Van Arsdale passed successfully through the long course of study required at the University of Leipsic in Germany, from which institution he graduated with honors, and afterward served the required term of service in the great hospital of that city as pupil of, and assistant to, the distinguished Professor Thiersch. Returning to his native country he located in New York City, became connected as an assistant to the chair of surgery in the New York Polyclinic Medical School and Hospital in the early days of its organization, and served with such faithfulness and proficiency that he gradually rose to the professorship of surgery, which position he filled with entire satisfaction and held at the time of his lamented death. He was also assistant surgeon to the New York Cancer Hospital. For four years before his death he had been assistant visiting surgeon to Mount Sinai Hospital, where his conscientious and thoroughly scientific work was fully appreciated, and where his loss will be keenly felt. Dr. Van Arsdale was twice elected chairman of the Section on Surgery in the New York Academy of Medicine, and was an earnest working member of the New York Surgical Society. He contributed many valuable papers upon scientific subjects to the various medical journals, and was justly considered one of the clearest writers of his day upon surgical topics. *Committee*: John A. Wyeth, M.D., Chairman; Francis J. Quinlan, M.D.; A. Ernest Gallant, M.D.

New York's New Dispensary Law.—The following is the text of the Dispensary bill which was signed by Governor Roosevelt on April 18th last: "Section 1. Article one of chapter five hundred and forty-six of the laws of eighteen hundred and ninety-six, entitled 'An act relating to State charities, constituting chapter twenty-six of the general laws,' is hereby amended by inserting at the end thereof the the following sections: Sec. 19. What is a dispensary?—For the purposes of this act, a dispensary is declared to be any person, corporation, institution, association, or agent, whose purpose it is, either independently or in connection with any other purpose, to furnish, at any place or places, to persons non-resident therein, either gratuitously or for a compensation determined without reference to the value of the thing furnished medical or surgical advice or treatment, medicine or apparatus provided, however, that the moneys used by and for the purposes of said dispensary shall be derived wholly or in part from trust funds, public moneys, or sources other than the individuals constituting said dispensary and the persons actually engaged in the distribution of charities of said dispensary. Sec. 20. Licensing of dispensaries by the State Board of Charities.—A license may be issued by the State Board of Charities to a dispensary, as provided in this section. An application in writing for such license shall be made to such board in the form and manner prescribed by it, which shall be uniform for all schools of medicine. There shall be attached to such application a statement, verified by the oath of the applicant, containing such facts as the board may require. If, in the judgment of such board, the statement filed, and other evidence submitted in relation to such application, indicate that the operations of such dispensary will be for the public benefit, a license shall be issued to the dispensary applying therefor. The form of such license shall be prescribed by the board. A dispensary shall not enter upon the execution, or continue the prosecution of its purpose unless licensed by the State Board of Charities, as provided in this act. A license shall be issued, on application, to all dispensaries legally incorporated, and to unincorporated dispensaries conducted in connection with incorporated institutions at the time of the passage of this act. Sec. 21. Rules and regulations.—The State Board of Charities shall make rules and regulations, and alter or amend the same, in accordance with which all dispensaries shall furnish and applicants obtain medical or surgical relief, advice or treatment, medicine or apparatus. But such rules and regulations shall not in any case specify the particular school of medicine in accordance with which a dispensary shall manage or conduct its work or determine the kind of medical or surgical treatment to be provided by any dispensary. Sec. 22. Revocation of licenses.—The State Board of Charities or any of its members may at any and all times visit and inspect licensed dispensaries. They may examine all matters in relation to such dispensaries, and ascertain how far they are conducted in compliance with this law and the rules and regulations of the board. After due notice to a dispensary, and opportunity for it to be heard, the board may, if public interest demands,

and for just and reasonable cause, revoke a license by an order signed and attested by the president and secretary of the board. Such order shall state the reason for revoking such license, and shall take effect within such time after the service thereof upon the dispensary as the board shall determine. The said board is hereby directed to apply to the supreme court to revoke the license and annul the incorporation of any dispensary legally incorporated, or conducted in connection with an incorporated institution at the time of the passage of this act, for wilful violation of the rules and regulations made by said board. Sec. 23. Drug-store or tenement-house not to be used by dispensary; unlawful display of signs.—After the taking effect of this act, no dispensary shall make use of any place commonly known as a drug-store, or any place or building defined by law or by an ordinance of the board of health as a tenement-house; nor after such time shall any person, corporation, institution, society, association, or agent thereof, except a duly licensed dispensary, display or cause to be displayed a sign or other thing which could directly or indirectly or by suggestion indicate the existence of the equivalent, in purpose and effect, of a dispensary. Sec. 24. Any person who wilfully violates any of the provisions of this act, or any of the rules and regulations made and published under the authority of this act, shall be guilty of a misdemeanor, and on conviction thereof, shall be punished by a fine of not less than ten dollars and not more than two hundred and fifty dollars. Sec. 25. Any person who obtains medical or surgical treatment on false representations from any dispensary licensed under the provisions of this act shall be guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than ten dollars and not more than two hundred and fifty dollars. Sec. 26. All acts or parts of acts inconsistent with the provisions of this act are hereby repealed. Sec. 27. This act shall take effect on the first day of October, eighteen hundred and ninety-nine.

NOTABLE BOOKS.

PRACTICAL HYGIENIC AND MEDICAL GUIDE FOR THE UNACCLIMATED IN HOT COUNTRIES, AS CUBA, PUERTO RICO, AND THE PHILIPPINES. BY FEDERICO MONTALDO.

THIS book was crowned by the Spanish Royal Academy of Medicine of Madrid just before the Spanish-American war was declared, and was recommended to prospective emigrants and colonists in the islands that have since passed under the jurisdiction of the United States. The recommendations it contains are strictly practical in character and evidently come from a man who has himself had a large experience in the tropics, and who has seen and knows thoroughly the dangers to which the unacclimated colonists expose themselves, and how these dangers may be avoided. During the next few years most American medical men will probably have friends and patients who are about to set out for these countries, and as they will be consulted about the precautions necessary it has seemed opportune to review some of the practical suggestions Dr. Montaldo offers.

Before setting out for the tropics every one is advised to consult a physician and on no account to go without his approval. Absolute contraindications of removal to a tropical climate are chronic diseases of important organs, especially of the gastro-intestinal tract, the liver, or the kidneys. The heat and the change of diet it necessitates, with the introduction of unusual forms of bacteria are almost sure to cause a certain amount of dyspeptic and gastro-intestinal disturbance even in the most healthy subjects. In those whose resistive powers are already below par serious illness that will be fatal or become hopelessly chronic will probably supervene. In these changed conditions, instead of dissipating heat in order to keep the body temperature up, the vital forces must neutralize heat reception from without in order to keep the temperature down to the normal. This produces an alteration in metabolism, and throws an excess of unusual work upon the liver and the kidneys. Substances absorbed, and in temperate climates, simply burned up in order to furnish heat, must now be excreted. Serious and unusual calls are thus made upon the excretory functions of these important organs, and their resistive vitality is distinctly lowered. While in this state they are not infrequently called upon to excrete the toxins of certain infectious diseases so common in the tropics that no one can hope to entirely escape them. It is evident then, if the adoption of the new environment is to be successful, that these important organs must be unimpaired in their functional capacity.

The choice of season for emigration is of the greatest importance. There are in tropical climates practically only two seasons, the wet and the dry. The wet is much the more dangerous for the unacclimated, and it is advisable that the newcomer be prepared for it by several months of previous residence in the country so that much of the unusual shall have worn off. Time spent in waiting for the favorable moment to emigrate is not lost, but will be more than compensated for by time saved from restrained methods of life, or perchance, confinement to bed during acclimatization at an unfavorable season England and Germany have issued formal advice to intending colonists in this matter and do not, unless from some serious necessity, send officials, civil or military, to tropical colonies during the wet season. This is a precaution which Spain, typically enough, despite her 400-years' possession of tropical colonies, as Montaldo points out, had never taken.

The constant dangers that threaten the unacclimated in tropical countries are, the heat, the sun, the changes of temperature which are quite different and much more marked than in temperate climates, the humidity, and malarial infection. The heat precludes the possibility of doing as much work as in a temperate climate, and to attempt it is to invite disaster. The intensity of the sun in its directness requires that the middle of the day shall be given

[1] *Guia practica, higienica y medica del Europeo en los Paises torridos* (Filipinos, Cuba, Puerto Rico, etc.). Par Federico Montaldo. Madrid: Ricardo Rojas, 1898.

up to rest within doors. To brave the noonday sun is foolhardy beyond peradventure. The custom of the inhabitants in this matter of midday rest must be unquestionably adopted. A sudden fall of 30° or more of temperature during the night is not uncommon in the tropics. Humidity is a marked feature of all tropical climates. It interferes with cutaneous perspiration and other functions and calls for special care of the skin, frequent bathing, warm as well as cool, and brisk rubbing in order to keep the skin functions at their acme of availability. For malaria quinin must be taken as a prophylactic in doses of 5 grains or more according to individual susceptibility.

The temptation in tropical climates is always to drink too much and too frequently. This but increases the perspiration, adds to the discomfort and relieves the thirst only for the moment. Alcoholic drinks should not be taken at all by the unacclimated, since they but add to the store, already too large, of heat-producing materials in the system. Water alone, especially if cold, will always be drunk to excess. Montaldo advises to mix it always with lemon- or orange-juice, or to take it in the form of weak tea or coffee. He recommends from personal experience that it should be taken slightly warmed. The temptation to take too much is not so apt to become irresistible, and besides when warm it seems to assuage the thirst better. Montaldo also advises to begin at once, on arriving in a tropical climate, the formation of the habit of not drinking between meals. He says it is easily acquired by a little force of will.

As to eating, much less is required of course than in a temperate climate, yet there is always the danger from old habits and the appetite that has been acquired by years of plenteous indulgence in a variety of food. Foreigners in the tropics always eat too much, especially too much meat, and this is one of the main factors in their liability to gastro-intestinal, hepatic, and renal disease.

For clothing, light-weight, and light-colored, loosely woven flannel is recommended. It should be covered with some other garment whenever it becomes damp from perspiration to avoid the constant evaporation which abstracts too much heat from the cutaneous surface, disturbs the visceral circulation, and so gives the opportunity for an infective agent that may be present to secure a foothold in the tissues.

With regard to venereal indulgence there is a special word of warning. The old habits of internal-heat production, so necessary for obvious protective purposes in a temperate climate, are retained by the organism during its preliminary period of acclimatization, even though not needed in the tropics. The genital sphere especially bears the brunt of the increased tissue metabolism that this involves, and besides the relaxation incident to the tropics prevents a normal amount of exercise and so discourages the working off of surplus energy by physical means. The result is a greatly heightened unaccustomed *nisus generativus*. Excesses in venery, however, are especially trying to the unacclimated, and yet the character of the women of the tropics is apt to be such that opportunities are not wanting for the satisfaction of passion. It is this matter that forms, according to Montaldo, one of the most frequent sources of unhealthiness on the part of immigrants to tropical countries. Of course a word is added as to the great frequency of venereal disease in these countries owing to promiscuous intercourse.

CORRESPONDENCE.

APPENDICITIS AND TERMINOLOGY.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I trust to your generosity to allow me to say that I have not been quoted quite corrrectly in the issue of your most excellent journal for April 22d, where you honor me in giving a report of my paper "The Term Appendicitis and Other Unscientific Words in Our Nomenclature," and further, that the object of my remarks has been overlooked in your editorial on the subject. Neither my insignificant self nor even a single much better man can change at will the habit of employing unscientific, incorrect, and sometimes directly *misleading* terms. If the whole profession will adhere to appendicitis, *habeat sibi!* If there are people who insist on "*per orem.*" *habeant!* So much the worse for the profession, so much the worse for those men. I confined myself to positive facts and no more and no less, and I leave it to the profession at large, not to the German Medical Society of the City of New York alone, to judge of the correctness and the value of my positive statements. Allow me here to add that I have already conclusive evidence that my labors are being noticed favorably by many good men, by some of the best men of our profession. It happens sometimes that the contrary of what we say is reported. I have not said that the term "scolicoiditis" might be adopted by our Greek colleges. I stated that this word is the exact translation of our word appendicitis, but that the Greeks employed it rarely. I am not guilty of having coined a new impossibility "nosogeny" as I am quoted with, and I have not said that skolex is the term for appendix. I wonder what my Greek friends would think of me if I had done such awful things! As to one of Dr. Jacobi's remarks, who did me the honor to discuss my paper rather favorably, I gave the exact reasons why it is of importance to distinguish well between nosology and pathology, since these are two essentially different matters.

A. ROSE, M.D.

NEW YORK, April 22, 1899.

ANOTHER BIT OF NASAL SURGERY.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—A strong parallel to your recent excerpt from the *Lancet*, entitled "An Interesting Bit of Nose Surgery," occurred in my practice a few years ago. A boy, aged six years, was looking down through a broken skylight when something suddenly attracted his attention; he turned sidewise and the sharp edge of the glass cut the tip of his nose off. Being summoned to see him, two blocks away, I inquired for the piece, which had dropped into the cellar. The father found it there and brought it;

time at least twenty minutes; size almost as large as a copper cent and about three millimeters in thickness. After aseptic cleansing and placing in correct position I fastened the piece by laying over it a thin film of cotton soaked in aristol collodion. Healing was by primary intention. The piece remained redder than the rest of the nose for a couple of years but looks now almost natural.

A still more striking success I have obtained with a finger. A waiter from a hotel next door came into my office, having chopped off one-third of the last phalanx of the left index-finger with a sharp bread-knife. I sent his companion for the piece, which he found on the table. The larger part of the nail and a piece of bone were in place. After trimming the nail I attached the piece in the same manner as the nose. For further protection a support projecting beyond the finger was fastened to the hand. Perfect union ensued but it required great care to remove the remnants of the nail without destroying the fresh attachment. I should advise in a similar case in future to remove the nail of the piece at once, although a man is naturally shy to handle the piece much, as the growing of the matrix pushes against the piece and has a tendency to force the piece off from the new union. Although I succeeded without stitches I have the feeling that a couple in the finger would have been wiser, as with all superadded hardening material a finger-tip cannot be held so quiet as a tip on the nose, where stitches are certainly undesirable.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

ACETO-SOLUBLE ALBUMIN—CHANGES IN THE RETINAL ARTERIES INDICATIVE OF GENERAL ARTERIAL DISEASE FROM THE OPHTHALMOSCOPIC STANDPOINT—THE NEW ALLENTOWN HOSPITAL—CHANGES IN THE BUREAU OF HEALTH—ELECTION OF THE NORTHAMPTON COUNTY MEDICAL SOCIETY—THE MEDICAL CLUB'S RECEPTION TO DRS. BULL AND COLEY—PERSONAL NOTES—OBITUARY—HEALTH STATISTICS.

Philadelphia, April 25, 1899.

At a meeting of the Pathological Society, held April 13th, Dr. W. M. L. Coplin reported two interesting cases of aceto-soluble albumin in the urine, under the title of "Two Cases of Albuminuria, the Albumin Not Being Recognizable in the Acetic Acid and Boiling Test." In In 1889, Pattein called attention to the occasional presence in the urine of a form of albumin which was precipitated upon boiling in the absence of acetic acid, but which, nevertheless, became resolved upon the addition of acetic acid, even in minute quantities, and if urine containing this form of albumin was rendered ever so faintly acid by the addition of acetic acid, the albumin failed to be precipitated upon boiling. Pattein also reported later that it was possible to convert serum-albumin into aceto-soluble albumin by the addition of certain sodium salts and other means, and believed, therefore, that the serum-albumin enters the glomerulus as such, and is altered in its descent through the tubes. Two of the cases so far reported have been in eclamptic women, the second of whom had true albuminuria as well. A third case was that of a parturient, who had a large amount of true albumin in the urine, though she did not have eclampsia. In this case the aceto-soluble albumin appeared just before labor. Two cases have also been reported as occurring in males which would tend to preclude the idea of an intimate relationship between some condition of pregnancy, and the presence of this particular form of albumin. Dr. Coplin reported two cases of his own, the first of which occurred in a woman suffering from typhoid fever, who was pregnant also for the second time, the first labor having been normal in every particular. The albumin entirely disappeared later, and at no time were casts found in the urine. The second case was that of a child who was suffering from acute follicular tonsillitis. In both of these cases albumin could not be demonstrated by means of the *heat and acetic acid*, *overlying nitric acid*, nor by the *nitric-magnesian* test, but was proved to be present by the ferrocyanid of potassium with acetic-acid test, and by Tanret's reagent, from which Dr. Coplin concludes that the boiling and acetic-acid test, and the overlying nitric-acid test, can not be depended upon in all cases.

At the same meeting Dr. de Schweinitz read a paper "Concerning the Changes in the Retinal Arteries Indicative of General Arterial Disease from the Ophthalmoscopic Standpoint," in which he called attention to the tortuous condition of the arteries, their alternate contraction and dilatation, and the whitish streaks about their walls. Stress was laid also upon the influence of arterial pressure on the venous blood streams where artery and vein cross one another, and the impeded venous circulation. Frequently an ophthalmoscopic manifestation is edema of the retina and retinal hemorrhages consequent upon this condition which has recently been called attention to by Marcus Gunn, and which is of great prognostic value according to Dr. de Schweinitz.

About May 1st the New Allentown Hospital will be formally opened to receive patients, of which it can accommodate about thirty. The necessary funds were largely raised by the Ladies' Auxiliary of Allentown, and the last Legislature appropriated $5000 for its maintenance. The building is of granite and brick, equipped with the latest improvements in sanitary appliances, and the plans call for extensions which are to be made from time to time as need arises and money can be obtained.

The general expectation that there would be a "shake-up" in the Bureau of Health has been fulfilled, and four assistant-medical inspectors have been notified that their services will not be required after the first of next month. The $4800 a year which is thus saved is to be utilized in paying the Chief of the Bureau a yearly salary of $4000, which is the amount provided for under the reorganization. Members of the Board of Inspectors protest against this reduction in their number and say that as the

work now done is all they can well accomplish this reduction will mean more work than can be properly attended to with consequent deterioration in the measures taken for the protection of the city's health.

At the eleventh annual meeting of the Northampton County Medical Society, held at Easton, April 21st, the following officers were elected: President, Dr. Charles McIntyre, Easton; vice-presidents, Drs. J. O. Berlin of Bath, and D. H. Keller of Bangor; recording secretary, Dr. F. H. Erwin, Bethlehem; corresponding secretary, Dr. H. T. Edwards, South Bethlehem; treasurer, Dr. Amos Seip, Easton.

The Medical Club of Philadelphia gave a reception to Drs. William T. Bull and William B. Coley of New York at the Bellevue Hotel on Saturday night. Dr. Anders, the President, introduced the members and addresses were made by Drs. Bull, Coley, Keen, De Forrest Willard, and Rodman. Among those present were Drs. Hare, Musser, Guy Hinsdale, La Place, Burr, Montgomery, Judson Daland, and J. Chalmers Da Costa.

Dr. M. P. Ravenal will address the Associated Health Authorities of Gloucester County at their annual meeting to be held in Woodbury during May.

Major William H. Lambert, for the past several years President of the Department of Charities and Correction, has resigned as a member of the Department much to the regret of all who know him. The resignation, it is stated, was not due to political influence but to pressure of private business.

At the celebration of the Fiftieth Anniversary of the Lycoming County Medical Society, held last week, Drs. W. S. Forbes, H. A. Hare, and Thomas Mays delivered addresses. Dr. Osler of Johns Hopkins was also present and spoke.

Dr. J. William White has been appointed a member of the Board of Visitors to the Military Academy, West Point, for the year 1899.

The annual banquet of the Alumni Association of Jefferson Medical College will be held at the Art Club on May 15th; Dr. Orville Horwitz is Chairman of the Dinner Committee.

By the will of the late Mary Dwyer, $3000 is left to the Sisters of St. Francis for a Dwyer bed in St. Agnes Hospital, and $1000 to St. Mary's Hospital.

The Legislature has increased by $25,000 the appropriation made to the University Hospital, and to Jefferson; the Medico-Chirurgical receives $45,000 additional, which gives it a total of $120,000 as against $75,000 which the two former institutions receive.

Dr. Thomas W. Flanner, a graduate of the University of Pennsylvania, died last week at his home in Philadelphia, aged seventy-nine.

The total number of deaths occurring in Philadelphia during the week, ending April 22d, as reported at the Bureau of Health, was 505, of which number 122 occurred in children under 5 years of age. The total number of new cases of contagious disease was 337, reported as follows: Diphtheria, 53 cases, with 18 deaths: scarlet fever, 42 cases, with 1 death; typhoid fever, 242 cases, with 1 death.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE CANCER NUMBER OF "THE PRACTITIONER."—RETIREMENT OF DR. SOPHIA JEX-BLAKE—STRUGGLE OF WOMEN DOCTORS—SINGULAR INFLUENZA-LIKE EPIDEMIC AMONG DOGS—"POISON BY POST"—PROPOSED MINISTER OF HEALTH—SANITARY PROGRESS IN THE ANTIPODES.

LONDON, April 17, 1899.

THE prominent topic of the past week. both professional and lay has been the cancer problem, brought into bold relief by the interesting and striking "cancer-number" of *The Practitioner*. This symposium of the views of a number of experts from both sides of the Atlantic, each one treating a phase of the subject, to which he has devoted much thought, if not actually won fame in, is most timely and reflects much credit upon its enterprising organizer and editor, Mr. Malcolm Morris. Its effect upon public opinion and interest has been most marked, and appeals for the adequate endowment of laboratories for cancer research will hereafter not fall upon deaf ears.

The ablest and most impressive paper of the entire group is that by Dr. Roswell Park of Buffalo, on the "Nature and Causation of the Cancer Process," which was published simultaneously in the MEDICAL NEWS, and which has provoked much comment in the press. Dr. Arthur Newsholme discusses the oft-alleged increase of cancer in recent years, reaching the unexpected conclusion, after a very thorough examination of the vital statistics, that it is apparent and not real. The much larger number and proportion of deaths by cancer recorded, he regards as due chiefly to completer reports and greater accuracy of diagnosis. His conclusion contravenes what most of us have accepted almost as an axiom, yet he makes out a very strong case for his view, showing for instance, that the enormous diminution in the number of deaths from "unknown causes" is alone sufficient to account for a large proportion of the increase in cancer, allowing it its due percentage of these.

Dr. Alfred Haviland takes up the geographical distribution and reaffirms the oft-enunciated dictum, that the disease is most prevalent on clay soils, in low swampy districts, and depends largely upon fluctuations in the ground-water. But this, of course, lands him in the difficulty that modern agriculture and drainage have enormously diminished both the ground-water and its fluctuations, while he declares cancer to be increasing, a dilemma which he endeavors to escape from by alleging that drainage has in some mysterious manner increased the liability of river-valleys to floods and thus produce the retention-dampness conducive to cancer. Altogether the paper leaves one with the decided impression that nothing definite can yet be said in regard to the soil-proclivities of cancer.

Plimmer, after a brief review of the parasitic theory of cancer, relates in greater detail his own results, alluded to in my last letter. He found a yeast-organism in 95 per cent. of some 1200 cancers examined by him, and from its cultures succeeded in producing tumors in inoculated guin-

ea-pigs, after many trials. But as these so-called tumors took the form of abundant, translucent tubercles upon the peritoneum, in the liver, spleen and lungs (in fact ordinary yeast-tuberculosis), affected *the connective tissues only*, and proved fatal in from *thirteen to twenty days*, they could hardly be even remotely regarded as carcinoma, except by a pure bacteriologist.

Dr. Sophia Jex-Blake, Dean of the Edinburgh School of Medicine for Women, and one of the founders of the London Woman's Medical College, has just been tendered a farewell reception on the occasion of her retirement to her old home in Sussex. Dr. Blake was first attracted to medicine as a career while on a visit to America thirty-three years ago and studied for two years in Boston under Dr. Lucy Sewall. Then she returned to England, and apparently from sheer love of battle, determined to complete her education and secure a degree, at the same time vindicating the rights of her sex in this regard. Her plucky fight lasted eight years, but succeeded at last in 1876, when Parliament passed an Act formally enabling the colleges to admit women to their examinations. She began her campaign in London, but rebuffed there, moved upon Edinburgh, where, after being admitted on sufferance for four years, the little band of women-students were flatly refused their degree, and after an expensive lawsuit driven to fall back upon London. Here they at last succeeded in establishing the Women's School of Medicine, in 1874, which was formally recognized two years later.

But life had become too easy in London for such a born Alexander and, after only two years of inglorious peace, Dr. Blake returned to the siege of Edinburgh, where, after eight years of delightful war, she succeeded in planting the banner of the still flourishing School of Medicine for Women in the very heart of the citadel. Now, covered with honors and the spoils of victory, she is retiring at the early age of fifty-nine to the home of her girlhood, though one can scarcely help wondering what influence will be found in "Sleepy Sussex" antagonistic enough to make life worth living.

The death is announced of Dr. William Squire at the ripe old age of seventy-four. For some years past, withdrawn from active, professional life, Dr. Squire will be remembered by his admirable "Essays in Preventive Medicine," which many years ago laid the foundations of the science of epidemiology, and is still a classic work of reference. He also wrote the section on diphtheria in Reynold's "System of Medicine," and that upon the exanthemata, in "Quain's Dictionary."

A new and singular epidemic among dogs is reported by Professor Penberthy as extremely prevalent in various parts of England. Its onset is characterized by dulness, stiffness, vomiting, and thirst, quickly followed by severe, pulpy congestion of the mucous membranes of the mouth, going on to even gangrene of the gums and tongue. A similar condition is found post-mortem throughout the entire alimentary canal, and in some cases in the lungs. The disease is extremely fatal, nearly 60 per cent. of the cases ending in death in from six to ten days. Bacteriologic examination reveals no distinctive organism, nor can the disease be communicated to other dogs, even by feeding them upon the viscera and stomach-contents of animals dead of the epidemic. The interesting feature is that Professor Penberthy regards it as analogous to a form of canine influenza.

The rôle of imitation or, in the fashionable terminology of the day, suggestion in crime is a curious one. For months past the papers here have been full of the sensational Cornish case in New York and "Poison by post" has become a familiar head-line. Now London has use for this on its own account, a young girl, Mary Ansdell, inmate of a home for the feeble-minded, having received a few weeks ago a cake by parcel-post, after eating which she fell ill and died with symptoms of irritant poisoning. Three of her little friends who had assisted were also made very sick, but not having eaten an "owner's share" recovered. After careful search the police succeeded in tracing the cake and letter accompanying it to the victim's elder sister, a girl of twenty-two, living in London as a servant. The chief link in the chain of evidence was the purchase by the wretched girl of several packages of a phosphorus-paste, put up as a rat-poison, this element being found in abundance in the stomach of the victim by the well-known toxicologist, Dr. Stevenson, chemist to the Home Office. For a long time motive seemed utterly lacking, but it was at last discovered that the depraved creature had taken out an insurance-policy upon her sister's life and apparently planned her cold-blooded murder for the magnificent reward of $55.00. It is but charitable to hope that the feeble-mindedness will be shown to run all through that family, but the opportunity for getting rid of some of it, permanently, is too good to be let slip.

There is a strong movement on foot for the establishment of a Ministry of Health, with a seat in the Cabinet. The sanitary administration of the country has hitherto been in the hands of the Local Government Board, a body which has done some admirable work, but which is loaded with an immense amount of other business, lacks initiative and enterprise, and that sense of responsibility only to be developed in a department with a single head.

The honorary degree of M.A. has been conferred by the University of Cambridge upon Dr. Sims Woodhead, in view of his recent election to the chair of Pathology.

Things "do move" in Australia. One of the legislatures has just passed a bill directing physicians to report every case of tuberculosis which they are called to attend to the Board of Health, and, marvel of marvels, provoiding a fee of sixty cents for each notification! All milk-cows are to be tested with tuberculin and renumeration paid for those slaughtered, only in case the post-mortem shows the diagnosis to have been mistaken.

Cremation Increasing.—In 1898 there were 179 cremations in Gotha, 105 in Heidelberg, 98 in Hamburg, and 21 in Jena, an increase of 31 over the preceding year. At Woking in England the number of bodies cremated in 1897 was 173; in 1898 it was 240. Four other crematories have been built in England and Scotland in the past five years.

REMOVAL OF HYDATID CYSTS OF LIVER AND LUNG—INCISION AND DRAINAGE THE BEST OPERATION FOR PANCREATIC CYSTS—AN IMPROVED METHOD OF OPENING THE ANKLE-JOINT—AORTIC ANEURISM CURED BY THE INTRODUCTION OF SILVER WIRE—SUCCESSFUL OPERATIONS ON THE PYLORUS—RADICAL CURE OF INGUINAL HERNIA—FUNCTION OF THE PERICARDIUM—MODERN VIEWS ON GOUT—TUBERCULOSIS IN IRELAND.

AT the Clinical Society of London, March 10th, ROBINSON described the successful treatment of hydatid cysts of the liver and lung of a boy, aged six years. In each situation there was a single cyst, that in the liver holding about a pint, and that of the lung being as large as an orange. The two were removed at separate operations two months apart. In each instance the cyst was incised, its contents evacuated, and its lining membrane peeled out whole. The fibrous sac was not disturbed. The cavities were drained and healed readily. The cyst in the right lung was exposed by resection of a portion of the second rib anteriorly. For ten days afterward there was a high temperature and evidence of localized pneumonia, though there was no connection between the sac and the bronchi, nor any bloody expectoration or cough during or after the operation. The boy made a good recovery and was well when last heard from.

BARKER reported the successful treatment by incision and drainage of a pancreatic cyst holding three or four pints. The cyst made its appearance in a boy, aged fourteen years, after a fall some weeks previous. In a month's time after the operation the wound had entirely closed. Antiseptic drainage and not extirpation seemed to the speaker to be the proper treatment in such cases.

In this respect DORAN agreed with him. An accurate diagnosis is not always possible until the operation has been partly performed, and several surgeons have remarked after an extirpation, that had they known the origin of the cyst, they would not have attempted its removal. Even if a cyst is situated in the most favorable part of the pancreas, namely, in its tail, it may be necessary to tie either or both of the splenic vessels, surely a serious procedure.

LANGTON also advocated incision and drainage. He gave the details of a case in which a pancreatic cyst, also of traumatic origin, contained 9.5 pints of old blood.

LANE reported three cases treated by incision and drainage, in one of which the cyst was opened from the back.

LANE described an improved method of opening the ankle-joint in case of tuberculosis. Previously he divided all the structures around the joint except the internal lateral ligament, the tibialis posticus, and the flexor tendons of the toes. In spite of careful suture the tendons sometimes united imperfectly. Besides the transverse cutaneous incision, he now makes vertical incisions of sufficient length to enable him to expose the several tendons for a considerable distance. In the young infant he found he could expose the interior of the joint by dividing the peroneus tertius alone, as well as the external, anterior, and posterior ligaments, the other tendons being turned out of their sheaths and hooked aside. In older children he also divides the peroneus longus and tertius high up, cutting through muscular and tendinous fibers, securing larger and more vascular areas in accurate apposition, and keeping the sutured portion at a distance from the joint, and so minimizing infection of it. By this means the objections to the former operation were avoided without diminishing its thoroughness.

At the session of March 24th, LANGTON reported a case of aneurism of the abdominal aorta, successfully treated by the introduction of silver wire into the sac. The aneurism was in the epigastric region and was first noticed after the birth of the patient's child. It increased in size until three months later an exploratory laparotomy was performed. A trocar was thrust into the sac, and after its withdrawal five feet of silver wire were passed into it. There was not much hemorrhage. One year later there was a hard mass, much smaller than before operation, the thrill and bruit having disappeared. Six similar cases have been reported, four of the operations proving fatal.

MORISON showed a number of patients upon whom he had operated for pyloric obstruction. Pyloroplasty he had performed nineteen times for benign stricture without a death. In no instance was there a recurrence of the trouble. He began the incision an inch and a quarter above the pylorus and continued it clear through the pylorus. He passed his suture through all the coats of the viscus, suturing the longitudinal wound transversely. Five patients were presented from whom he had removed carcinomatous growths of the pyloric end of the stomach. All were much improved and none as yet showed any sign of recurrence. The periods of time since operation varied from six weeks to eighteen months. He considered the operation safer than gastro-enterostomy, and advocated it for all movable tumors, no matter whether large or small.

At the Medical Society, March 13th, LANGTON read a paper on the radical operation for inguinal hernia. He described four methods of procedure: (1) Reconstruction of the inguinal canal with transplantation of the vas deferens and its vessels to the upper angle of the incision so as to form a new inner ring; (2) operations in which the whole or part of the sac is utilized to form a pad or buffer within, or close to, the inner ring, so that the peritoneal fossa usually met with was converted by the boss into a convex buffer; (3) ligature of the sac close to the inner ring, its excision, and the reconstruction of the inguinal canal; (4) partial removal of the sac, its ligation and torsion, its withdrawal through the conjoined tendon, and the inner pillar of the external abdominal ring, and its retention in this situation by sutures. It was impossible to determine the exact method to be adopted until the parts were exposed and the conditions thoroughly examined, but he preferred and practised, whenever possible, the operation first described, with certain modifications. He used kangaroo tendon as a continuous, rather than an interrupted suture, the coaptation of the canal being

thereby made more complete. Drainage was rarely needed, only when hemorrhage had been profuse or when a cavity was left after a large hernia. In males between ten and fifteen years of age, especially when omentum presented, his practice was to drag down a considerable piece, returning it into the peritoneal cavity after securely ligaturing. Rest and recumbent position for a month is a most important element in the after-treatment. He expressed himself as opposed to operating upon children under six years of age, as they can usually be cured of their trouble by the use of a truss. In speaking of recurrence after operation, he said that the records of the City of London Truss Society showed that in the last six years 242 operated patients were treated for failure of the operation, from which it might be inferred that the total number of failures must be very considerable. In private practice the results were better known and were encouraging, eighty per cent. being successful, at any rate for several years.

March 27th, Barnard spoke of the value of the pericardium to the heart. It has been shown that the heart cannot carry on the circulation unaided. The contractions of the muscles of the legs and abdomen are necessary to force the blood into the right auricle. If these muscles all act at the same time a pint or two of blood might be forced into the heart were it not for the fact that the overdistention of the thin-walled auricle is prevented by the fibrous pericardial sac, just as the outer leather cover of the football prevents the overdistention of the thin rubber ball within it. The pericardium limits the possible diastolic distention of the heart by about one-half. When the pericardium is softened in pericarditis, coughing, or moderate exercise will not only fill the heart with blood, but will also stretch the pericardium, which probably never regains its normal size. The right heart then will always dilate, and its valves will become incompetent even with moderate exertion.

Mouillot read a paper before the Harveian Society, March 15th, on the modern views of gout in relation to treatment. He believed that the proximate cause of the gouty state lay in a defective metabolism of proteids due to a functional disease of the liver or intestinal glands, and that the deposit of sodium biurate was due to deficient elimination by the kidneys owing to a diseased condition, or through their action being inhibited by an impure condition of the blood. In the differentiation of gout from rheumatism stress was laid on the condition of the fingers, and also on the deposit so often found in the conjunctival surface of the lower eyelid. In speaking of the treatment, Mouillot argued from the action and success of colchicum that the objects aimed at should be to diminish the quantity of uric acid formed, and to stimulate the intestinal glands and liver, whilst endeavoring to remove all the uric acid formed through the excretory organs. Colchicum probably acts by its effect on the liver and intestinal glands, which increases the quantity of bile, thus removing, in the form of glycocolic acid, one of the antecedents of uric acid. Colchicum completely meets the indications in acute gout. Chronic gout and goutiness must be treated mainly by diet and periodic visits to watering-places. The main points in diet are to drink fluid freely apart from meals, and to make the meals as little complex as possible. Stimulants should never be taken except at meals on account of their effect on the liver.

Luff urged the importance of avoiding the use of salicylic acid or sodium salicylate in the treatment of gout, since it is not only useless, but in many cases he had found it do positive harm. Many gouty people drink too little. Especially is this the case with female gouty patients, in whom the total amount of daily fluid consumed frequently averages not more than eighteen or twenty ounces. Alkalies and their congeners are useless when administered with the object of dissolving gouty deposits, but he frequently employed alkalies in the treatment of gouty dyspepsia and of gouty affections of the liver.

Armstrong said that, as a general rule, a certain amount of butcher's meat is necessary. In a considerable number of cases on a non-meat diet he had observed that although the actual amount of uric acid formed got less, the rate of excretion diminished to a still greater degree. Beef and mutton certainly stimulate the process of excretion. In nearly one hundred cases of patients dieted exclusively on minced meat and hot water, there was at first an enormous increase in the quantity of uric acid excreted, which, no doubt, the advocates of a non-meat dietary would say was conveyed into the system by the beef; but as the gouty troubles improved, the excretion gradually fell to normal, although the food was unchanged. In giving red meat to the gouty, it is necessary to cut down, as far as possible, the consumption of carbohydrates and of milk, and also to insist upon the drinking of hot water one hour before each meal. Fresh vegetables are of the greatest value, but they should be well cooked. A separate vegetable course at dinner is most useful.

At the Medical Section of the Royal Academy of Medicine in Ireland, February 17th, Grimshaw read a paper on the prevalence of tuberculosis in Ireland. He dealt with a period of three years, 1895 to 1898, during which time phthisis caused 11.7 per cent. of all the deaths in that country. The rate in the cities was notably higher than in the country districts.

McWeeney called attention to the relative infrequency of tuberculosis among cattle in Ireland. The practice of keeping them on grass for six months each year, may be looked upon as the open-air treatment of tuberculosis applied to the bovine race.

Letters said that the most correct test of the tuberculous character of a locality is when the mortality from tabes mesenterica and tuberculous meningitis combined bear a high rate to that from phthisis. This high proportion of juvenile to adult tuberculous mortality in Ireland invariably corresponded with a high degree of urbanization.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 20, 1899.

THE President, DR. WILLIAM H. THOMSON, in the Chair.

DISCUSSION ON MALARIA.

(Concluded from page 512.)

The first paper of the evening, entitled

MORPHOLOGY OF THE MALARIAL ORGANISM, ILLUSTRATED BY LANTERN-SLIDES,

was read by DR. JAMES EWING. He showed on three stereopticon-slides sketches of red blood-corpuscles containing malarial parasites of the three forms of malaria generally recognized, the tertain, the quartan, and the estivo-autumnal, in the various stages in which they occur in human blood, and described their phases, and discussed their significance in the life history of the parasite, and the clinical picture of the disease.

The achromatic spot that occurs in all forms of the malarial parasite, and which takes a greenish-tinge with hematoxylon, Dr. Ewing considers to be the nucleus of the protozoon, and always referred to it as such. The ring form of the parasite Dr. Ewing's sketches brought out very clearly. Even when the ameboid movements become noticeable, though the ring may be very thin and difficult to see, with care it can always be demonstrated. As to the significance of the ring appearance he considers it not a mere optical delusion due to the presence of an achromatic vesicular nucleus at this point, but an actual ring enclosing a certain amount of hemaglobin of the red blood-corpuscle. The latest and best authorities seem to be drifting toward this opinion.

In certain very severe forms of tertian malaria, almost malignant in type, importations from Cuba and Mexico, that Dr. Ewing has seen here in New York City, he has observed in a number of instances multiple infection of the red blood-corpuscles. A species of conjugation of the parasite seems to take place in these cases since after a certain stage of its life history is reached never more than one parasite can be found in a red blood-cell, the twin parasites being all young forms. He can scarcely help connecting the observation of this presumed conjugation with the severity of the disease in these cases.

The quartan type of malaria is rare in the neighborhood of New York, and all of Dr. Ewing's specimens were procured from a distance. Arkansas and Missouri furnish characteristic examples of this form of malarial parasite. A marked peculiarity of the effect of infection with the quartan parasite is that the red blood-corpuscles do not swell up as inevitably occurs after infection with the tertian parasite but, on the contrary, shrivel up, becoming markedly smaller even within a few hours of invasion, when the parasite is as yet very small and young. In the young forms the quartan parasite cannot be differentiated with certainity from the tertian type. As it grows older, however, the quartan becomes densely pigmented, and the ring is coarser than in the tertian form. There are intermediate forms where it still remains difficult to distinguish them even when the life history is pretty well advanced, but they are comparatively rare.

There are perhaps grouped under the estivo-autumnal type of malarial parasite a plurality of species, but the subject has not yet been definitely settled, and workers generally, as yet, assume but one form. The parasite is at first smaller than either the tertain or quartan, and affects the red blood-cell less, causing it neither to swell nor to shrivel. The signet-ring form of the parasite is very characteristic. The ring portion is geometrically fine and regular, perfectly linear in outline. While the ring of the tertian form can be sketched with a brush, that of the estivo-autumnal parasite requires a fine pen for its reproduction. This parasite seldom contains much pigment, and this makes a striking differential sign.

The rosette form, when it reaches the sporulation stage, is also very characteristic, but it cannot always be found in the peripheral blood, though it can usually be demonstrated in smears from the organs, especially the spleen, post-mortem. Dr. Ewing found it a number of times at Montauk last summer in peripheral blood-specimens from living patients, and also in smears made from the organs at autopsy. In his experience there seem to be almost always eighteen spores to the rosette, though it has usually been stated in the literature of the subject that there were less than this—twelve to fourteen. Occasionally nineteen, and once or twice twenty spores, were counted in specimens procured at Montauk. Finally, Dr. Ewing demonstrated varieties of the, as yet, mysterious malarial forms, the crescentic bodies. He does not agree with those who think that they are sterile, as it were, superannuated forms of the malarial parasite, though they may represent a resting stage. They constitute a valuable sign of the age of the infection because of the absence of hemaglobin that they present. Recently, Russian observers have shown that they contain certain chromatin particles that are evidently nuclear in character so that all evidence of life in them is not lacking.

There is a tendency noticeable now among Italian students of malaria to come back to the old idea of only one form of parasite for malaria which is modified by circumstances into the various forms which are now and have been for so long admitted. It may even be that one may change into another under certain conditions. Certain cases observed last summer, among the soldiers at Montauk, by Dr. Ewing, and followed up since, seem to confirm this idea as to the essential unity of the malarial parasite. In one case, in September, blood-examinations showed characteristic parasites of the estivo-autumnal type; in January the blood-picture had changed, and it was very hard to say whether the parasites were of the estivo-autumal or the tertain type. In March they were frankly of the tertain type. This observation was confirmed by others which were not, however, so complete.

The second paper of the evening,. on

MALARIAL NEPHRITIS

was read by Dr. H. S. THAYER of Johns Hopkins University, Baltimore, Md. He thinks that the frequency of

the occurrence of nephritis after malaria has been underestimated, and agrees with Rem Picci, who discussed the subject very thoroughly in Rome last year, that malarial nephritis is by no means rare. He agrees also with that observer that it may occur as well with mild as with severe malaria, and that its etiology is the elimination by the kidneys of abnormal tissue-products produced by the irritation of the disease, and the toxins of the malarial parasite.

Dr. Thayer inclines to the view that the incidence of nephritis complicating malaria is even more frequent in this country than pointed out by the Roman observer. Forty-four per cent. of all malarial cases treated at Johns Hopkins Hospital, during the last three or four years, were complicated by albuminuria. Considerably more than one-half of all the patients suffering from the estivo-autumnal type of malaria had albumin in their urine. The negro seemed especially liable to suffer from nephritis during an attack of malaria, proportionately more than three times as many negroes as whites suffering from malarial nephritis.

The course of the nephritis was uniformly favorable, especially when treated by quinin. Patients with relapsing malaria, complicated by nephritis, during the first attack were apt to have relapses of their nephritis with the recurrence of the malaria. Dr. Thayer gave the details of some cases in which malaria finally led up to chronic nephritis. In one case, autopsy in a child showed the large, white kidney, while microscopically, there was considerable interstitial change to be seen. In general, nephritis occurs as frequently after malaria as after diphtheria, so that it deserves careful looking for in all cases of the disease.

The nephritis may only manifest itself after convalescence has become well established, and long after the acute symptoms of the disease have subsided, as happens also with other infectious fevers, notably scarlet fever. In general, it may be said that as sharp an eye should be kept for renal involvement after malaria, as after any of the other infections.

The presence of nephritis does not require any modification of the routine treatment of the malaria. There is an impression abroad that quinin is irritating to the kidneys, and should not be used, or but sparingly in these cases. There is no good warrant in the serious literature of malaria, or in the clinical experience of good authorities on malaria for such an opinion. Especially has it been said and thought that the occurrence of bloody urine formed a positive contraindication to the administration of quinin. This is not true, however, and whenever there are acute symptoms of malaria quinin should be used freely, and will be the very best thing for the patient. Much harm is liable to accrue from the prevalence of opinions opposed to this, so that Dr. Thayer considers it advisable to express himself very explicitly and definitely on the subject.

The third paper of the evening, entitled

SOME OF THE LESS COMMON EFFECTS OF MALARIA WITH REMARKS UPON THE TREATMENT OF CHRONIC INFECTION

was read by Dr. Wm. H. Thomson. Though malaria was for so long considered, as the name indicates, an air-borne disease, a true miasm we now know that it is not. It is probable that with the passing of this idea goes all notion of a genuine miasma, a true malaria or bad-air disease being discovered. The change of base with regard to the etiology of the disease is no greater, however, than is the development that has come in our ideas as to peculiar clinical symptoms that may be occasioned by it.

Recently Dr. Thomson has had two cases of coma in his service, one each at Bellevue and at Roosevelt, the cause in each case being undoubtedly malaria. It is evident that the parasite of malaria may take the membranes of the brain as a special habitat and that comatose conditions are oftener due to malaria than is thought. In every case of obscure coma, when other ordinary causes of the condition can be eliminated it would be well to think of a possible malarial origin for the condition. A blood examination will decide the interesting question and the therapeutic test will confirm the diagnosis, for, as Dr. Thomson's cases showed, the coma yields promptly to quinin.

Another unusual and interesting symptom is neuralgia. This may take the form of a periodical headache or of intermitting aches and pains almost anywhere in the body. A specific in controlling these attacks of pain is ergot; a dram of the fluid extract by the mouth or rectum rapidly relieves the pain. Quinin is often ineffectual. Curiously enough, however, when quinin and ergot are given together cinchonism is produced much more quickly than when quinin alone is administered. Dr. Thomson has known 12 grains of quinin to produce pronounced cinchonism, where ergot was administered simultaneously, while before double that amount had been used with but very little effect.

Quinin is not as a rule administered with sufficient method and persistency in ordinary cases of malaria or there would be fewer relapses. If there has been even a single paroxysm of malaria, quinin should be prescribed for six weeks. The dose need not be large but if it be kept up there need be no fear of relapses; subsequent attacks will be due to reinfection not recrudence of the old attack.

A very important desideratum of our knowledge now is to know how long the parasite may live in the human body causing practically no symptoms and yet under special circumstances favoring irresistance give rise to fresh attacks. Professor Smith of Harvard in talking of Texas fever and its analogy with malaria, at the last meeting of the Academy (see Medical News April 22d), said that the parasite of Texas fever had been known to exist in an animal in a latent stage for five years.

As to the incubation period of the disease, light is gradually being thrown on this much mooted point. A very striking case bearing on this has been reported from Switzerland. Seventeen persons from a little Swiss town where there was no malaria and in none of whom any malarial symptoms had ever been noticed, visited Italy. All of them acquired malaria, the incubation periods being from two weeks to four months. Malaria running what formerly was considered a latent course, should not

be permitted to continue its existence. Blood examinations should be made for nine months after the attack and if malarial organisms are found at any time treatment should be renewed.

With regard to treatment in general, personal susceptibility to quinin plays a considerable rôle in the matter. Last summer there came to Roosevelt Hospital some hundred soldiers, who had suffered from malaria from one to three months, despite the fact that they had received and were receiving 15–90 grains of quinin per day. Even cinchonism had been produced and maintained for some time in many of these cases, yet malarial parasites continued to be found in the blood.

Quinin is *the* drug for malaria and even such cases as these do not demonstrate its non-specificity for the disease but adjuvants are necessary and a method of treatment that permits the action of the quinin to be most effective. For this Dr. Thomson has found these directions of great practical service: First, a mercurial laxative should be given before the close of the febrile paroxysm. The relief of hepatic congestion and the purgation of the intestines cause the drug to be absorbed sooner and besides removes any quinin in the intestinal tract. This is an advantage since quinin changes into a non-active form if allowed to remain long in the intestines. Second, the quinin should be given one or two hours before the chill in order to have it in the system during the sporulation stage, *i.e.*, when the malarial parasites are especially sensitive to its action. It is usually advisable, because of its irritating properties, to give it in 3 equal doses, the last one or two hours before the chill. Third, spices have long been known to be antiperiodic themselves and to assist the action of quinin, as the popularity of Warburg's tincture in malarial countries shows. Equal parts of powdered ginger in chronic malaria is often of great help. Ginger will sometimes of itself abort malaria even where quinin has failed. Fourth, another adjuvant often of service is the oldest antiperiodic in use, *viz.*, opium. Last summer in the cases of the soldiers at Roosevelt Hospital, the camphorated tincture in half-ounce doses t. i. d. gave immediate relief in combination with quinin. No relapses occurred after its use. Roberts in India pointed out that it is the alkaloid narcotin of the opium that is antiperiodic and that it is better than quinin in certain cases. He also stated that far from producing sleepiness, it stimulates. Its name should be anarcotin; it is distinctly anticomatose.

DR. THAYER, in discussion, said that he agreed with Dr. Ewing that there was not in the crescentic bodies any direct evidence of a capsule. The crescents seemed to him more important, however, than had been set forth. They were intimately connected with the flagellate bodies, and these recent researches, especially those of MacCallum, had shown to be significant for reproduction, very probably being sexual elements. Crescentic bodies might be sterile for their possessor but they could give rise very probably to malaria in others. As to the possibility of the unity of the malarial parasite, Dr. Ewing's suggestions were extremely interesting. They were confirmed by the fact that malarial recrudescences in the springtime were usually tertian in character.

There did not seem to be enough facts, however, as yet to justify any conclusion in this direction and he asked Dr. Ewing if he had observed the transition of one form into the other. As to long periods of incubation Dr. Thayer would rather think of an infection from other patients than accept months of incubation. Infection was comparatively easy if the mosquito-theory were true and all the work on it had been excellently done by trustworthy workers who had mutually confirmed each other's observations.

In reply to Dr. Thayer's question as to the transitional types between the various forms of malaria, Dr. Ewing said that only in the one case given in his remarks had he been able to observe what he considered actual transition between distinct types of the malarial organism. In other cases, however, there had been enough to make him suspect that transition had taken place.

THERAPEUTIC HINTS.

For Trachoma.—Applications of iodin in glycerin or of oil of white vaselin are recommended by NESNANOFF. For instance:

℞ Iodi pur. . . . . parts 1–3
Ol. vaselini alb. . . . . parts 100
Etheris . . . . . q. s.
M. Sig. External use.

The conjunctiva is dried with absorbent cotton, and the iodin then applied, at first in strength of one-half per cent. in glycerin. After a few treatments a one-per-cent. solution in oil of white vaselin can be used. Occasionally it is found necessary to increase to one and one-half or even three or four per cent. Abnormal secretion is quickly checked, and the affection entirely cured by carrying out the iodin treatment.

For Pain in Bones Due to Syphilis.—

℞ Ext. aconiti . . . . . gr. x
Pulv. glycyrrhizæ . . . . ʒ i
Ext. glycyrrhizæ . . . . q. s.
M. Ft. pil. No. LX. Sig. One pill morning and evening.—*Devergie.*

Lubricant for Instruments or Fingers.—The mixture given below is stated by KRAUS to be an excellent antiseptic lubricant for sounds, or in making vaginal or rectal examinations. It has the consistence of cold cream, but is quite soluble in water. It can easily be sterilized, and causes no irritation to delicate tissues.

℞ Tragacanth . . . . . gr. xl
Glycerini . . . . . ʒ iiss
Aq. carbolici (three per cent.) . ℥ iii.
M. Triturate in the cold. Sig. External use.

For Lichen Urticatus.—

℞ Hydrarg. chlor. corros. . . gr. iii
Chloroformi . . . . *m.* xx
Glycerini . . . . . ʒ ii
Aq. rosæ . . . q. s. ad. ℥ viii.
M. Sig. Lotion.—*Goodhart.*

ORIGINAL ARTICLES.

ON THE USE OF ANTISTREPTOCOCCIC SERUM IN INFECTIONS BY THE STREPTOCOCCUS.[1]

BY A. T. BRISTOW, M.D.,
OF BROOKLYN, N. Y.

ONE attack of a zymotic disease usually confers protection against the second. When a second attack does exceptionally occur it is not serious and complete immunity is the rule. Clinicians have been aware of this fact for centuries but so far as we know not until the days of inoculation for smallpox was there an attempt made to produce artificial immunity. Subsequently inoculation gave place to the equally certain immunity conferred by vaccination. This was the first instance in which protection was sought from the lower for the higher organism. The distinct difference between this method of producing immunity and the modern serum treatment of disease is that in the older treatment the patient was made to manufacture the source of immunity from his own cells and was therefore subject to all the risks which are attendant on this process. In inoculation for smallpox these, although far less than the disease itself, were by no means insignificant and sometimes people died as a result of the inoculation. Moreover, an inoculated patient was just as deadly an agent of infection as the individual who had contracted the disease in the natural way. Vaccination of course obviates the objectionable features of inoculation and is the ideal method of conferring immunity through the cell processes of the individual himself. Had we such an agent against the other zymotic diseases and the suppurative processes we should have a treatment far superior to that which is furnished us by the serums.

Unfortunately the immunity which is conferred by serum-therapy is brief and we are therefore compelled to wait until the individual is either stricken with the disease or is in immediate attendance on others or is in the midst of an epidemic. It is impracticable to use the inoculation-method which has been in use during a century and a half, because the process of securing immunity by graduated doses would take too long and much risk would be incurred in the process. Therefore we call to our aid the lower animals and make them take all the risks of the process which requires often a year for a good serum and this we use to prevent the disease in those exposed or to heal its actual victims. Incidentally one may remark that it is difficult to see what rational objection can be made to this plan of procedure even by the most rabid of antivivisectionists, for if we are justified in sustaining life at the the expense of the lower creation we are certainly equally justified in prolonging it by protecting ourselves from disease through the action of animal serums. That objection is nevertheless made to this use of animals by these people should be remembered, for if the bill of the Washington society had passed it would have empowered them to put a stop to the production of all antitoxins in the District of Columbia and this power of course would have been sought by other societies of similar scope and purpose. As guardians of the public health our duty in the matter is obvious.

Of all the serums that the laboratories have furnished, that which protects infancy from the ravages of the disease well named "the destroyer" has the most brilliant record. The serum of Haffkine promises to serve a purpose equally important for the peoples of Asia. It is not strange, then, that the attention of investigators in this line of research should have been turned to the problem which must be of the greatest interest to surgeons—the production of a serum which shall be protective or curative against the organisms which are responsible for wound infection. Some work has been done in the direction of prophylaxis against the staphylococcus infections in Italy by Brazzola and Paracandola, but as yet there are no tangible results of use to the surgeon. In the year 1895 there appeared in the "Annals of the Pasteur Institute" an article by Marmorek in which he announced that he had succeeded in producing a serum effective against the organism of erysipelas. Subsequent articles by the same investigator appeared in other journals in which he detailed the results of his work in erysipelas, scarlet fever and other affections in which the streptococcus was the cause either of the disease itself or, as in scarlet fever, of serious complications. Since then many observers all over the world have reported cases in which Marmorek's remedy against this the most dreaded of the pyogenic organisms has been successfully used. Other observers have reported

[1] Read at the Ninety-third Annual Meeting of the Medical Society of the State of New York, held at Albany, January 31 and February 1 and 2, 1899.

negative results in similar cases, so that at present there is much confusion in the evidence submitted for adjudication. On the whole, however, it seems favorable and of sufficient weight to justify us in putting it to the test in suitable cases. It thus becomes the duty of those who have made use of this antitoxin to put on record their experience and conclusions with regard to its usefulness. Accordingly the histories of fourteen patients are here submitted, classified as follows:

Erysipelas, 3; streptococcic inflammations of the hand and forearm following so called poisoned wounds, 7; streptococcic inflammation of the leg and foot, 1; suppuration of the knee-joint, 1; post-operative pneumonia, 1; acute gangrene of the foot with an ascending lymphangitis and phlebitis, 1.

Case I.—My associate in the Long Island College Hospital contracted erysipelas of the face starting from a pimple about the ala nasi of the left side. He had dressed a case of cellulitis of the forearm on the day previous to the onset of the disease in his own person and it is likely that he infected himself by scratching the pimple. His constitutional symptoms were severe from the start although his temperature did not rise above 104° F. at any time. The upper lip became much swollen and the erysipelas rapidly extended in the direction of the forehead. An incision was made into the upper lip through the mucous surface for the purpose of relieving tension, and local applications of ichthyol were made to the affected area. He was able to take but little nourishment and no stimulants by the mouth whatever, on account of extreme irritability of the stomach. The area of redness and infiltration slowly advanced as far as the eyebrows and the general condition was most serious. I then determined to give him the serum of Marmorek, and accordingly administered 15 c.c. of a serum which I procured from Parke, Davis & Co. Here it is proper to state that in all my cases I have made use of the serum manufactured by this house. Following its use in this case the severe constitutional symptoms rapidly disappeared, the area of redness ceased to advance, and the threatening nature of the disease became mild. A small collection of pus was subsequently evacuated in the region of the nasal fold. I regret to say that I made no further injections in this case as the graver conditions had subsided which caused me to make use of an untried remedy. The patient had a subsequent metastasis in the pectoral region and a tedious convalescence. Had I used the serum freely I believe this might have been avoided. This was in the summer of 1897. But few reports had then been published concerning this treatment, therefore I did not feel justified in using it as boldly as in subsequent cases.

The other cases of erysipelas were treated in December of 1898.

Case II. occurred as the result of an infection starting from a small granulation in a healed stump after amputation at the middle third of the arm. This patient was treated for two days before I saw her. During the first twenty-four hours the affected area was kept wrapped in gauze wrung out of a three-per cent. solution of carbolic acid. The day following applications of a 25-per-cent. ointment of ichthyol and vaselin were substituted. On the third day I saw her. The erysipelas had then extended to the top of the shoulder and her temperature was 105.5° F. I immediately sent for the serum and injected 10 c.c. that night. Her temperature fell about eight hours after this injection and the tenderness and redness of the affected area almost disappeared. As an area of redness still persisted, together with some temperature, forty-eight hours afterward, I gave a second injection, which seemed to effect a cure.

Case III.—About the same time that I was treating the last patient I was informed that there was in the emigrant ward a bad case of erysipelas following vaccination The surgeon in charge, Dr. Tappan of the United States Marine Hospital Service, consented to use the serum as the patient had been for four days on other treatment. The arm had been soaked in hot bichlorid of-mercury solution, 1 to 5000, every three hours. The area of redness was extending both up and down the arm. The patient's temperature was 104° F. and she suffered a good deal of pain. The area of redness was rapidly spreading and blebs were appearing all over the arm. Ten c.c. of Parke, Davis & Co.'s antistreptococcus serum was injected at 4.25 P.M. At 5 P.M. her temperature was 104° F., at 9 P.M. 100.4°, and at midnight, 103.6° F. On January 1st, her temperature at 9 A.M. was 101.8° F. Ten c.c. of serum was injected at 10.45. Her temperature at 3 P.M. was 103 6° F. On January 2d at noon, an additional 10 c.c. of serum was injected and the patient's temperature was normal at six o'clock. Her evening temperature rose a little, but then fell, and continued normal.

I have seven cases of virulent infection to report following the infliction of trivial wounds.

Case IV.—From this patient I believe my associate received his infection. The man was an Italian picture-frame maker who had punctured the base of his thumb a few days before with a wire nail clean from the package. Four days afterward I saw him in consultation. The entire hand and forearm was then much swollen. I made free incisions and evacuated a moderate amount of pus. There was an area of redness extending above the area of actual infiltration, and this I scarified. A day or two later I was called in again and found that the suppurative process had extended further up the arm. I had him removed to the hospital and found another collection of pus, which I evacuated. By this time the tissues above the elbow were threatened as the redness had extended a third of the way to the shoulder. I sent for a bottle of the serum, which at that time was put up in vials of 30 c.c. and not, as at present, in packages of three vials of 10 c.c. each. I injected the entire quantity and was gratified by seeing the advance of the process stop. I did not give him

more serum. Much sloughing occurred as a result of the suppurative process in the arm and the patient's convalescence was retarded by a septic pneumonia. He ultimately recovered.

This was the first case in which I used the serum, my associate's case being the second. As I have before stated, I was somewhat timid in the use of a new and untried remedy, and I regret that I did not make freer use of it in both instances. Had I done so my present belief is that I might have saved both patients' subsequent complications.

CASE V.—The second case of streptococcic inflammation in which I tried the serum was that of a man, aged nineteen years, who had his hand drawn between the smaller rollers of a printing-press. No bones were broken, but the soft parts were badly squeezed. There was a large hematoma on the back of the hand, and two very slight lacerated wounds on the palmar surface of the wrist just internal to the lower end of the radius. I evacuated the hematoma, and carefully cleansed the two little wounds with green soap and water, and applied a bichlorid-of-mercury compress. He rapidly developed a virulent infection of the palmar surface of the hand and lower forearm, which was promptly incised, the incision running from the base of the middle finger upward to a little below the middle of the forearm, and a small quantity of pus was freed. The entire arm and hand was then put in a 1 to 100,000 bath of sublimate, which was kept continuously at 102° F. His temperature in a few hours reached 106.5° F., when recourse was had to the serum. He was given 10 c.c. of Parke, Davis & Co.'s serum at four-hour intervals until he had received 60 c.c. in all. At the time I made the first injection an attempt to save the arm seemed almost hopeless, but the boy was but nineteen years old, he was an artisan, and I determined to take great risks before subjecting him to the loss of his right arm. The result justified the risk taken, for he had no further extension of the infection, and although subsequently his temperature went up in the evening to 103° F. for several days, and once to 104° F., still the general direction of the temperature curve was downward, and the case terminated in recovery without the loss of a single tendon, and the young man now has a most useful hand.

CASE VI.—An engineer inflicted a trivial wound at the base of the thumb with a belt hook, it being almost the precise location of the wound reported in Case IV. I saw him in consultation four days afterward. The hand was then very much swollen, his temperature was 102° F., and his pulse 100. An incision under anesthesia evacuated a lot of bad-smelling pus. Mindful of the course of Case I., in which, in spite of a free incision, the infection traveled rapidly up the arm, I sent for the serum and injected 10 c.c. at once. The next day the local conditions were much better, his temperature was 100° F., and pulse 90, and evidently the infection had not extended either into the palmar bursa or up the sheath of the flexor longus pollicis. However, I gave a second injection of 10 c.c., and within forty-eight hours thereafter had nothing but the abscess cavity to deal with, which rapidly healed by granulation. Another incision was required to obtain free drainage, but the infection was confined to the original area involved when the serum was first administered.

CASE VII.—A man came under my care at the County Hospital who had been kicked on the shin by a horse a day or two before. The bone was not broken, but a lacerated wound was inflicted which was the seat of a rapid infection, so that when I saw him it was necessary to make an incision which exposed the whole length of the tibialis anticus tendon down as far as the mediotarsal joint. Several counter incisions were also made to secure thorough drainage. Continuous irrigation by warm bichlorid solution, 1 to 100,000, was maintained for three days. This was then changed to irrigation by hot saline solution. The fifth day after the long incision was made I injected 10 c.c. of the serum, whereupon his temperature dropped to 100° F., and maintained a distinctly lower point than before. In forty-eight hours he received another injection of the serum. His temperature then dropped continuously, until in twenty-four hours it had reached 99° F. I did not see the patient after that for two days, but then finding that his temperature, in spite of the drainage, had reached 103.8° F., ordered the serum given again. This last dose was followed by a decline in the temperature, but a careful examination disclosed the fact that the ankle-joint had become infected. I believe that this infection existed at the time of the first incision and was overlooked, and it was the fact that the temperature still continued to rise in spite of the serum that finally induced me to open the joint, which I found purulent. Subsequent to this the administration of the serum seemed to have a favorable effect on the man's general condition besides the fall in temperature which invariably followed its use, and there was no further infection of the cellular planes of the leg.

CASE VIII.—This case I am permitted to report by the courtesy of my colleague, Dr. Delatour, in whose service at the Norwegian Hospital it occurred. A fireman, twenty-five years of age, three months before suffered an amputation of the terminal phalanges of the middle, ring, and little finger. These had healed with the exception of a small granulation on the ring finger. He was intoxicated Saturday and Sunday nights. Monday morning his hand pained him, and he saw red streaks extending up as far as the elbow. Next morning he was removed to the hospital. The hand was then greatly swollen. There was a gangrenous area on the tip of the index-finger in which was found a splinter of wood, evidently the point of infection. Red streaks extended up the arm to the axilla. Free incisions were made on the dorsum and palm of the hand, which were followed by free hemorrhage but no pus. The hand was put up in carbolic solution, and

an injection of 10 c.c. of serum given at 7 P.M. Temperature, 105.5° F. at 8 P.M. At 5 o'clock next morning his temperature had fallen to 100.5° F. Afterward two elevations, one to 102.3°, and a second to 100.8° F. occurred, but his temperature then fell to normal and the patient was convalescent.

CASE IX.—For permission to use this report I am also indebted to Dr. Delatour. The patient was a fireman on a steamer. His hands had numerous small abrasions on them and were very dirty. He first noticed pain and swelling over the supracondyloid gland of the left arm, which gradually increased until distinct lumps were formed which were hard, red, and tender. Next day he had headache, fever, and chills On January 1st his temperature was 106.5° F., and pulse 130. Incisions three inches long were made over the reddened area reaching to the bone. The supracondyloid gland was necrotic and contained foul pus. It was curetted and packed with iodoform gauze at 11 A.M. At 5 P.M. 10 c.c. of serum was injected. At midnight of January 2d his temperature had fallen to normal. Until January 8th there was an evening rise of temperature, but after this it remained normal, and the patient was convalescent without further involvement of the arm.

CASE X.—There came into my service at the County Hospital on January 29, 1898, a woman with a diffuse cellulitis of the arm without suppuration which had apparently started from a needle puncture on the dorsum of the middle finger. At six o'clock in the evening her temperature was 101° F., and she was in much pain. She was given an injection of 10 c.c. of serum at that time. The following morning her temperature had fallen to 99° F., the pain was much diminished, and the condition of the arm was much improved. She received another injection of 10 c.c., and at night her temperature was reported to me as being normal. The temperature in this case remained about normal for two weeks, when it suddenly shot up again, and an incision became necessary; a small quantity of pus was evacuated.

CASE XI.—This was a case of suppurative inflammation of the knee-joint in which free drainage did not control the symptoms of sepsis, and in which the patient was too weak to submit to amputation. But one injection of the serum was given, wholly without effect, and as the man was in extremis I did not renew the dose. There were no unfavorable effects produced by the serum.

CASE XII.—This was a patient upon whom I had performed a Kocher operation for excision of the tongue, together with the removal of a glandular infection in the submaxillary triangle. A preliminary tracheotomy was performed. The patient did perfectly well until the sixth day, when he developed pnuemonia. In the hope that it might be a streptococcus infection I gave him during twenty-four hours 30 c.c. of serum, but wholly without effect. No unfavorable results apparently followed the use of the serum, but consolidation of the entire left lung rapidly occurred and the patient succumbed.

CASE XIII.—In the case of this patient I had performed a Heinecke-Mikulicz pyloroplasty for contraction following ulcer. For four days he did well, the abdominal conditions being perfect. Then he developed a left-sided pneumonia. I gave him 10 c.c. of the serum without effect, and as there was absolutely no reason to suppose that the infection was streptococcic I did not give more, and one week from the day of operation he died of the intercurrent affection.

CASE XIV.—On January 26, 1898, I saw in consultation a physician who, a few days before, had cut a corn on his right foot. Acute inflammation had developed, and the entire foot become gangrenous. I removed him to the hospital. His temperature was 103.2° F., pulse 130. There were red streaks extending up the leg and the superficial veins were very tender. That night I gave him 10 c.c. of the serum. In the morning the tenderness of the veins had disappeared, and his temperature had fallen to 100° F., and his pulse to 110. During the day he received 20 c.c. more of the serum, and the following afternoon, January 28th, it being evident that it was hopeless to attempt to save the foot I amputated at the point of election. In the evening of the same day he received 10 c.c. of serum, and on the 30th the primary dressing was removed and the wound found to be uninfected. An examination of the urine, however, showed sugar in abundance, and the patient subsequently died from diabetes.

The conclusions which I have drawn from these fourteen cases and a critical examination of the literature of the subject, are as follows: Cases of cutaneous, or so-called idiopathic, erysipelas may be quickly terminated by the early use of antistreptococcic serum, the initial dose being from 10 to 20 c.c., according to the severity of the case, followed by additional doses if necessary. Rarely more than two or three injections will be required. With regard to the cases of phlegmonous inflammation, the use of the serum has seemed to prevent the extension of the infection beyond the parts first attacked, but has had little if any effect on the sepsis produced by the retained pus. In other words, the same necessity exists whether the serum be used or not to secure prompt drainage and the evacuation of the products of inflammation. This agrees with the experience of Marmorek himself, who in reporting ten cases of phlegmonous inflammation[1] states that if the serum is used before the appearance of suppuration this does not occur. If foci exist, when evacuated rapid recovery ensues without extension of the inflammation. Post-operative pneumonia, unless of streptococcic origin, cannot be expected to improve under serum-therapy until we are provided with a mixed serum which shall be protective both against the streptococcus and the pneumococcus.

[1] *Annals de l'Inst. Pasteur*, No. vii, p. 593, 1895.

A complete summary of the literature on the subject shows that the serum has been used in 476 cases of erysipelas, 456 of which were reported by Marmorek himself, leaving 66 reports by other observers. Marmorek states that the average mortality of the diseases in the erysipelas wards of the Paris hospitals is 5 per cent., whereas, in a series of 306 cases, excluding 3 patients who died from causes unconnected with the erysipelas, the mortality when the serum was used fell to $\frac{9.7}{100}$ of 1 per cent.; also, that of the 306 cases, 145 were mild and 165 serious. The serious cases furnished the two deaths, a rate of but 1.27 per cent. in 165 cases of grave erysipelas. All the patients whose cases have been reported by other observers, including my own, recovered. Among these was a case occurring in an infant aged three weeks (Charrin and Rogers); another in an infant aged six weeks (Ganchex); one in a baby aged three weeks (Steele); and one in a child aged four weeks (Poliewkto). The average dose in the case of infants seems to have been about 5 c.c. My own experience with the serum corroborates the statement made by Marmorek, that for an hour or two following the injection the patient's temperature rises, but that then it commences to fall and reaches its minimum in from eight to ten hours thereafter. All my patients seemed to be promptly influenced by the serum, and in my opinion it promises to cut short the disease in most of the cases in which there is naturally a low mortality, while in some gravely ill cases, occurring in the very young or very old or in persons otherwise debilitated, the patients may be saved by this remedy, who under other treatment would succumb.

I have collected records of 275 cases of scarlet fever in which the serum has been used with somewhat varying success, the average mortality being in the neighborhood of 12 per cent. Marmorek, in reporting a series of 95 cases, expressly says that the serum does not at all influence the course of the disease, which depends on the scarlatinal poison, whatever this may be, but only affects those complications due to streptococcus infection, such as the sore throat, the glandular swellings, nephritis, and otitis media. With regard to these complications, themselves often the sole cause of death, Marmorek makes the following statements: In 19 cases of scarlatinal bubo in which the serum was used not one suppurated; albumin disappeared from the urine after one or two injections, and in four cases of suppuration from otitis media this promptly ceased after the use of the serum. The dose given ranged from 10 to 30 c.c. in ordinary cases, in grave cases from 40 to 90 c.c.

Baginsky, in his series of 48 cases, makes a similar though more guarded report. Low reports the case of a child said to be dying from scarlatina with acute hemorrhagic septicemia and otitis media which improved at once on the administration of the serum, recovery taking place after the use of 263 c.c. On the other hand, Josias reports a series of 95 cases and states that the serum apparently was without effect, the mortality not being appreciably decreased. Other writers have had a somewhat similar experience. In the cases imperfectly reported by Fischer it does not appear that the serum was used for the streptococcus infection, but rather in a general way, and without avail. From the evidence at hand, weighing the reports of the different observers, it seems that benefit may be expected when the serum is used as Marmorek directs for the complications due to the streptococcus. The scarlatinal fever itself, however, will not be influenced.

The puerperal cases merit more discussion than the limits of this paper permit. The reports which the writer has collected include 201 cases, with a mortality of thirty-three per cent. This is not encouraging and the opinions are conflicting. In the larger series of cases, such as that of Bar and Tissier, the mortality is much increased by including cases of patients already in extremis when the remedy was used. The same is true of the Philadelphia cases reported by Baldy, Hirst, Noble, and others, in which the serum was not used until the tenth or twelfth day of the disease. The dosage seems to have been small considering the formidable nature of the infection and the extent of the tissues involved. Thus a number of cases of puerperal fever are reported in which but one or two doses of 5 c.c. of serum were given, and in a series reported by Bar and Tissier, in fourteen of which the dosage was stated, the average total quantity administered was but 86.4 c.c., the average daily dose being 17.5 c.c.

As is well known to bacteriologists the protective power of this serum is low at present and varies considerably, some specimens being fourteen times the potency of others, according to Marmorek's own statement. It seems idle, therefore, to expect results from so timid a use of a relatively feeble serum. If good is to be expected from the use of the serum in this class of cases it must be used in far larger doses than hitherto. Quantities of less than 60 c.c. a day will not as a rule avail much, and much greater daily quantities may be necessary. Moreover, it must be used early in the disease before multiple abscesses have formed in the uterine walls and septic thrombi have collected in the vessels of the pelvic structures. It has been noted in commenting on the use of this serum in the phlegmonous cases that while it seemed to limit the range of infection, or prevent suppuration

where this had not already occurred, that after pus had actually formed drainage was still absolutely essential to the recovery of the patient. The same rule will evidently apply to the uterine cases. This is probably the chief reason why the results of the serum in the puerperal cases have been so discouraging. The serum has been used late, after septic foci have become established and drainage has become a necessity. This, however, is most difficult to secure without the shock of a hysterectomy, in itself sometimes sufficient to carry off the patient. The early and free use of the serum will, it is to be hoped, give better results.

What is the proper dose of the serum? This is a practical question and at present it can only be answered by saying that too much rather than too little must be given because the serum has not as yet been standardized. An average dose is 10 c.c. Twenty c. c. will often be required and daily quantities of 60 to 100 c. c. may be needed. It is possible that the varying experiences of different observers has been due to the use of serums of different degrees of strength. It is not possible to give a definite dosage until the manufacturers succeed in standardizing their products, something which I am informed they hope to do at no far distant date. Until this has been accomplished the experiences of different observers must be of quite limited value.

In connection with the question of dosage a second most practical query will suggest itself as to the possible dangers incurred in introducing large quantities of foreign serum into the circulation. Aside from the occasional appearance of erythemata and urticaria the writer does not believe that any serious risks are to be apprehended. In a series of reports of more than 1000 cases collected by the writer the only instances in which the serum was charged with ill effects were in four or five puerperal cases. The unfavorable symptoms were classified as follows: Sudden high temperature; collapse; uncontrollable vomiting. If these symptoms were the result of the serum we should expect to hear of their occurrence in some of the 800 remaining cases of the 1000. On the contrary there is no record of such symptoms except in the puerperal cases, notwithstanding that much larger doses were given to children, particularly, one child receiving 263 c.c. and another 90 c.c. Now it is a fact that these very symptoms (sudden high temperature, obstinate vomiting, collapse) are all features in the pathologic history of abdominal sepsis. It does not, therefore, seem good reasoning to attribute these symptoms, evidently coincidences, to the use of the serum when it cannot be shown from the evidence at hand that they occurred in any other of the 1000 patients, but as a matter of fact occurred in those instances alone in which they were to have been expected apart from the use of the serum.

The serum has been used in cases of so-called malignant endocarditis with success, and in the bronchopneumonia of children (forty-five cases, Marmorek) without a single death. This affection, Marmorek states, is almost always of streptococcic origin. Considering the usual mortality of the disease in children this record is noteworthy.

UNUSUAL LOCALIZATIONS OF TUBERCULOSIS.

BY ALDRED SCOTT WARTHIN, M.D.,
OF ANN ARBOR, MICH.;
INSTRUCTOR IN PATHOLOGY IN THE UNIVERSITY OF MICHIGAN.

THE following rare localizations of tuberculosis are selected from the records of twelve hundred examinations made by me during the last four years in my capacity as examining pathologist to the University Hospital. These examinations were made for the purpose of diagnosis, and the material was obtained chiefly from the surgical clinic of Dr. Nancrede and the gynecologic clinic of Dr. Martin, though much of it has been sent to this laboratory by physicians residing throughout the State of Michigan. The majority of these cases are very rare, a few, I believe, being noted for the first time. The diagnosis was based both upon the structure and the presence of tubercle bacilli.

Sarcoma and Tuberculosis.—The subject presented a clinical history of a wart in the skin of the forearm. In the subcutaneous tissue beneath the wart a large tumor mass developed with great rapidity. Ulceration of the wart followed. The arm was amputated. The microscopic examination of sections of the tumor showed it to be a large spindle-cell sarcoma. The ulcerating wart gave the microscopic picture of caseating tubercles of the skin. The tuberculous tissue extended into the tumor tissue, so that in some areas there was an appositional growth of the two processes. At the border line between the sarcoma cells and the tuberculous tissue there were numerous giant-cells of very large size. A few caseating giant-cells could be found surrounded by the sarcoma cells. In my opinion the two processes were separate and the combination was purely accidental. Either the wart was tuberculous from the beginning or became infected after the sarcoma began to develop. The study of the sections does not show any evidence of any intimate relation between the two processes.

Carcinoma and Tuberculosis.—In two cases of tumor of the mammary gland a combination of tuberculosis and carcinoma was found, the axillary

glands in one case showing the same combination. A full report of these cases will shortly be published. It is sufficient to say here that in one case the tuberculous process seems to be the primary affection and the carcinoma secondary; in the other the tuberculosis is either a coincident or secondary process.

Primary Tuberculosis of the Mamma.—The tissue removed in one case of enlarged and suppurating mamma was proved to be tuberculous. This case, with the two mentioned above and the one reported in my table of fifty autopsies on tuberculous subjects,[1] adds four cases to the literature of tuberculosis of the mammary gland.

Primary Tuberculosis of the Nose.—A hard fibrous polyp was removed from the left side of the nasal septum. It was about the size of a large cherry. It had been diagnosed clinically as a fibroid polyp. Examination showed the mass to be made up of reticulated tubercles, showing many giant-cells and beginning caseation, and containing tubercle bacilli.

Primary Tuberculosis of Lobe of Ear.—A tuberculous mass was removed from the right ear-lobe around the point of perforation for the wearing of an ear-ring. The exact manner of infection could not be ascertained. Similar cases have been reported.

Primary Tuberculous Ulcer of Heel.—This case is mentioned only because of the unusual site of tuberculous infection of the skin.

Primary Multiple Tubercles of Brain.—The patient was a young woman in good health and of good family history. She suddenly became insane and died within a short time after removal to an asylum. A clinical diagnosis of brain tumor had been made. The brain was sent to my laboratory for examination. Two tubercles the size of a hen's egg were found in the left lateral ventricle, a similar one in the right ventricle, one in the right half of the cerebellum, and a number of diffuse tubercles scattered through the cerebral cortex. No other tuberculous lesions were found in the body.

Tuberculosis of Graafian Follicle.—In the MEDICAL NEWS for September 19, 1896, I reported a case of ectopic gestation with tuberculosis of tubes, placenta, and fetus. At the time of report the ovaries had not been completely examined though tubercles had been found on the surface of both organs. On further study of the ovaries sections were obtained of an enlarged Graafian follicle, into which a pedicled tubercle was growing. The pedicle was continuous with a tuberculous nodule situated in the ovarian stroma beneath the epithelium of the follicle. Other small tubercles were found in the stroma of the organ.

[1] MEDICAL NEWS, April 15, 1899.

Tuberculosis of the Placenta.—While working as assistant in the Stadt-Krankenhaus in Dresden last summer I made systematic examinations of a large number of fresh placentas. In one I found scattered miliary tubercles in the chorionic villi. The history of the mother and child could not be obtained as it could not be determined to which one of a number of patients this particular placenta belonged. The case is, however, important, as it adds another instance of the occurrence of this rare and very important condition.

Primary Tuberculosis of the Fallopian Tube.—Twenty per cent. of all the tubes examined were tuberculous. This condition can certainly no longer be called rare; the more frequently careful examinations are made of diseased tubes the more common is its occurrence found to be. In the majority of the cases there were numerous miliary tubercles in the plications of the mucosa; in one case the lumen of the tube was filled with a cheesy mass, the mucosa having entirely disappeared, and the tuberculous process extended into the wall of the tube. In several cases the tubercles were very scarce and were scattered throughout both the mucosa and the muscular coat of the tube. Tubercles were found in the peritoneum in every case, usually about the fimbriæ of the tube, but in two cases a general tuberculosis of the peritoneum was present. The process was always farther advanced in the tubes than in the peritoneum. None of the subjects had tuberculosis in other organs.

Tuberculosis of Artificial Anus.—This very interesting case is from the surgical clinic of Dr. Nancrede. The history very briefly is as follows:

Mr. P., a farmer, aged sixty-seven years, gave a negative family history. His health had been good until fifteen years ago, when he acquired a double inguinal hernia, but this had given him no trouble until shortly before the commencement of the present condition, when there was descent on both sides. Reduction was easily accomplished, but shortly afterward constipation and severe abdominal pain set in very suddenly. In a short time he became very ill; he had severe headache, vomiting, and severe pain in the lower part of the abdomen. Slight movements of the bowels were obtained at rare intervals during the next three weeks, and then he became very much worse. Fecal vomiting began and the patient became so weak that he could not talk. Operation, however, was deferred for a week, when his condition became so alarming that consent to operation was finally given. Colotomy was performed and an artificial anus was formed. Immediate relief was obtained; the wound healed well and in a month the patient was able to walk and to ride about his farm. Three months after this he began to have normal passages by the rectum. All symptoms had disappeared, and the patient at this time entered

the University Hospital for resection of the colon and closure of the artificial anus This was done by Dr. Nancrede. The wound, to all appearances, healed rapidly, and the patient was just on the point of leaving the hospital when the scar began to ulcerate. In a short time this had healed but only to again break down. This alternate ulceration and healing continued for some time, when the patient considered himself so nearly cured that he left the hospital. Communication was had with him at rare intervals for a year and a half, when he died. During this time he remained fairly well, but occasionally passed blood and pus with his stools, and the old scar continued to discharge at intervals. Death was said to have been caused by "gangrene," but I have been unable to obtain any satisfactory information regarding his final condition and the hopes of a post-mortem which we had entertained were not fulfilled.

The artificial anus with the portion of intestine and skin removed was sent to my laboratory, not so much for the purpose of diagnosis as for the interesting teaching sections that it might afford. When these sections were prepared an unexpected condition was revealed. There had been perfect union between the intestine and the skin. The intestinal muscularis and the dermis were intimately united, and there was but a very small amount of scar-tissue present. The squamous epithelium of the skin had advanced for some distance into the lumen of the intestine over the muscularis, and then passed abruptly into the glandular mucosa of the colon.

Throughout the submucosa, the muscularis, and the dermis there were numerous miliary tubercles, the majority having caseating centers, and containing numerous giant-cells. In these tubercle bacilli were found in scanty number. The tubercles were largest and most numerous in the site of the scar at the point of union of the dermis and intestine. There was no inflammatory process surrounding the tubercles. All were subepithelial with the exception of one small ulcerating tubercle in the mucosa of the colon. All of the tubercles exhibited about the same degree of development except those at the site of the wound, where they were larger and showed a greater amount of caseation.

The material was not examined until several weeks after the operation, so that the patient had left the hospital when the diagnosis of tuberculosis was made. The question immediately arose as to the source of the tuberculous infection of the artificial anus. Had it been from without, a primary wound infection, or had it been a secondary infection of the wound from bacilli contained in the stools? Had the patient a primary intestinal tuberculosis, and were all of his symptoms referable to this condition? The latter seemed most probable, and it was hoped that we should be able to prove it. Efforts were made to induce the patient to return for further examination, but he showed more satisfaction in the results of the operation than interest in the diagnosis. Efforts to obtain the blood and pus passed in the stools for bacteriologic examination were also futile; and still more unfortunate was our inability to obtain a post-mortem examination.

On summing up the case it seems very probable that the original obstruction was due to a primary tuberculosis of the intestine leading to stenosis of the colon, and that the artificial anus became infected from bacilli in the feces. That the process continued in the skin and intestine is shown by the ulceration of the scar and the presence of blood and pus in the stools. I regret that I am unable to settle the question positively. The case is, nevertheless, an extremely interesting one, being, I believe, the first of the kind reported.

ECLAMPSIA FROM THE SURGICAL STANDPOINT.[1]

By GEORGE L. BRODHEAD, M.D.,
OF NEW YORK.

In the wide field of subjects of interest alike to obstetricians and general practitioners it would be difficult to select one of as great importance and one the discussion of which would prove so profitable as that of puerperal eclampsia. From time immemorial the greatest diversity of opinion has existed with regard to the medical as well as the surgical treatment of a malady which is at best fraught with the gravest dangers which can come to the pregnant woman. Theories propounded from time to time as to the etiology of the disease have led to the adoption of as many lines of treatment, but at the present day we are still in ignorance of the precise cause operating in these cases and therefore do not possess a specific, thoroughly scientific method of procedure. To be sure the majority of writers of the present day are inclined to the theory that the essential cause of the convulsions is a toxemia produced in all probability by a number of different poisons, associated usually with renal insufficiency and albuminuria. That the nervous temperament of the woman must be taken into consideration is proved to our minds by the frequency with which the convulsions appear in primiparæ, in whom the mental strain is certainly greater for obvious reasons and in whom the nervous centers are much more stimulated reflexly by impulses coming from the genital tract. In the consideration of the subject my province will be limited to the surgical or obstetrical treatment. For the sake of convenience let us consider (1) eclampsia occurring before labor, and (2) eclampsia during labor, the latter being subdivided so that each division will include cases in the corresponding stage of labor.

1. *Treatment of Cases of Eclampsia Occurring*

[1] Read before the Society of the Alumni of the Sloane Maternity Hospital.

During Pregnancy but Prior to the Onset of Labor.—It is perhaps in the consideration of this particular group of cases that the widest variations of opinion have been held, not only as to whether labor should be induced, but more particularly as to the manner in which the uterus should be emptied, provided this has been deemed advisable. The question is often asked, "Is it necessary in every case of eclampsia to terminate pregnancy as soon as possible?" Can we not follow the advice of Gooch, "Take care of the convulsions and let the uterus take care of itself"? There have been distinguished advocates of the doctrine of non-interference and among these stands to-day Charpentier, who claims to be in accord with the great majority of French obstetricians. At the International Congress of 1896, held at Geneva, he said: "I believe and am convinced not only that the induction of labor is useless, but that to have recourse to *accouchement forcé* is to expose ourselves to the greatest mortification, and far from being the means *par excellence* for the cure of eclampsia, should be abolished by obstetrical practitioners." His reasons among others are (1) that the evacuation of the uterus does not cause the convulsions to cease at once; (2) that not only do attacks often continue in spite of delivery, but in some cases they appear for the first time post-partum; (3) induction requires time to be accomplished with safety to the mother, and this surpasses the duration of the malady; (4) any irritation suffices often to bring on a convulsion; (5) it is often the interruption of pregnancy by fetal death and not the actual delivery which causes the cessation of attacks; (6) all operative interference aggravates the prognosis in labor and the effects are much worse in eclampsia; (7) *accouchement forcé* is admitted to be a serious operation by practically all authorities. Charpentier also takes exception to the statement of Dührssen that "the greater the number of convulsions, the more grave the prognosis," by declaring that "it is not the number of attacks but the way in which they act on the economy."

Taking up these reasons very briefly, the weight of authority seems to be that while convulsions continue oftentimes after delivery, much more frequently they cease altogether or are much less severe, and that, therefore, the best plan is to empty the uterus. Again, the delivery can as a rule be completed in a moderate length of time under chloroform (hence with no irritation), and as a rule without serious injury. While fetal death often occurs and may terminate the attacks, the woman is still in a grave condition and should be entitled to the additional element of safety which the evacuation of the uterus will give. That interference must be accomplished in a most careful and painstaking manner, all will agree. But Charpentier, while advising us to wait until labor begins spontaneously and allowing it to proceed undisturbed as far as possible, recommends the use of forceps or version in the second stage when labor is at all slow. His experience, that labor proceeds as a rule rapidly in cases of intra-partum eclampsia, does not coincide with the observations which we have made in such cases. In our experience labor has been as a rule slow, with weak and inefficient pains. In 1892 Charpentier collected reports of a series of 454 cases in which he claimed that the mortality to the mother was only 13 to 15 per cent. in the spontaneous cases, 29 to 31 per cent. in cases of induced labor, and 40 to 74 per cent. in cases in which *accouchement forcé* was employed. In 1896 his views as expressed at the Geneva Congress were the same. The English writers are also inclined to allow pregnancy to proceed, but Playfair in his latest work[1] says, "If the os is undilated and labor not yet begun, no active means to induce it should be adopted *although* the membranes may be ruptured with advantage, since that causes no irritation." Evidently, then, he thinks that it is better to have the uterus emptied, although he is against forced dilatation and especially version.

Professor Byers of Belfast,[2] claiming to represent the British school of midwifery, also advises against the induction of labor, for the following reasons: (1) because the methods used increase reflex excitability; (2) in many cases the time required is so great that the fate of the patient is decided before delivery is effected; (3) the onset of labor would increase the dangers; (4) because the necessary manipulation increases the risks of sepsis. To our minds the use of chloroform, proper dilatation, and strict asepsis would offset these objections. Byers says that of 30 cases of eclampsia at the Rotunda Hospital, 4 occurred during pregnancy. The labor in none of the patients was induced, *yet all recovered.* Three of these women were delivered normally, one four days, another ten days, and the last twenty-two days later, the fetus in each case being macerated, while the fourth patient left the hospital three weeks after her eclampsia, undelivered, no further reference being made to her. These cases are quoted merely to show that these patients do recover at times under medical treatment alone.

In our own country the weight of evidence is certainly in favor of the induction of labor, and further, in the emptying of the uterus as soon as possible consistent with the welfare of the mother. The late

[2] Congres. Internat., 2d session, Geneva, 1896.

Professor Lusk,[1] although recognizing the fact that labor occurs spontaneously in most cases, and that a certain number of patients under medical treatment alone will recover and pregnancy continue, said that in his own experience, "waiting had been uniformly disastrous," while the induction of labor had furnished a certain proportion of recoveries. That the uterus should be emptied as soon as possible by appropriate and well-chosen methods is the belief also of Tucker, Flint, and Edgar of New York, Jewett of Brooklyn, and many others of excellent experience. Of the German writers Winckel is conservative, Dührssen radical, as we shall see, while others occupy a middle ground of "prudent" interference.

To my mind the best and safest plan to pursue is that which will place the woman in the best possible condition for recovery, that is, the evacuation of the uterus with the greatest possible care and with strictest aseptic precautions. If, then, the uterus is to be emptied, what methods are available, and which are best? During the first few months of pregnancy, at which time eclampsia rarely occurs, the best procedure is to place the patient under chloroform to the surgical degree, and under strict aseptic precautions to dilate the cervix with hard rubber and steel dilators removing fetus and secundines with the curette. If the cervix proves very rigid and dilatation difficult the better plan would be to introduce strips of iodoform gauze, under strictest aseptic precautions, into the uterine cavity between the membranes and the wall of the uterus, tamponing the lower uterine segment and cervix. The gauze acts as a foreign body, thus starting up uterine action, softening the cervix, and finally bringing about the expulsion of the fetus, secundines, and tampon. For the general practitioner the latter method is advised as being the safest and best. Medical treatment must of course be given to these, as to all patients, in conjunction with operative measures. After the first few months, treatment will vary according to the condition of the cervix. If the latter is soft and yielding the best treatment would seem to be that of manual dilatation, preceded if necessary by the use of the hard rubber dilators of Hanks, and the steel dilator, such as that of Goodell. By careful and gradual stages, with the aid of the bimanual method of dilatation, the details of which cannot be entered upon here, the cervix can be fully dilated or almost so, at which time the membranes can be ruptured and the child delivered by forceps or version as may seem best to the individual operator. If the child is dead craniotomy will enable one to extract the child through an os not fully dilated, but as a rule dilatation should be made as complete as possible in order to avoid laceration with the forceps or after-coming head. If the cervix is tough and unyielding, it will be far better to rupture the membranes and use the water dilator, following this with manual dilatation; or to introduce several bougies, pack the cervix tightly with iodoform gauze, and thus bring about a relaxed condition of the cervix, with partial dilatation, at least, of the internal os. When softening has occurred the labor can be completed by manual dilatation succeeded by forceps or version. In the great majority of cases, however, delivery can be safely accomplished within a moderate number of hours by careful, painstaking manual dilatation. We lay great stress on the necessity of deep narcosis during operative procedures, not only for the purpose of obtaining complete relaxation, but also to avoid all possible irritation of the patient. We maintain also that the rupture of the membranes alone is but a temporary expedient and its action far too slow in inducing labor, the latter being frequently much more difficult because dry.

Another plan of procedure, of which much has been heard and a great deal said during the past few years, is that known as Dührssen's method. This consists in removing the cervix as a barrier to delivery by the use of four to six incisions extending out as far as the uterovaginal junction, the method to be employed, however, *only* when the supravaginal portion of the cervix has been fully obliterated. Dührssen[2] maintained that in 93 per cent. of cases the attacks ceased at once or soon after delivery and therefore that the sooner the uterus is emptied the better. If the supravaginal portion were still present he would rupture the membranes and use a water dilator until the time should arrive when incisions could be made. The mortality according to his figures was between 19 and 24 per cent., a result certainly gratifying if experience should prove its correctness. But almost all operators condemn its use except in cases in which manual dilatation is impossible, or when emergency calls for it, as in the case of a moribund patient. But even in an emergency Cæsarian section is far easier, if consent can be obtained to perform it. Charpentier[3] has steadily opposed it, saying that Dührssen's own figures show that the method is not as harmless as he claims. Lusk said the method was unnecessary; Winckel[3] that it had been proven dangerous by von Herff and Mackenrodt (*Centralbl. f. Gynäk.*, p. 128, 1892) and was certainly not to be used by men not skilled in gynecologic operations. Morisani of Naples[4]

fears, not the hemorrhage or septic infection, but rupture of the uterus during the extraction of the child, the laceration extending upward from the limit of the incision into the lower uterine segment. That this accident has occurred there are cases on record to prove, but there can be no question that the operation has been performed many times in unsuitable cases, with consequent evil results. At the present time, however, it must be said that the procedure is considered as a rule unnecessary, as often attended by danger even in skilled hands, and, according to Edgar,[1] should be undertaken only by those who are thoroughly skilled in surgical anatomy and technic.

So much for the method of Dührssen. Cæsarian section at the end of pregnancy, or during labor, need not detain us long. Although used by some, as Halbertsma of Utrecht,[2] the method is considered far too radical and dangerous by the majority of accoucheurs, who reserve the operation for moribund patients or when the cervix is undilatable. Morisani prefers it, however, to the incisions of Dührssen.

2. Coming now to the second class of cases, or those in which labor has begun when the convulsions appear, let us take up first the treatment of patients in the first stage. Labor pains having begun, authorities almost universally agree that progress should be hastened by all means compatible with the safety of the mother. Charpentier and Winckel prefer to wait until the cervix is fully dilated or dilatable, but the greater number aid in hastening the progress of labor in various ways. The English school uses hot douches, Barnes' bags, and the dilator of Champetier de Ribes, but American operators as a rule prefer the hand for purposes of dilatation, maintaining that usually manual dilatation is successful in accomplishing the desired result safely, in a moderate length of time, and without rupture of the membranes (thus facilitating version). During the second stage of labor *all* agree, even the most conservative, that delivery should be completed as soon as possible, by forceps or version, or by craniotomy, if the child is dead. In the third stage of labor moderate bleeding (providing, of course, the patient be able to withstand the loss of blood) should be encouraged by allowing the uterus to remain relaxed, and deep narcosis should be kept up until the placenta has been removed and labor completed. Further treatment of these cases and those of postpartum eclampsia consists in the use of hot salin enemata and such medication as appears to each individual as the most efficacious.

CLINICAL MEMORANDUM.

A CASE OF INSTRUMENTAL RUPTURE OF THE UTERUS.[1]

By JOHN O. POLAK, M.D.,
OF BROOKLYN, N. Y.;
ADJUNCT PROFESSOR OF OBSTETRICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; INSTRUCTOR IN OBSTETRICS IN THE LONG ISLAND COLLEGE HOSPITAL; SURGEON TO THE WILLIAMSBURGH HOSPITAL.

THE subject of this report is a Polish woman, aged twenty-eight years, married, whose first pregnancy occurred some nine months ago within the right tube. Ectopic gestation was diagnosed before rupture and an abdominal section performed at St. Catharine's Hospital during the summer of 1898. Menstruation has not recurred since the operation. The patient was referred to the writer by Dr. Emerson.

No satisfactory history could be obtained owing to the patient's inability to speak English or German. An examination resulted in the following findings: An abdominal scar in the median line showed evidence of previous suppuration; a hernial impulse could be made out near its lower angle. The vulva and vagina presented nothing abnormal. There was a purulent discharge coming from the uterus, which was increased by uterine manipulation. The uterus was in a normal position, the fundus fixed, though the cul-de-sac and fornices seemed free of inflammatory products. What seemed to be a displaced left ovary was found just posterior and to the left of the fundus, and on following out the left cornu a tube was felt which appeared continuous with a loop of the intestine. No adnexa were found on the right side. These findings were thought to be verified under anesthesia. Celiotomy was advised. On January 21, 1899, under ether, the cervix was dilated preparatory to curetting. A Wylie instrument was used, followed by one of the Goodell pattern. The last-named instrument went through the uterus, causing a rent near the right cornu. This was promptly recognized on passing a curette into the organ. The curette was withdrawn and the uterus packed with iodoform gauze.

The patient's pulse immediately ran up to 160 and became almost imperceptible. She had a distinct chill which lasted some ten minutes. She was then placed in the Trendelenburg posture, the abdomen was opened, and a quart of hot saline solution poured into the peritoneal cavity. This improved her general condition. The intestines were found matted together by dense adhesions and covered the uterus. They were freed with the greatest difficulty. The gut was torn twice before the uterus could be brought into view. It was then seen that the tear through the posterior aspect of the uterus near the right cornu was an inch and a quarter long. Five very heavy braided silk ligatures were lying in the rent, evidently suppurating their way through the uterine wall. The end of the iodoform gauze which I had inserted was protruding from the wound. Both ovaries and tubes were absent. The supposed ovary was nothing but a

[1] Reported to the Brooklyn Gynecological Society, March 5, 1899.

localized mass of exudate and the supposed left tube turned out to be the sigmoid adherent to, and running out from, the left cornu. The vesico-uterine space was obliterated by adhesions to the bladder and the parietal peritoneum.

Hysterectomy was considered and decided against owing to the patient's condition. After removing the silk ligatures and trimming the ragged edges of the tear which I had made in the uterus, a strip of iodoform gauze was sewn to the piece already in the uterus, and an assistant pulled it through into the vagina. When sufficient had been drawn through I packed the balance into the uterine cavity from above and closed the uterine wound over it with interrupted sutures of catgut, covering these with visceral peritoneum by means of a Lembert suture. The rents in the intestine had been closed in the meantime by an assistant. Another quart of hot saline solution was left in the belly and the abdominal wound closed, two strips of twisted gauze being left for drainage, one extending to the cul-de-sac and the other to the wound in the uterus. The patient was kept in Clarke's position during the first twenty-four hours and reacted nicely. The after treatment consisted of the administration of $\frac{1}{30}$ of a grain of strychnin every four hours, and an enema of 1 pint of hot saline solution every six hours. The recovery was uncomplicated except for a stitch abscess. The temperature was normal in five days and has remained so since.

The points of interest in the case are: First, the character of the accident, which was undoubtedly due to a weakening of the uterine muscle consequent upon Nature's attempt to throw off the infected silk ligatures *via* the uterus. Finding them in the uterine structure indicates this; the purulent discharge from the cervix was from this process. Second, the manifestations of shock while under anesthesia. Third, the difficulties of intra-abdominal diagnosis even under anesthesia when peritonitis has been a forerunner.

NEW INSTRUMENT.

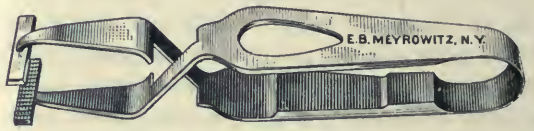
AN IMPROVED MICROSCOPIC FORCEPS.

By JOHN LESHURE, M.D.,
of New York;
Clinical Assistant in the Department of Laryngology, Vanderbilt Clinic.

The writer has found the instrument presently to be described a very useful addition to the pathologist's armamentarium, it being a modification of the well-known Cornet cover-glass forceps, and so constructed as to hold firmly glass microscopic slides as well as cover-glasses. Reference to the accompanying cut will illustrate the main points in its construction.

The jaws terminate in T-pieces which, being accurately ground on their opposing surfaces, grasp the slide firmly and allow of no sliding motion, this effect being enhanced by extra stiffness of the spring handles. Staining fluids can be applied to the slide while the latter is still in the grasp of the forceps, as the weighted handle tends to keep the preparation level and at a distance from the table when the apparatus is laid down. Lessened danger of infection and cleanliness are among the advantages claimed for it, as all of the various operations of fixing, staining, etc., can be performed without touching the glass slide with the hands.

The forceps can be used for cover-glasses as well as for slides, but in general it will be found much more con-



venient to make hematologic and bacteriologic preparations directly upon the glass-slide, much of the danger of breakage being thereby avoided. In this connection might be mentioned a useful hint regarding the staining of blood-preparations with eosin: the dye seems to penetrate much better if several applications are made, each portion being washed off with water before the next is applied. The method is as follows: the slide after having been fixed is flooded with a strong alcoholic solution of eosin, which is allowed to remain for about half a minute; this is then washed off in running water, and a second application made and washed off as before. This process may be repeated several times, depending upon the thickness of the preparation and the depth of staining desired. The preparations, however, are rarely overstained by this method. The counter-staining with methylen-blue, or the other basic dyes, is performed in the usual manner.

MEDICAL PROGRESS.

The Cold Bath in Typhoid.—Hare ("The Cold Bath Treatment of Typhoid Fever," London, 1898) reports a series of careful observations in the treatment of typhoid fever from the Brisbane General Hospital, Queensland, Australia. From May, 1882, to January 1, 1887, the expectant treatment was pursued in a series of 1828 consecutive cases. Following January 1, 1887, 1902 cases were treated by the Brand method up to January 1, 1897, and the author compares results in the two series. In a large majority of his cases he confirms the conclusions of Tripier and Bouveret, that the average temperature during the first days' treatment by the cold bath forms a maximum which is never exceeded on any following day, and that, therefore, defervescence begins with the first day of the treatment.

In order to confirm clinically the statement that cold bathing lessens the death-rate from circulatory failure in typhoid fever, two entirely comparable groups of charts were chosen, one from each series, which showed that the progressive acceleration in the pulse-rate due to cardiac degeneration from persistent pyrexia was deferred and less marked in the cold-bath cases. In no case of the author's second series was a bronchitis set up, and complicated pneumonia was less frequent, as was also the occurrence of nervous symptoms. In the two years 1888 and 1889, 934 cases of the fever were admitted to the

Brisbane Hospital, with delirium or stupor noted in 71, or 7.6 per cent. of the number, while Murchison found these symptoms present in 67 per cent. of all his cases. Of Hare's 71 cases, 34 presented the symptoms on admission, and of the remaining 37, 2 were not bathed at all, and 24 became delirious for the first time only after the baths were stopped, leaving therefore, only 11 cases out of the 934 admitted, in which nervous symptoms arose in spite of the bathing. The Brand treatment reduced the occurrence of nervous symptoms from over 50 per cent. to less than 8 per cent. Murchison notes diarrrhea in 93 out of 100 cases, while at the Brisbane Hospital 52 per cent. of 351 consecutive cases in the "expectant" series showed the symptom, and 39 per cent. of 934 consecutive cases in the "bath" series. Hare states further that intestinal hemorrhage was reduced about 2 per cent., and that the occurrence of relapse was not apparently influenced in either direction by the cold bath. The mortality under expectant treatment was 14.8 per cent., reduced 50 per cent. in the cold-bath series to 7.5 per cent. The author regards hemorrhage as a relative contraindication, and perforation as an absolute contraindication for the use of the bath.

Surgical Shock.—CRILE ("An Experimental Research into Surgical Shock") holds that there is sufficient evidence to show that surgical shock is in direct proportion to the nerve-supply and to the functional importance of the part injured. In his experiments on dogs, blood-pressure curves showed injury of the paws to be more productive of shock than that of any other superficial part of the extremities, the experiments being made without loss of blood. Cutting, crushing, fracturing, amputating, and burning the extremities were usually attended by a preliminary rise in blood-pressure, followed by a fall usually lower than before the operation. The author holds that there is no evidence of the correctness of the opinion expressed by many clinicians that there is considerable shock produced in sawing through the bone in amputations, nor of similar opinions as to opening large joints, and thinks that the error probably arose in confusing the effects of cutting or traction of the nerve-trunks in these operations.

Traction on a nerve-trunk was shown experimentally strongly to influence respiration and circulation, and shock was in direct proportion to the amount of excitable tissue injured, and the time occupied in the operation.

The Cancer Parasite.—BRA (*La Presse Med.*, February 12, 1899) decribes in detail his work on the isolation and cultivation of the parasite of cancer, and claims to have successfully reproduced the disease in animals by inoculation. He has spent four years on methods for the demonstration of his parasite, and states that in a vast number of malignant neoplasms, involving every region of the body, he has been able regularly to isolate a fungus belonging to the family of the ascomycetes. His report is accompanied by a number of illustrations in black and white, with careful descriptions of the appearance of the fungus under cultivation. The parasite may be isolated either from cancer-tissue or from the blood of the tumor or the general circulation, but the former is stated to be the proceeding of choice. Small cubes of cancer-tissue are plunged in 2½ per cent. carbolic-acid solution, followed by ether, and carried lightly through the flame of a Bunsen-burner. They are then placed in tubes of bouillon de mamelle (bouillon of cow's udder) and cultivated at a temperature of 30 to 35° C. for twenty hours, at the end of which period the fluid is rose-colored, and contains adult forms of the fungus. The best growth is obtained on agar. The parasite is described as presenting a round or ovoid cell body, varying in diameter from 3 to 12 μ, with an enveloping membrane. These spherules give rise by endogenous cell division to very minute reddish spores, which in turn develop a rich, branching myceliuni. The parasite stains by the aniline dyes, and by Gram's method, and the author holds that his parasite has undoubtedly been seen by previous workers but regarded as a product of cellular and colloid degeneration or nuclear division.

Inoculation experiments succeeded best with rabbits. The intravenous inoculation of 1 c.c. of a virulent bouillon culture produced a subacute infection on the fourth day, with depression of the body temperature, somnolence, myosis, salivation, diarrhea, polyuria, and paresis of the hind legs, followed by complete immobility and profound coma. A dose of 2 c.c. produced an acute infection with similar symptoms in 24 hours, and 3 c.c. produced the diarrhea with polyuria in 16 hours. The author states also that it is possible to immunize the animal to the fatal dose by previous subcutaneous injection of minute doses. Animals dead of the infection showed mycotic nodoles on the pericardium, the endocardium, or within the heart-muscle.

The heart was atrophied, the liver granular, the kidneys and mesentery congested, and Pyer's patches enlarged. Examination of the blood and urine, and of cultures made from the liver, kidneys and supra-renal bodies revealed the parasite. The tumor, however, which develops at the site of inoculation is stated to present indifferently the structure of fibrosarcoma or of carcinoma. Sometimes typical fibrosarcoma is shown, and sometimes in an animal of the same variety the growth presents the usual appearance of carcinoma. The parasite may be isolated from these tumors as well as from the human new growth.

Death with Cerebral Symptoms in a Case of Extreme Dilatation of the Stomach.—V. JUERGENSEN (*Deutsche Archiv für klin. Med.*, Bd. lx.) reports a case of gastrectasis and death with cerebral symptoms, which is noted in the *Centralbl. für Innere Medicine*, February 25, 1899. The patient, an emaciated man, forty-three years of age, complained of intense thirst and continuous vomiting. During one night he drank ten liters of water, and the following day developed general convulsions, which terminated in complete coma in the course of forty-eight hours. The respiratory movements were Cheyne-Stokes in character, the pupils were contracted, and did not react to light, and the tendon reflexes were abolished. Death occurred at the end of the third day. Autopsy

showed only extreme gastrectasis, as a result of contraction in an old scar at the pylorus. The urine had not been voided, but only 100 c.c. (3 oz.) were found in the bladder. Concentration of the blood in gastrectasis, due to the collection of fluids of the body in the dilated gastric sac, may explain the terminal exhibition of nervous phenomena, but the clinical picture in this case is so like that of acute uremia that an acute intoxication of the organism by the retained urinary elements may be assumed.

A Simple Prostatectomy.—PYLE (*Phila. Med. Jour.*, April 1, 1899) has performed prostatectomy a number of times in the following manner: A curved incision is begun at a point near the middle of one ischiatic tuberosity and carried in front of the anus, between the sphincter and transverse perineal muscles, to the other tuberosity. The sphincters are detached from the median raphe, and the surface of the levator ani followed up to the membranous urethra. The muscle is there divided, and the finger used to separate the urethra from the rectum until the fascia overlying the prostate is brought into view. The offending lobe of the prostate is seized with volsellum forceps and dragged down on its own side of the urethra, while the fascia overlying it is divided with a knife. By using the finger again, beginning at the upper and outer border of the lobe, it is separated from the bladder without injury to the mucous membrane of the latter. Both lobes may be removed if necessary. If one remembers that all the important blood-supply of this region lies in front, behind, and to the outer sides of the proper operative field, the whole operation can be performed with almost no loss of blood. Pyle did not have to ligate a single vessel in any one of his operations, and there was naturally little shock, and recovery was in every instance a prompt one. Calculi may be removed from the bladder or the organ drained by the same incision.

Typhoid Fever without Intestinal Lesions.—BRYANT (*Brit. Med. Jour.*, April 1, 1899) gives a history of a case of typhoid fever in which, on account of the irregular symptoms, there was some doubt as to the diagnosis. The serum reacted sharply to Widal's test, however, and at the autopsy the usual intestinal lesions were anticipated. To his great surprise there was no abnormality of any portion of the intestine as far as could be made out. The mesenteric glands were much enlarged, soft, and of a pinkish color. From them were obtained almost pure cultures of the typhoid bacilli. The spleen was somewhat enlarged. The patient was a male child aged twenty-one months, and was apparently in the third week of the disease when it was brought to the hospital. From then until its death, a week later, the chief symptoms were a daily fever of 104° to 105° F., and a greenish, watery diarrhea. There was a very little bronchopneumonia. Some fourteen similar cases have been reported, the patients varying in age up to sixty years. They make good the claim of Osler that "typhoid fever is no more primarily intestinal than is smallpox primarily a cutaneous disease." It is probable that if autopsies in obscure cases were carried out more thoroughly and bacteriologic tests were oftener applied, many more such cases would be noted.

A Case of Swallowing Stones.—CANE (*Lancet*, March 18, 1899) was called upon to treat a man, aged thirty-two years, for intestinal obstruction caused by the impaction of pebbles. When fourteen years of age this patient, in imitation of a juggler he had seen, swallowed a number of pebbles. They passed his rectum the following day without difficulty, and finding it not so unpleasant to be a juggler, he many times repeated the performance, at first for the amusement of his friends, and afterward in connection with a circus. He often swallowed several dozens of the stones in one day, and never had any difficulty in passing them, except that occasionally he inserted a finger in his rectum to assist in their evacuation. Two days before he entered the hospital he gave three performances, morning, afternoon, and evening. The next day he failed to pass the stones, and toward evening he began to have colicky pains. Castor oil, which he had taken, increased his pain, and produced besides a little blood and mucus six stones. His sphincter was gradually dilated without an anesthetic, and sixty-six stones were extracted from the rectum. This procedure was attended by considerable pain, apparently due to a single stone with a jagged edge, as after its extraction no more pain was experienced. In all, ninety-one stones were removed at that time and during the following day weighing exactly two pounds. Recovery was uneventful. This case affords another illustration of the remarkable tolerance of the alimentary canal for foreign bodies.

The "Strumous" Diathesis.—DUCKWORTH, in the Harveian Oration for 1898 advises the free surgical excision of disordered lymphatic glands in strumous individuals, even though in many cases neither tubercle bacilli nor caseous matter can be detected in them. They represent a good soil wherein tubercle bacilli may lodge and induce caseation should they gain entry. This peculiarity of the lymph system in the strumous subject justifies the use of the term "strumous inflammation," independent of the modern idea of tuberculosis. A strumous habit of body has doubtless a marked influence in modifying other morbid conditions which may occur in earlier or later life. The specific reaction to simple irritants giving rise to strumous inflammation of lymphatic glands, which is common in youth, may remain in the adult, and extend into advanced life, and the consequences of infections as by scarlatina or syphilis, or the gouty irritation, may be, and probably are, greatly modified by this tendency, giving rise to varieties in the several manifestations of these diseases. Thus gout appears to have a tendency to linger in strumous subjects, and in its articular form to be attended here by greater effusion, while chronic tubal nephritis in such subjects is more than usually grave and resistant. The author concludes, in short, that the strumous diathesis is a bad one for the coincidence of the most morbid conditions.

TRAUMA IN THE ETIOLOGY OF MALIGNANT DISEASES.

At the recent meeting of the German Surgical Congress, a condensed account of whose proceedings appears in this issue of the Medical News, a committee was appointed to investigate the connection between injuries of various kinds and malignant diseases.

This concerted effort at serious investigation of a large number of cases will undoubtedly serve to throw light on that extremely important subject—the immediate etiology of cancer. It has long been recognized that in females cancer occurs at points especially liable to recurring injury and irritation—the uterus and the breast—and is found not infrequently to have its origin in the scar-tissue of an old laceration or fissure. In the gall-bladder cancer occurs with noteworthy frequency in cases in which gall-stones have been present. In the stomach the beginning of cancer in the scar of an old ulcer is so frequently met with that it scarcely attracts special attention when found at autopsy. Cancer of the gastro-intestinal tract generally occurs at points subject to frequent trauma and frequently repeated irritation: on the tongue, at the two points of narrowing of the esophagus, at the pylorus, at the colic flexures, and in the rectum.

What is needed now, however, is a thoroughly scientific investigation of the other conditions preceding the development of cancer in these cases and the manner in which the first cancerous degeneration manifests itself. The editor of *The Practitioner*, in the recent cancer number of that journal, calls attention to the fact that there is in modern medical science too much individualization in investigation. Not only is too little account taken of what is being done by others, but above all too little opportunity is given to other workers in the same line of scientific investigation to substantiate or disprove what has been supposedly discovered. There is certainly in this matter of collecting the statistics and comparing the experiences of a large number of professional men with regard to trauma and malignant disease an opportunity to bring us nearer to the heart of the greatest mystery that now remains in medical science.

American contributions to our knowledge of cancer have been, in the last twenty-five years especially, very considerable. When the report of the Committee of the German Surgical Society shall be submitted next year it is not too much to hope that a very considerable body of trustworthy, carefully sifted, American statistics may be at hand to aid in making the question clearer.

LAMINECTOMY AND DRAINAGE FOR CEREBROSPINAL MENINGITIS.

Lumbar puncture has come in to more or less general use, but it is as a diagnostic not a therapeutic measure that it has won its place in medicine. The hopes originally raised that it would prove to be a valuable therapeutic resource by relieving pressure in simple serous meningitis, and even provide a certain amount of drainage in purulent cases with evacuation of toxic material have been utterly disappointed. It has even been thought sometimes in purulent conditions to hasten the end by giving occasion for the generalization of infection through lowering the pressure in the spinal canal and so permitting the spread of infectious material beyond its original limits. Despite this disappointment, however, all hope of giving surgical relief to purulent cerebrospinal affections was not abandoned.

The question even of direct medication through the spinal canal by the injection of remedies was discussed and certain experiments upon animals and observations on very bad cases in human beings were made by German investigators.

At least one British surgeon has trephined and opened the occipital fossa in order to relieve intraventricular pressure in chronic serous meningitis. It is somewhat as the climax of these various efforts that Herbert Allingham and H. D. Rolleston report (London *Lancet*, April 1st) a case of cerebrospinal meningitis successfully treated by laminectomy in the dorsal region with drainage until all secretion had ceased.

The patient was a young man aged twenty-four, under Dr. Rolleston's care who presented certain symptoms that led to the diagnosis of cerebrospinal meningitis, though all the typical signs of that disease were not present. His condition grew continually worse for seven days. There was great rigidity of the neck, knee-jerks were absent, pupils failed to react, increasing drowsiness became manifest and trophic changes in the skin at certain points set in. Death seemed the only possible issue when Mr. Allingham was consulted and consented to operate.

The dura was found bulging after laminectomy in the dorsal region. It was incised to the extent of an inch in the long axis of the cord and after the evacuation of about three ounces of coagulated lymph and cerebrospinal fluid a drainage-tube was inserted down to the cord, tapping the subdural space. The day after the operation the patient was much better and he continued to improve. After about five weeks the drainage-tube was permanently removed and at the expiration of seven weeks the wound was completely healed.

Of course there remains the doubt whether a case like this might not have improved without any surgical intervention. Cerebrospinal meninigitis, when it does not kill early, often produces very serious symptoms for a good many weeks yet goes on to recovery. In this case the impression produced on the medical attendant by the patient's condition was that death was inevitable. Then the surgeon was called in. The dorsal region was chosen because laminectomy is easier there than in the lumbar region, the spinal laminæ are more readily cut through and section of the thick lumbar muscles is avoided. The drainage-tube was used so long, seven weeks, because attempts to remove it earlier had been followed by a rise in temperature and symptoms of intraventricular pressure. As the first successful operation of its kind this will probably constitute a landmark in the history of surgical intervention in cerebrospinal affections.

OPERATIVE INTERVENTION IN CASES OF ANEURISM.

There comes into surgical practice every few years a wave of operative, quasi-radical intervention in cases of aneurism. This extends even to cases in which the lesion involves main arterial trunks. This effort toward surgical relief is not to be wondered at since of themselves the lesions are practically always progressive, and a fatal termination can be confidently and not distantly anticipated. Attention was called some months ago to a new radical method of dealing with aneurisms that was being tried in France. It consists in the injection of gelatin into the aneurismal sac. On theoretic grounds it looked eminently dangerous. The chance of embolism resulting from the clot thus formed seemed so great as to make the method at first sight unjustifiable. It was tried, however, without the serious consequences that had been foretold and the lasting results obtained have in certain cases been most satisfactory.

At the last meeting of the Clinical Society of London, March 24th, the President, Dr. John Langton, presented the report of a case of aneurism of the upper part of the abdominal aorta on which he had operated successfully by the introduction of five feet of silver wire through a cannula. The tumor in the epigastrium had developed after a pregnancy, was pulsatile, had a thrill, and was movable laterally but not vertically. As the pain was severe and increasing, an exploratory laparotomy was performed. The tumor was found to be as stated, an aneurism of the upper part of the abdominal aorta. A cannula with a trocar was inserted into it, through which silver wire was passed; very little blood escaped. The trocar opening was closed by a silk ligature. There was some restlessness and vomiting after the operation, but this gradually disappeared, and the patient recovered. Some months have elapsed since and the patient is in excellent health. She has gained in

weight, and is absolutely without symptoms. There is still a hard mass to be felt in the median line but it is much smaller than before operation, and the thrill and bruit have disappeared.

Since 1895 there have been at least six operations, not unlike this one, on aneurisms of the abdominal aorta. Of these, two patients, both operated on by Loreta, recovered, so that even in this primary and, as it were, tentative stage of the operation, there are fifty per cent. of recoveries.

When we consider how hopeless the cases are, and with how much serious discomfort their inevitable progress to a fatal termination is involved, it can be seen that the results are eminently encouraging. Recent experience with the radical treatment of aneurisms of important arteries indicates that bold surgical procedures in these cases give a very fair chance to the patient for prolonged life without serious discomfort and put an end to the unendurable, boring, continuous pain that complicates the condition when the enlarging tumor presses on important sensitive structures.

SCARLET FEVER AND MILK.

THE March report of the Buffalo Board of Health details a very striking illustration of how scarlet fever may be spread through the agency of milk and how comparatively easy it is with effective inspection and investigation to prevent the further distribution of infective material and so put an end to a serious epidemic. Within three days in February, twenty-one cases of scarlet fever were reported from a certain section of Buffalo. They all occurred along a single milkman's route. Investigation showed that everything was in satisfactory sanitary condition as far as the milkman himself and his family were concerned, also that the city milk-dealer's premises and help were above suspicion. One of the farmers, however, who supplied the dealer with milk was found to be a convalescent from some disease, the exact nature of which could not be determined, but four other members of his family were found to be suffering from undoubted scarlet fever. No more of this farmer's milk was allowed to be sent to the city for some time. The spread of the epidemic immediately stopped and the only fresh cases that occurred were reported from families already infected with the disease.

The connection of the milk-supply with the spread of scarlet fever has often been noted before. Some years ago his observations in this matter led Klein, the English bacteriologist and histologist, to the view that a form of scarlet fever occurred among cattle bearing the same relation to that disease in human beings that vaccinia does to variola under like conditions. These conclusions have not been confirmed as yet but the observations showed the importance of the most minute scrutiny of the milk-supply.

There have been few such well-conducted investigations into the relation of milk-supply and scarlet fever as this one at Buffalo. The Buffalo Board of Health is to be congratulated on its excellent scientific work, and we sincerely hope that it will attract throughout the country the attention that it deserves. The results should serve the useful sanitary purpose in disease epidemics of directing attention always to the milk-supply as well as the water-supply of the infected neighborhood. So-called sporadic cases of contagious disease, cases that occur seemingly without a source of contagion are growing rarer as better methods of sanitary investigation come into use. If present-day methods are persisted in and developed as they have been during the last ten years, we venture to say that in another decade we will have no further reports of cases of sporadic or idiopathic contagion.

THE YALE UNIVERSITY BICENTENNIAL AND YALE'S MEDICAL DEPARTMENT.

WE noted in our column of "Echoes and News" last week that a movement is on foot to secure for Yale University in honor of her bicentennial in 1901 a fund of $2,000,000. Nearly half a million of this is to go, directly or indirectly, to the medical department.

The reorganization of Yale under President Dwight has been marked by distinct advance along all scientific lines, but the medical department has scarcely shared, in due proportion, the development of the institution. We sincerely hope that the present movement will be crowned with success, and that especially the medical life of the university will be given an impetus that will make this department as powerful a factor in educational matters in this country as the other university departments have become.

We are not of those who think that progress in

scientific medicine depends absolutely on the work done in great centers of population where clinical material is abundant. We know how distracting to any real scientific medical advance a surplus of material may prove. We know, too, that much of the great scientific work of modern medicine has been done in the quiet of the study or with but small material at hand. The medical departments of German universities situated in towns of 12,000 to 25,000—Jena, Marburg, Göttingen, Heidelberg, and Greifswald—have done too much valuable work in scientific medicine to allow any illusion to remain as to the impossibility of great medical advances being made in small towns.

Of late years has come, too, for the medical profession the realization of how much more can be accomplished by a medical school that is under the ægis of a great university. Oldtime selfish methods, super-conservative attention to the interests of the faculty rather than to the higher interests of the students and of medical education, disappear before the straightforward, disinterested motives of a board of university trustees whose only motto is the development of the university, and whose one great purpose is its advance in educational methods. It will be distinctly to the advantage of medicine in America to have one more great university medical department, and such undoubtedly the medical school at Yale will prove to be if present purposes fail not. There is presented in this appeal for funds not alone to Yale graduates, but to all the philanthropically inclined whose interests are the development of the humanitarian side of modern scientific medicine, a magnificent opportunity for the exercise of the most practical beneficence. We can confidently look for great contributions to American medicine from Yale if once the opportunity is afforded. Let us hope that the effort that is being made will be crowned with the success it deserves.

ECHOES AND NEWS.

Professional Secrecy.—The Conference of Advocates of the Paris Court of Appeals has discussed and decided affirmatively the question: Does the publication in a book by a medical man of observations made upon a person treated in a hospital constitute a violation of professional secrecy?

President of the Next German Surgical Congress.—Professor von Bergmann, the Director of the Surgical Clinic of the University of Berlin, has been elected President of the next German Surgical Congress which will be held at Berlin during Easter week, 1900. He succeeds Professor Hahn, also of Berlin.

Dr. Frederic S. Dennis Honored.—Dr. Dennis of New York enjoys the distinction of being the first American physician to be honored by having conferred upon him the degree and title of Fellow of the Royal College of Surgeons of England. To be eligible to this honorary degree a man must be a graduate of the college of twenty-years' standing; only two are chosen each year.

Measles Probably Transmitted by Mail.—Thomas Marshall, a Sioux Indian died from "black" measles at the Government school at Carlisle, Pa., on April 24th. A week before his death he had received a letter from the Pine Ridge Agency, South Dakota, stating that his brother and sister had died from malignant measles. The infection was, doubtless, carried in the envelope.

Nurses' Association Convention.—The second annual convention of the Nurses' Associated Alumnæ of the United States and Canada was held at the New York Academy of Medicine May 1st, 2d and 3d. The objects of the association, as given in its constitution, are to establish and maintain a code of ethics, to elevate the standard of nursing education, to promote the usefulness and honor of the profession and guard its financial and other interests.

The Body of Dr. Gibbs Brought Home.—The transport Crook appeared in New York harbor on April 26th, with its second load of soldier-dead. The bodies of Surgeon John B. Gibbs and 11 other soldiers who died at Guantanamo were on board, also 98 bodies from Ponce and 246 from Santiago. Seventy per cent. of the dead were regulars. About 300 bodies of those who died from contagions remain near Santiago; these will not be brought home until cold weather arrives next fall.

Congress of American Physicians and Surgeons.—At a recent meeting of the Executive Committee of the Congress of Physicians and Surgeons, the following officers were elected: Dr. H. P. Bowditch, Boston, Mass., president; Dr. W.H. Carmalt, New Haven, Conn., secretary; Dr. Newton M. Shaffer, New York City, treasurer; Dr. Landon Carter Gray, New York City, chairman of Executive Committee; Dr. W. K. Simpson, New York City, secretary of Executive Committee. The next Congress will meet at Washington, D. C., in May, 1900.

International Dermatological Congress.—The Fourth International Dermatological Congress will be held at Paris from the 2d to the 9th of August, 1900. Physicians of all countries are eligible, on the payment of 25 francs, before June 1, 1900, to the general secretary, Dr. G. Thiebierge, Paris, rue de Surene 7. The titles of papers may be sent to the same address. The section on dermatology and syphilography of the Thirteenth International Medical Congress will be held in Paris at the same time, the meetings of the two organizations being joined.

The Newspaper Paragrapher Abroad.—An English newspaper reporter in a London morning journal recently made the following announcement in describing a street accident: "The unfortunate victim was taken to Guy's Hospital, where he now lies progressing favorably, although he is sedulously attended by Dr. J. R. Robinson, the resident surgeon, and some of the leading members of the staff." It is evident that there are even worse things in store for the poor medical man in England than being heartlessly pursued by some yellow-journal reporter for the details of the latest accident.

Improper Use of the X-Ray.—A suit instituted by a Chicagoan against W. C. Fuchs and Dr. O. L. Schmitt, who conducted an X-ray laboratory, to recover for the loss of a limb and other injuries which he claimed to have sustained by the improper application of the X-ray to his foot, has been decided in favor of the plaintiff, who was awarded $10,000 damages. It was alleged that in order to ascertain the cause of the stiffening of the plaintiff's ankle-joint the defendant exposed the ankle three times to the X-ray, the result being that the flesh became decomposed and that three amputations were necessary to save the patient's life.

The New Dispensary Law in New York State.—President William R. Stewart of the State Board of Charities has appointed Commissioners Stephen Smith, M.D., of New York City, Enoch V. Stoddard, M.D., of Rochester, and Simon W. Rosendale of Albany a special committee on dispensaries in order that early consideration may be given to the provisions of the recently enacted Dispensary bill. The committee will soon give hearings in New York City and elsewhere to those interested in the management of dispensaries. Later it will formulate for the board's consideration rules covering the granting of licenses to dispensaries and the giving of medical and surgical assistance by such institutions.

Bread-winning Begun at Thirty.—Professor Isaac Franklin Russell of the New York University Law School, at the annual dinner of the Society of Medical Jurisprudence, deprecated the tendency of modern professional education to keep a man from getting to work until he is nearly or quite thirty years of age. This tendency is most marked in medicine. "A bright boy, ambitious to become a physician, goes through the public school in preparation for college, where he spends four years working for his bachelor's degree and a year or two more in post-graduate study, then goes to a medical college and studies three or four years for his doctor's diploma, and, winning distinction, is awarded a staff appointment at a hospital, where he spends two years and then finishes his education by study abroad. He will now be thirty years old and without experience in bread-winning."

Typhoid Fever Spread by the Use of a Rectal Thermometer.—In a hospital of Turin three patients developed typhoid fever while under treatment for other troubles. As the cases all occurred in one ward the matter was thoroughly investigated and the conclusion was arrived at that the infection had been caused by the careless use of a rectal thermometer. In all the other wards of the hospital the thermometer after use was thoroughly washed in a 1 to 1000 sublimate solution. In this ward, however, it was the custom to take the thermometer from the rectum of one patient and after wiping it with a cloth, to insert it into the rectum of the next patient. Laboratory tests showed that numerous typhoid bacilli remained upon the instrument after it had been withdrawn from the rectum of a typhoid patient and cleaned in this manner. No new cases developed after the thermometer used in that ward was properly disinfected each time it was used.

Halle Students Protest against the Presence of Women in Their Clinics.—Halle has been one of the first of German universities to admit women to the clinical lectures in medicine. This is not at all to the liking of the young men, who have sent a written protest to the medical students of all other German universities, in order that they may by their active opposition to the introduction of a similar plan, be spared the "painful situations which mock at modesty," which, according to the protestors have become their daily lot. In the opinion of these ungallant males, "the emancipation of women in this case leads to calamity; it comes into conflict with decency, and therefore the bars must be raised against these practices." The faculty at Halle does not share this opinion and has joined in denouncing these statements as entirely unwarranted by the facts. Newspaper criticism of the "protest" is that it will do no harm to the higher education of women, while it has given a most unpleasant exhibition of the character of the German medical students.

Margarin and Butter.—The Butter Association of England has for years been making strenuous efforts to prevent the sale of margarin as butter, but with only indifferent success. Special labels and laws, and the conviction of many hundreds of offenders, do not deter tradesmen from selling as butter mixtures containing from 70 to 90 per cent. of margarin. Out of 500 samples collected and analyzed over 100 were found to be thus adulterated. The truth is that it is well nigh impossible for any one but a chemical expert to distinguish one from the other, and at a butter show not long since the product which won the first prize was afterward proven to be margarin. The butter-growers are now working for a law that shall make it an offense to color margarin, while permitting the artificial coloring of butter. In this way they hope to enable the public to distinguish the genuine from the false. While no words of condemnation are too severe for those who sell falsely labeled and injuriously adulterated foodstuffs, the matter partakes of the nature of a burlesque, when the real has to be adulterated with a dyestuff in order to protect it from its imitators.

Professor Chandler, President of the Society of Chemical Industry.—A cablegram of April 28th announces that Professor Charles F. Chandler of the School of Mines of Columbia University, New York, has been named President of the Society of Chemical Industry, which was in session last week at Glasgow, Scotland. The society is mainly composed of English chemists, and this is the

first time that an American has been chosen President of this society or, for that matter, of any English scientific society to which English-speaking scientists from both sides of the Atlantic are admitted as members. Professor Chandler will succeed to an office that has been held by such distinguished men as Sir Henry Roscoe, R. A., Sir Frederick Abel, R. A., Sir John Evans, and Sir Lowthian Bell. Professor Chandler was one of the founders of the Columbia School of Mines. He was connected for many years with the New York City Board of Health. In 1866 he was appointed chemist to the Board of Health, and became its President in 1873. He held this position until 1884. It is proposed to tender Professor Chandler a public reception upon his return from the Industrial Congress.

Meeting of Rectal Specialists.—The following is the program of the First Meeting of Rectal Specialists which will occur at Columbus, Ohio, June 6 to 9, 1899. "The Importance of Giving Rectal Diseases Special Study," Jos. M. Mathews, Louisville. "Pruritus Ani," Jas. P. Tuttle, New York City. "Surgical Treatment of Non-Malignant Stricture of the Rectum," Joseph B. Bacon, Chicago. "A Modification of Whitehead's Operation for Hemorrhoids," Samuel T. Earle, Jr., Baltimore. "The Proctoscope as a Factor in the Diagnosis and Treatment of Simple Ulceration of the Rectum," Leon Straus, St. Louis. "A Consideration of the Various Forms of Ulceration of the Rectum," Lewis H. Adler, Jr., Philadelphia. "Rectal Carcinoma—Excision and Subsequent Colotomy," B. Merrill Ricketts, Cincinnati. "The Limitations of the Kraske Operation," Charles C. Allison, Omaha. "The Act of Defecation," Thomas Charles Martin, Cleveland. "Constipation Considered from the Standpoint of the Proctologist," A. Bennett Cooke, Nashville. Paper and Exhibition of New Instruments, S. G. Gant, Kansas City. "Rectal Adenomata," William M. Beach, Pittsburg.

A Reversal of Judgment in the St. Vincent's Hospital Case—The Appellate Division of the Supreme Court of New York has ordered a reversal of the judgment of the lower court which had decided for the defendant in the case, the hospital. The plaintiff it will be remembered sued because she was severely burned by hot water bottles which were applied after an operation and while she was still under the influence of ether. The reversal was unanimously concurred in by the supreme bench but not on the grounds of damages for negligence, but for breach of contract. In taking the patient on the "pay side" of the house the hospital had agreed to furnish a trained nurse to the plaintiff, but instead of fulfilling this agreement had allowed her to be waited on by a pupil nurse who had studied but nine months out of the course of two years. Judge Barrett, who wrote the decision, said that the contract to furnish the nurse was express, specific, and valid, and the plaintiff was entitled to the same damages as if the action had been for negligence pure and simple.

The evidence for the defendant tended to show that the nurse had had experience in attending surgical cases and that she had given satisfaction, especially that she had been instructed by a competent teacher in the proper use and placing of hot water-bottles. The court held that though the nurse's single act of negligence did not necessarily establish her general incompetence, it was for the jury to decide whether this act was one of negligence on the part of an ordinarily skilful, trained, and competent nurse, or whether it was attributable to inexperience and lack of that continuous training which a full two-years' course would have afforded.

ANNOUNCEMENT.

REVISION OF THE PHARMACOPŒIA.

IN accordance with instructions given by resolutions passed at the National Convention for Revision of the Pharmacopœia of the United States of America, held in Washington, A.D., 1890, I herewith give notice that a General Convention for the Revision of the Pharmacopœia of the United States of America will be held in the City of Washington, D. C., beginning on the first Wednesday in May, 1900. It is requested that the several bodies represented in the Convention of 1880 and 1890, and also such other incorporated State Medical and Pharmaceutical Associations, and incorporated Colleges of Medicine and Pharmacy, as shall have been in continuous operation for at least five years immediately preceding this notice, shall each elect delegates, not exceeding three in number; and that the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Surgeon-General of the Marine Hospital Service shall appoint, each, not exceeding three medical officers to attend the aforesaid Convention.

It is desired that the several medical and pharmaceutical bodies, and the Medical Departments of the Army, Navy and Marine Hospital Service shall transmit to me the names and residences of their respective delegates, so soon as said delegates shall have been appointed, so that a list of the delegates to the Convention may be published in accordance with the resolutions passed at the 1890 Convention for the Revision of the Pharmacopœia, in the newspapers and medical journals in the month of March, 1900.

Finally, it is further requested that the several medical and pharmaceutical bodies concerned, as well as the Medical Departments of the Army, Navy and Marine Hospital Service, shall submit the present Pharmacopœia to a careful revision, and that their delegates shall transmit the result of their labors to Dr. Frederick A. Castle, 51 West 58th Street, New York City, Secretary of the Committee of Revision and Publication of the U. S. Pharmacopœia, at least three months before May 2d, 1900, the date fixed for the meeting of the Convention.

H. C. WOOD, M.D.,
President of the National Convention for Revising the U. S. Pharmacopœia, held at Washington, D. C., A. D., 1890.

UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, May 1, 1899.

CORRESPONDENCE.

THE NEW DISPENSARY LAW.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Your article in the issue of the MEDICAL NEWS for April 29th, entitled "The New Dispensary Law of New York" is one with which we agree in the main, but we must call attention to your statement that "the bill, which has just become a law, is the same, with a few unimportant modifications, as that which was introduced during last year's session of the Legislature, and which failed to be reported back from the committee to which it was referred." These modifications are not only far from being unimportant, but are so important, that, but for them, the bill would not have become a law. They are to be found in sections 20, 22, and 25.

In section 20 of last year's bill the State Board of Charities could have refused a license to any dispensary, no matter how long established, if in the judgment of the Board the operation of such dispensary was not for the public benefit. In the bill which has just become a law the Board is *directed* to issue licenses to all dispensaries incorporated at the time of the passage of the act, and to unincorporated dispensaries conducted in connection with incorporated institutions at the time of its passage.

In section 22 the Board is directed to apply to the Supreme Court to annul the licenses granted such dispensaries for wilful violation of the rules and regulations made by the State Board of Charities.

Last year's bill gave sweeping and arbitrary powers to the State Board of Charities, allowing it to deny licenses to institutions already incorporated, and to revoke licenses to such incorporated bodies after having issued them, without giving reasons for doing so, beyond saying that "in its judgment" the operation of the institutions was not for the public benefit. Of course, an institution feeling itself unjustly treated could appeal to the Supreme Court; this, we believe, is a privilege it does not require an act of legislature to grant. Under the law just enacted, if an institution incorporated at the time of the passage of the act, does not feel that the rules and regulations made by the State Board of Charities are reasonable and just, it can refuse to obey them, and the State Board must apply to the Supreme Court to enforce them. This modification to the bill of last year we offered as a check on the State Board of Charities, believing that the Supreme Court would refuse to endorse unjust rules and regulations. We felt also that this was the surest way to secure the enforcement of reasonable and just rules and regulations. This law does not give permission to the State Board of Charities to make rules and regulations; the Board is *directed* to make them and is also *directed* to see that they are enforced.

Section 25, which makes it a misdemeanor to obtain aid at a licensed dispensary (and there can be no unlicensed dispensaries) is also an important modification of the bill of last year, and one which in itself can be made a potent factor in preventing abuses.

While there are weak points in this law, taking it altogether it is a reasonable and just measure, and one which will protect the medical profession and the dispensaries as well. These modifications, which removed all opposition to a dispensary law, were offered directly to the State Board of Charities by the representatives of the Medical Society of the State of New York, and represents that Society's idea of justice to all concerned.

Very truly yours,

FRANK VAN FLEET, M.D.,

Chairman of the Committee on Legislation of the Medical Society of the State of New York.

NEW YORK, April 29, 1899.

[It is true as our correspondent says that the methods of procedure of the State Board of Charities in performing its duties are decidedly different from those prescribed in the Bill of last year, but the end to be accomplished is the same. It has been stated that the credit for the passage of this Bill belongs to the Committee on Legislation of the State Medical Association. It is gratifying to know that the Bill also has the endorsement of the Committee of the State Medical Society. With so unanimous a sentiment there should be no difficulty in the execution of the law.—ED.]

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

AN INTERESTING CASE OF ANEURISM OF THE AORTA—SEPTIC PERITONITIS FOLLOWING INFLAMMATION OF THE UTERUS CONSEQUENT ON CANCER—COMMENCEMENTS OF THE MEDICAL COLLEGES--DECISION IN FAVOR OF THE GERMAN HOSPITAL IN THE AUTOPSY SUIT—CERTIFICATES OF HONOR FOR VOLUNTEER NURSES—PERSONAL NOTES—HEALTH STATISTICS.

PHILADELPHIA, May 2, 1899.

AT a recent meeting of the Pathological Society Dr. W. E. Hughes presented an unusual and interesting case of aneurism of the thoracic aorta which occurred in a man sixty-three years of age who was free from any history of syphilis or alcoholism. The patient suffered from a winter cough for two years, with slight dyspnea and some palpitation. Examination of the chest proved negative. Gradually symptoms of ataxia developed, of which the most prominent was excrutiating pain through the thighs and legs. The patient finally died after two or three severe coughing spells. At the post-mortem an aneurism extending from the lower part of the thoracic arch down to the middle of the thoracic aorta was found, which had eroded the thoracic vertebræ deeply and had ruptured, the blood escaping into the mediastinal cellular tissue in front of and around the sac. The two interesting features of the case are, the complete absence of any symptoms or signs of aneurism on the one hand and the associated locomotor ataxia on the other. Dr. Hughes believes this association was accidental, "though the possibility remains that the cord lesion may have been the direct result of the irritation of the aneurism."

Another interesting case, also reported by Dr. Hughes, was "Septic Peritonitis Following Inflammation of the Uterus Consequent on Cancer." This occurred in a woman seventy-two years old, who suffered from cancer

of the rectum for two years and then suddenly developed a septic peritonitis which was very rapidly followed by death. At the post-mortem the abdomen was found to be filled with pus, and the coils of intestines were covered and glued together with lymph. The uterus was large and flabby and its mucous membrane congested and in places almost polypoid. In the lower part of the rectum was an extensive cancer which involved not only the vagina but also the cervical portion of the uterus. This cancer tissue was sloughing extensively. There was no cancer of the body of the uterus. Before death the peritonitis was thought to be due to the direct infection from the rectum, but Dr. Hughes believes it occurred as follows: The cancer had occluded the uterine os and by irritation had caused hypersecretion from the uterine mucous membrane and distention. Then breaking down of the cancer mass had introduced into the uterus infecting germs from the rectum with consequent septic inflammation, local destruction of the uterine wall and general peritonitis.

Commencement day for the University of Pennsylvania will be June 15th, the latest of any of the colleges, and this spring will celebrate the 125th commencement day of the Medical Department. Jefferson Medical College is to have its commencement the 15th of May, and in the evening the annual banquet of the Alumni Association will be held.

Judge Audenried roundly scored the guilty physician when he decided last week that a charitable hospital could not be made to suffer for an alleged unauthorized autopsy by its officers or employes. The decision was given in the case of Alice Hanmore, who brought suit to recover damages from the German Hospital for the alleged mutilation of her dead mother's body. The mother was taken to the hospital on January 28, 1897, and died two days later from apoplexy. The plaintiff contended that the hospital authorities delayed surrendering the body to her, and the next day an undertaker whom she sent to the hospital for the body found that a post-mortem had been performed by the hospital physicians without authority, and the body badly mutilated. Judge Audenried characterized the action of the hospital physicians as outrageous, but said that under the laws of this State, in his opinion, a verdict for the plaintiff could not be sustained.

To the many who volunteered their services as nurses to the Medico-Chirurgical Hospital last fall, when its own staff was insufficient to care for the sick soldiers, last Wednesday was a gala day, for public exercises were held at the Broad Street Theatre, at which Mayor Ashbridge conferred certificates of honor upon them. He thanked the volunteer nurses in a few brief remarks and was followed by Surgeon-General Shoemaker, who especially commended Mrs. Katharine A. Taylor, the directress of the Nurses' Training School.

The Woman's Medical College has appealed to the Mayor for the reinstatement of Dr. Florence Van Gasken, who is one of the City Assistant Medical Inspectors dropped from the list. He replied that the dismissal was for the good of the service and neither sex nor politics had influenced him and that the matter must be considered closed. He said also that in the near future two or three additional inspectors will be dropped.

Governor Stone last week appointed Dr. Henry D. Heller of Northampton County, Quarantine Physician for the Port of Philadelphia, to succeed Dr. Henry C. Boenning.

Two Philadelphia Physicians have been honored this week, Dr. Edgar F. Smith, Professor of Chemistry at the University, by being elected a member of the National Academy of Science, and Dr. Edward P. Davis, Professor of Obstetrics at Jefferson Medical College, by being offered the Chair of Obstetrics and Gynecology at Rush Medical College, Chicago, which he declined.

The total number of new cases of contagious diseases occurring in Philadelphia during the week ending April 29th was 308, reported as follows: Diphtheria, 46 cases with 14 deaths; scarlet fever, 44 cases with 5 deaths; typhoid fever, 218 cases with 37 deaths.

MEDICAL MATTERS IN CHICAGO.

VORTICOSE VEINS—SYNCHYSIS SCINTILLANS—EMBOLISM OF THE CENTRAL ARTERY — FURTHER BACTERIAL EXAMINATIONS ILLUSTRATING THE PROTEAN MANIFESTATIONS OF THE CANON-PFEIFFER BACILLUS—COMPETITIVE EXAMINATIONS FOR INTERNES AT THE COOK COUNTY HOSPITAL — QUARTERLY MEETING OF THE STATE BOARD OF HEALTH.

CHICAGO, May 1, 1899.

AT the April meeting of the Chicago Ophthalmological and Otological Society, Dr. Charles H. Beard presented a case of vorticose veins which was remarkable for two reasons: First, owing to lack of choroidal and retinal pigment and thinness of the chorio-capillaries, the venæ vorticosæ of both eyes being clearly visible, and second, because of the number of these vorticose veins. Most works on ophthalmology, in describing the anatomy of the globe, state that these venous trunks are four in number. In dissections of the eyeball the speaker had more than once counted as many as seven. In each eye of the little Italian lad whom he exhibited, exactly nine such vortices could be clearly seen with the ophthalmoscope.

At the same meeting Dr. Lyman Ware reported an interesting case of synchysis scintillans, or sparkling synchysis. Dr. C. P. Pinckard has seen three or four cases of synchysis scintillans in which there were larger pieces of cholesterin than in the case reported by Dr. Ware. Dr. William T. Montgomery had also seen a well marked case. He also found the vitreous full of beautiful, gold-like scintillæ. Dr. Wheelock saw a case of synchysis scintillans in a man eighty years of age, it being associated with colloid degeneration.

Dr. Gradle presented a case of embolism of the central artery with preservation of some central vision.

Dr. Wynekoop of the Chicago Health Department, reports that out of 206 bacterial examinations made for diagnostic purposes during March he found the influenza organism in 57 cases. Of this number a clinical diagnosis of influenza had been made by the attending physician in 16 cases; no diagnosis had been attempted in 23 cases.

Of the remainder, 8 cases had been pronounced tonsillitis, 4 diphtheria, 1 each pneumonia, measles, "ulcerative tonsillitis," "tonsillitis or diphtheria," "scarlet fever and diphtheria," and "influenza and diphtheria." As illustrating the protean manifestations of the Canon-Pfeiffer bacillus Dr. Wynekoop reports the following case in detail: About February 10th, a boy of seven years was suddenly seized with a chill, which was of short duration. This was followed by headache and a temperature of 103.4° F. For a number of days prior to the chill there had been a condition closely resembling typhoid—general languor, loss of appetite, coated tongue, constipation, slight headache, nose-bleed, and a slight cough. The second day following the chill his temperature rose to 105.6° F., and the pulse to 160 beats per minute. There were delirium, stupor, and slight convulsions—symptoms suggestive of meningitis, but which could not be interpreted as such in the absence of any muscular rigidity. The temperature continued near 105° F. another twenty-four hours, when a slight erythema appeared over parts of the body. A consultation was called, but a positive diagnosis was not made. Scarlet fever with a delayed rash was suggested, and a hot pack ordered with the hope of bringing out the rash should this be the nature of the disease. The results were negative. A microscopic examination was then made of the contents of the throat, and the presence of great numbers of influenza bacilli was revealed. The child was now treated for influenza, with prompt and decided improvement, the temperature falling to 102°–101° F., and the pulse to 120–116. The cough continued, however, and became more harsh and distressing. No involvement of the lungs or pleura could be discovered at this time. During the remaining two weeks the symptoms resembled a typhoid condition. The temperature varied from 100° to 103° F. The cough became less pronounced. The intestines became greatly distended with gas; there was iliac tenderness, and stools of a typhoid character. The nervous symptoms, however, were not those of typhoid, the child being supersensitive to the touch, and exhibiting an abnormaliy active mental condition. A consulting physician was again called in, who made a probable diagnosis of typhoid fever complicated by influenza. Widal's test was made on several occasions, but at no time was a satisfactory reaction obtained. What seemed to be a partial reaction was obtained about the eighteenth day, but could not be obtained later. Bacteriologic examinations were made of the stools, and, after several attempts, the influenza organism was isolated, which would lead to the conclusion that this organism alone was responsible for the intestinal symptoms. On the tongue there were several small ulcers, and similar patches were noticed on the mucous membrane of the lips and cheeks. During the second week the Eustachian tubes became affected, and later the cavities of the middle ear. The otitis media ran the usual course. Pus examined at the time of the rupture of the tympanum contained the influenza bacillus, and cultures made from the discharge revealed the organism present in a pure condition. In cultures examined at a later period there were found streptococci. The intestinal symptoms disappeared during the third week and the stools became normal, but the temperature, which for several days had been in the neighborhood of 100° F., began to rise a little each day, and respiration became more rapid. This condition was found to be due to an involvement of the right pleura. Fluid began to accumulate, and soon the entire chest cavity of the affected side was filled. Aspiration demonstrated the presence of pus. Microscopic examinations were made of the aspirated fluid, and a few influenza organisms were observed. Small portions of the pus were transferred to blood serum and cultures obtained in which the bacillus in question was found in a pure state. It would be of interest to know whether this bacillus can produce a pathologic condition of the small intestines similar to that caused by the typhoid bacillus.

The result of the competitive examinations for internes at the Cook County Hospital was announced a day or two ago. Dr. Theodore Ticken, of the College of Physicians and Surgeons, secured the highest average of the thirteen candidates who passed the examination and were accepted. Of the other successful contestants, five were from Rush Medical College, and the others from the College of Physicians and Surgeons. These internes will serve for eighteen months at the County Hospital.

The State Board of Health held its quarterly meeting in this city April 28th, and passed rules covering the branches in which practitioners will be examined hereafter by the Board. This action is taken under the Medical Practice Bill which will go into effect in July. The Board will require a diploma from some first-class school of medicine, and the applicant will be examined in anatomy, physiology, chemistry, pathology, histology, obstetrics, diseases of women, therapeutics, practice of medicine, hygiene, and medical jurisprudence. Midwives will be examined in the same branches as at present—physiological chemistry, histology, pathology, and hygiene. It was decided to endorse a movement to establish a school for the instruction of local health officers at the State University.

THE CENTENNIAL CELEBRATION OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

[From a Special Correspondent.]

BALTIMORE, April 29, 1899.

NEVER in the history of medicine in Maryland has there been such a gathering of physicians as was witnessed here in Baltimore during the past few days. Over 1000 medical men from all parts of the State and also from other States, together with many ladies, assembled in McCoy Hall, Johns Hopkins University, to attend the opening meeting of the centennial of the Medical and Chirurgical Faculty of Maryland. Governor Lowndes of Maryland presided and Cardinal Gibbons, attired in his red robes, delivered the invocation. This was followed by the address of welcome delivered by Dr. S. C. Chew, President of the Faculty, in which he referred to striking events that marked the close of former centuries, and then

spoke of the remarkable scientific discoveries of this now passing era, particularly in the realm of medicine. After mentioning some of the most important discoveries of our time, such as vaccination, auscultation, the wonderful results of pathological study, and the revolutionizing discoveries of anesthetics and antiseptics, he closed by urging his fellow members to still greater faithfulness in the future.

Wednesday, Thursday, and Friday were given up to demonstrations, clinical lectures, and the visiting of various hospitals and asylums. In the afternoons scientific papers were read in McCoy Hall by especially invited physicians. As many of the demonstrations were conducted at the same time it will be impossible to speak of them all. One of the most interesting was given on Wednesday by Dr. Keirle on the Pasteur method in the diagnosis and treatment of rabies. This Pasteur Institute was established in Baltimore about two years ago by the College of Physicians and Surgeons, and many cases have been successfully treated. A clinic on gastrodiaphany by Dr. C. Urban Smith at the Baltimore University, also a surgical clinic by Dr. Biedler, a gynecological clinic by Dr. Sellman, and an eye and ear clinic by Dr. T. Cooke, Jr., were held.

Dr. Wm. Osler of the Johns Hopkins Hospital delivered a clinical lecture on cerebrospinal fever in which he said that there were three important points in the history of this disease: First, its discovery as a separate entity; second, the discovery by Quincke of the importance of lumbar puncture, and the third was the discovery of the specific organism. He said that the symptoms of this disease were singularly diverse; no disease shows such differences. Cases may last from six hours to six months. Fatal cases run out in six hours or less, while recurring or relapsing cases may drag along for six months or more. The diagnosis is not usually difficult when many cases prevail, but in isolated cases the diagnosis is usually very difficult, and it is not easy to differentiate this disease from any other form of meningitis. Quincke's work on lumbar puncture makes a diagnosis easier. To illustrate the disease a case was shown of a boy who was in the seventh week of the illness. This case illustrated an interesting point which was the curious intermission. He came in with a temperature of 104° F. He had been ill with all the characteristic features, such as headache, abrupt onset, vomiting, retracted head, much pain, and in addition there was a very marked erythematous characteristic rash. This was the sixteenth case of cerebrospinal fever that had been brought into the hospital. Lumbar puncture was performed on several occasions. Dr. Osler exhibited the fluid from the fifth puncture. There were about five ounces of turbid liquid. He stated that the patient began to improve rapidly after the puncture. Also that the turbidity of the fluid was a characteristic sign. The position of the patient was very characteristic; the slightest movement of the head was exceedingly painful, but he was comfortable as long as he remained still. Lumbar puncture had been performed on him seven times. The other case shown was also, in some respects, characteristic. It was a little like typhoid fever. The onset was very abrupt; he was seized with headache and vomiting as he was returning from work and he at once showed the characteristic symptoms, such as stiffening of the neck, head, and back, and a skin rash. The rash was a very curious one. Each spot was covered by a vesicle and there was a hemorrhage into the vesicle. Lumbar puncture was performed the next day after admission and the specific organism was found. The patient presented an almost characteristic typhoid condition. Still there were differences which would not deceive the clinician. The head and neck were rigid, which is not common in typhoid fever and the diplococcus was found. The patient was in the third week of the disease and responded to questions, but his consciousness was often benumbed. There are different forms of meningitis. The serum from the puncture must be carefully studied bacteriologically. Out of twenty-nine cases with careful bacteriological study, eight were tuberculous meningitis, in eight the pyogenic organisms were present, in eight pneumococci were found, and there were five in which the characteristic diplococcus was present. These are the four different varieties of meningitis. There are certain marked differences between these four kinds. The onset of cerebrospinal fever is different from that of the streptococcic or tuberculous variety. Soon after the onset there is a pathognomonic skin rash which is not seen in other forms of meningitis. It is either an erythema, a purpura, or a herpes, and the latter is more frequent. The examination of the blood has not yielded good results. Lumbar puncture is of the most importance, not only as tending to a cure, but also to make a diagnosis sure. It is done at about the second, third, or fourth lumbar interspace and the needle is directed upward while the patient is bent forward.

Dr. William S. Thayer delivered a clinical lecture on "The New Researches on Malaria." (This will appear in full in a later issue of the MEDICAL NEWS).

Dr. Wm. S. Halsted then exhibited some cases of hernia, on which he had operated and spoke of his method, and he also showed some cases of mammary cancer, in which the breast had been removed, and explained also his method of cleaning out the axilla and removing much of the pectoral muscle. Dr. Howard A. Kelly gave a very skilful demonstration of the examination of the rectal mucous membrane and of a large part of the lower intestinal tract by the use of a rectoscope. He also demonstrated, very beautifully, the ease with which he examined the female bladder and catheterized the ureters. He put the woman in the extreme knee-elbow position, and let air into the vagina, otherwise the bladder would be ballooned. Then he put a little cocain into the urethra and gently dilated with a bulb passed inside of a cystoscope. After the entrance into the urethra was made the bulb was withdrawn and the cystoscope passed in, and the bladder at once was plainly seen. The inside could be studied on all sides, the residual urine seen and withdrawn. By turning the cystoscope to one side or the other the entrance of the ureters could be seen, and either one catheterized at will.

In the afternoon Dr. Herman Knapp of New York read

a paper on "Some Landmarks in the History of Ophthalmology." Drs. Janeway, Alexander, and Edgar were unable to come, but in their place Dr. Wm. H. Welch reviewed, in a most interesting manner, the collection of medical books on exhibition in the hall, the oldest being a photograph of the Ebers papyrus, dating from about 2000 B. C. Dr. George Ben Johnston of Richmond read a paper on "How Far Myomectomy Is to Supplant Hysterectomy," in which he said that in treating female diseases there was danger in being so conservative that one might be radical. There was no use in trying to preserve organs that had become useless, but that of course the age, the nature of the malady, and the extent of the lesion had to be considered. In the evening Dr. W. W. Keen of Philadelphia delivered the annual oration, his subject being "The Debt of the Public to the Profession." Dr. Keen reviewed the whole field of medicine during this century, and enumerated most of the terrible diseases from which the whole civilized world so frequently suffered, and what the remarkable discoveries in medical science had done to protect society from these terrors. The plague, cholera, typhus and yellow fever, and smallpox were diseases enlarged upon, and the contrast between present and former times compared. The great discoveries of anesthetics and antiseptics were commented upon, and also the tremendous addition to science through pathological study. In return for these gifts Dr. Keen said that the profession might well ask the public for support of the hospitals, libraries, and laboratories to aid in this great work for humanity. On Thursday morning a surgical clinic at the University of Maryland was held by Dr. Tiffany, a medical clinic by Dr. I. E. Atkinson, a demonstration of abdominal section by Dr. Ashby. The electrical illumination of the stomach was demonstrated by Dr. J. C. Hemmeter, who also later explained his method of intubating the duodenum. The tiny electric light around which cool water is kept flowing is swallowed by the patient to be examined, he having first swallowed some ice water to still further cool the stomach. Through the abdominal walls the tiny light could be seen and the size and position of the stomach could be mapped out. The most practical use so far, is diagnosing cancerous and other abnormal growths in the stomach. At the Baltimore Medical College Dr. Robert W. Johnson explained his proposed method of turning off the carotids in operations on the head and neck. He has as yet only tried this experiment on a dog, and the object is to show the carotid could be cut off temporarily while operating on the parts supplied by that vessel. His method is to lightly pass a ligature around the carotid without tying it, then to fasten the ligature together to form a knot. The knot is caught in a slit made in a small stick of wood which the assistant holds. As the stick is raised the blood is cut off. In the afternoon at the scientific meeting, papers were read by Dr. Jacobi on "European Medicine about 1799;" by Dr. E. H. Bradford of Boston, on "A Study of the Human Gait," and by Dr. H. C. Wood of Philadelphia, on "Nostrums, the Profession, and the Law." In the evening the annual dinner of the faculty was held. On Friday a demonstration of orthopedic cases and methods of treatment was given at the hospital for the relief of deformed and crippled children by Dr. R. T. Taylor. Many of the visitors spent the afternoon at the Sheppard and Enoch Pratt Hospital, where they were entertained at luncheon.

Luncheon was also served each day in the hall of the faculty, and a number of private dinners were given, and also several receptions. At the banquet on Thursday evening, Surgeon-General Sternberg was present, and also Dr. Jacobi of New York, Drs. Wood and Tyson of Philadelphia, Dr. Geo. Benj. Johnston of Richmond, and Dr. W. W. Johnson of Washington. A very unique and interesting collection of portraits, relics, books, diplomas, etc., was placed in McCoy Hall and excited much attention.

At the business meeting over 100 new members were elected.

TWO CASES OF SCLERODERMA—ATROPHY OF INFANTS—REMARKABLY LOW MORTALITY IN A HOSPITAL FOR INFANTS—PAROXYSMAL HEMOGLOBINURIA—EARLY DIAGNOSIS OF CHOLELITHIASIS—THE PORTION OF THE LUNG AFFECTED IN THE BEGINNING OF PULMONARY TUBERCULOSIS.

At the Berlin Medical Society, March 15th, Bloch showed a boy, aged six years, who had always been healthy until six months previous. Then his mother noticed that the skin of the right leg began to assume a peculiar dry, shrivelled appearance, the process extending until the thigh from the anterior superior spine of the ilium over the sartorius muscle and the leg on both sides as far down as the malleoli presented the typical characteristics of scleroderma. The kidneys, nervous system, thyroid gland, and other organs of the child seemed to be normal. There was besides the cutaneous change, a certain amount of muscular atrophy especially of the quadriceps, tibialis anticus, and the peronei of the affected limb; also, an atrophy of the tibia, which though slight was, nevertheless, demonstrable by means of the Röntgen-rays. There was a diminution of the electrical excitability of the affected muscles for both faradic and galvanic currents. On account of the loss of elasticity of the skin, and the attachment of that portion overlying the tibia to that bone, motions of the joints were somewhat limited. There was no change in sensibility. It is worth mentioning that since birth there had been a vitiligo patch behind the right ear which, in the last few months had increased in size, but did not show the characteristics of scleroderma. Within eight days there had developed under the eyes of the physician a sclerodermic area as a big as a dime over the seventh cervical vertebra. The treatment consisted in baths, galvanism, massage, and the use of salol, as recently advised by Phillippson of Hamburg.

Another patient exhibiting scleroderma was presented by Adler. She was ten years old, and well developed. Four years before, after a fall, bluish patches appeared in the skin about the left knee. Simultaneously there were gastric disturbances, loss of appetite, and vomiting, symp-

toms which have been mentioned as associated with the development of scleroderma. The bluish patches spread over the upper and lower leg, and gradually whitish areas appeared with retraction of the skin and the usual signs of scleroderma. At the time of exhibit the child had an atrophy of the left limb, both muscular and osseous. While no measures are at hand to stop this peculiar process it is possible to prevent contractions of the muscles, adhesions between the skin and the underlying bones, and excessive muscular atrophy by the systematic use of electricity, mechanical exercises, and baths, while the strength is kept up by strychnin, etc.

At the Union for Internal Medicine, March 20th, BAGINSKY spoke of atrophy of infants. Most of these patients have suffered from dyspepsia. In spite of abundant food, they grow thinner and thinner. Opinions have differed as to the cause of the atrophy. By examination of the stools he had discovered that 52.7 per cent. of the nitrogen of the food passed unused through the intestine. This indicated a severe disturbance of the intestinal absorption. Microscopic examination of portions of the intestinal mucous membrane, obtained one or at most two hours after death, showed that portions of it were useless for purposes of absorption, either because the glands of Lieberkühn had grown out into the intestinal cavity, or because such overgrown portions had sloughed away, leaving those parts devoid of absorbing mucous membrane or shrunken in cicatricial atrophy. The theories which have been advanced have not satisfactorily explained this condition. There was nothing in the urine nor in the organs to indicate an auto-intoxication. The author rejected Czerny's theory of poisoning by acid, because the respiration was not of a type to correspond. Examination of the blood failed to show the presence of microorganisms, and so the theory of septic infection rests on an unproved assumption. Treatment should consist in a change of diet and care, by which a cure may often be effected. Even the best hospital treatment leaves much to be desired.

HEUBNER, who some years ago made an examination of the intestines of fourteen patients dying from the cause mentioned, had failed to find the lesions mentioned by Baginsky. He queried if the meteorismus of the intestine had not so flattened out the mucosa as to lead to the impression that it was absent in places. The theory of Czerny is not so hastily to be pushed aside. He found the excretion of ammonia in the urine several times above normal, although not as great as reported by Czerny.

BERNARD said that the clinical picture of atrophy of infants is a varied one. The hypoplasia of the parenchyma of the glands may be either inherited or acquired by false diet. He had seen the intestinal lesions mentioned by Baginsky.

FINKELSTEIN defined the atrophy as a deep-reaching disturbance of the nutritive action. In the majority of instances there was a chronic poisoning due to auto-intoxication. There may be specific producers of poisons which lodge in the intestines. This often occurs in hospitals where originally healthy children slowly become marasmic. The periodic outbreaks of this affection, causing the death of numbers of children in a short time, points to the specific nature of the infection.

BAGINSKY expressed himself strongly against the idea that an infection is the cause of hospitalism. The blame rests much rather on the monotony of the diet and care.

The infants' hospital in Budapest which has been conducted by SZLARDI for twelve years boasts, with reason, that it has the lowest mortality of any infants' hospital. From September 1, 1897, to September 1, 1898, 1325 infants were cared for, with a loss of only 49, or 3.6 per cent. This mortality was 10.9 per cent. of those who were sick. Diseases of the stomach and intestine formed one-third of all cases of illness. The mortality of the babies sick with these troubles was 7.3 per cent. These low figures are reached by the custom, to which there were few exceptions, of admitting the mother and child together. During the past twelve years there has been only one severe outbreak of gastro-enteritis. The entrance and discharge of children were suspended for four days, the ill babies were isolated, and the hands of the nurses and the linen thoroughly disinfected. The epidemic was quickly at an end.

At the Imperio-Royal Society of Physicians of Vienna, March 24th, NEUMANN showed a patient who had been under treatment for recent syphilis four years before. Since that time there had been many recurrences of syphilides. One year ago there was fever and the passage of brownish urine. Such attacks recurred at first at long intervals, but later every day or so. The urine was found to contain hemoglobin, but no red blood-corpuscles. After three or four hours the normal appearance of the urine returned and the general symptoms disappeared. The causes of paroxysmal hemoglobinuria are high or low temperatures, poisons (potassium chlorid), malaria, and long-continued syphilis. This last cause explains the cures that have been reported after the use of antisyphilitic remedies.

POLLATSCHEK spoke of early diagnosis of cholelithiasis. Biliary colic is not always due to gall-stones, but may arise from inflammatory processes. Even in severe cases icterus may be wanting. Cardialgia is the commonest mistaken diagnosis. In the latter swelling of the liver is absent. This may be detected by the method of palpation recommended by the speaker, in which the four fingers of the left hand are placed lightly over the edge of the liver, while the necessary pressure is given to them by the four fingers of the right hand, placed upon their dorsal surfaces. The sensitiveness of the finger-tips is much greater if there is no muscular contraction in the examining hand. Cholelithiasis affects the digestion very little. In cardialgia disturbances of digestion are common. Colic, due to gall-stones, is almost always accompanied by severe peritonitic symptoms. Cholelithiasis patients usually bear well even large amounts of hot Carlsbad water.

At the Medical Society of Leipzig, February 21st, BIRCH-HIRSCHFELD spoke of the beginning of pulmonary tuberculosis. He had examined the lungs of thirty-four persons, supposedly healthy, who died suddenly by accident, but in whom there was a beginning

tuberculosis. The widespread idea that phthisis begins in a caseous lobular pneumonia found no support in the results. An interstitial formation of tubercles was also the rare exception. In the vast majority of the cases the process began as a subepithelial one in a bronchus of middle size, the peribronchial tissus being secondarily affected. By this means the lumen of the bronchiole is obliterated and the portion of lung beyond becomes atelectatic. At this stage a cure is possible by encapsulation of the process and cicatrization of the distal pulmonary tissue. If the infiltrated part of the bronchus breaks down, as is probably most likely to follow in mixed infection, the tubercle bacilli with the reopening of the lumen of the bronchus may be scattered in both directions. Hence the occurrence of initial hemoptysis is an unfavorable symptom, as showing the breaking of the mucous membrane. The portion of the lung especially favorable for the lodging of the tubercle bacilli is the posterior portion of the apex and the adjoining subapical region. This is supplied by the posterior subapical branch of the bronchus and is a part of the lung which, at puberty, is most cramped in its growth, and is, therefore, often imperfect. As is well known the right lung is more apt to suffer than the left in primary tuberculosis. According to Von Hasse this portion of the lung moves almost none at all in respiration. In the consideration of prophylaxis and therapy of pulmonary tuberculosis a greater attention must be paid to asepsis of the inspired air and to pulmonary gymnastics than has as yet been done.

SOCIETY PROCEEDINGS.

THE GERMAN SURGICAL SOCIETY.

Twenty-eighth Annual Meeting, Held at Berlin, April 5 to 8, 1899.

[Specially Reported for the MEDICAL NEWS.]

FIRST DAY, APRIL 5TH.

THE Congress was opened by PROFESSOR HAHN, the President.

KOENIG of Berlin opened the medical discussion with a paper on "Foreign Bodies in Joints." He said that the trouble is almost always confined to the young and is more frequent in boys than girls. The knee- and elbow-joints are particularly affected. The exciting cause is usually traumatism to a joint, the seat of previous inflammation. The separated particle is part of the bone or cartilage eroded by the inflammatory process and loosened by the injury. The symptoms are usually manifested by violent pains in the performance of certain movements, and a subjective "crack" in the joint. These bodies are generally to be seen by the Röntgen-rays.

VON BERGMANN of Berlin said that in his experience the disease is not confined to youth but is comparatively frequent in old people, subjects of rheumatic or other joint diseases.

In a paper on "Surgery of the Brain" KOCHER of Berne described some successful operations for epilepsy. He recommends operation in cases following wounds or tumors, but thinks it not worth while to remove scars of the cortex when they are found. He does not return the trephined bone to its place for fear of subsequent intracranial pressure.

VON BERGMANN said that he usually returns the bone to its place and does not believe there is need to fear intracranial pressure. He reported the case of an epileptic girl with a congenital defect in the skull 14 cm. long by 8 cm. wide. He closed this opening by a plastic operation, taking a periosteal flap from a neighboring region. The epilepsy disappeared. He said that well-developed cases of epilepsy give little hope of cure by operation. He showed a man who was shot in the head in 1895. Epilepsy developed three months after, but though he operated he could not find the bullet. Two years later an abscess developed in the brain which was opened and healed. Subsequent to the second operation he had no attacks until lately. They have now appeared again, probably caused by the presence of the bullet.

GUSSENBAUER of Vienna said that he found the removal of cortical scars successful, and even when absolute and permanent cure did not follow there was at least relief for a long time.

KROENLEIN of Zurich spoke especially on wounds of the brain by small-caliber bullets. He related a case of attempted suicide in which the ball perforated the skull anteriorly and posteriorly, probably running along the base of the skull, with no symptoms following it. Another case of suicide was detailed in which the whole top of the skull was blown off and the entire unbroken cerebrum thrown out.

BARKER of London told of a suicidal attempt in a Russian. He shot himself twice in the mouth, then walked to the police station and announced it. The bullets were not disturbed until some time later when epilepsy began to develop. The bullets were located by the Röntgen-rays and removed. A temporary hemiplegia followed the operation but passed off. The epilepsy was cured.

VON BECK of Karlsrühe detailed eight cases of epilepsy in which operation was performed by Czerny or himself. He, too, has a dread of intracranial pressure and does not believe in replacing the trephined bone.

LANENSTEIN of Hamburg described a severe case of epilepsy in a man, aged twenty-five years, with innumerable attacks, paralysis, and beginning blindness. On operating no lesion was found, yet marked improvement followed. He considered the improvement due to a relief of pressure.

"Resection of the Spinal Column for Spondylitic Paralysis" was the title of a paper by TRENDELENBURG of Leipsic, who described eight cases, all with successful results. The operation consisted in raising a flap of skin over the prominence and chiselling through the lamina. The posterior bony wall of the canal was removed on both sides of the prominence to a point where the dura did not press against the bone. The paralysis became more marked temporarily after the operation and began to disappear only after five or six months. In acute stages of inflammation the operation is contraindicated.

TILLMANN of Griefswald spoke on "Concussion of the Brain." He described an apparatus constructed to imitate the conditions present in the skull, and by it was able to find the cause for concussions. He claimed that it is only a matter of physics and is due to the difference in the specific weights of the gray and white substance, the blood, and the surrounding fluid.

GUSSENBAUER said that Professor Tillmann in forming his theory had left out of consideration the important fact that the blood and the cerebral fluid are under different degrees of pressure, and gave as a cause for the throwing out of the brain in Krönlein's case the hydraulic pressure of the intermeningeal fluid which was suddenly and forcibly thrown underneath the brain.

"Bacteria and Wounds" was the title of a paper by FRIEDRICH of Leipsic. He said that the danger of infection from bacteria floating in the air is overestimated; that even when they fall into the wound there is little danger since it requires eight hours (about) for them to develop their reproductive functions, and that the reaction in the tissues taking place almost at once is always sufficient to overcome any few so contaminating the wound. He claimed bacteria gain entrance to the circulation only when under pressure.

SENGER of Erefeld spoke on disinfection of the skin. He concluded that it is practically impossible, and that operators are only safe when they use, for their hands, an antiseptic that does not lightly or soon lose its effect.

SCHNITZLER of Vienna claimed that micro-organisms existing latently in an individual increase their virulence under the action of a predisposing cause such as general debility.

"Noma and Its Etiology" was the title of the next paper, read by PERTHES of Leipsic. He claimed the cause to be a bacterium similar to the ray-fungus, but that a favorable soil is necessary for its action, and that on this account the disease cannot be given to other animals.

LOEWENHARDT of Breslau then read a paper on "Epidemic Aleppo Boils" and described some interesting cases of this disfiguring disease in participants of the late royal tour through Palestine. He exhibited wax models and microscopical preparations of the lesions. In many cases the disease is limited to the face, running a severe course with marked constitutional disturbance, yet invariably the ulcers heal spontaneously. The prognosis, therefore, is favorable.

SECOND DAY, APRIL 6TH.

HOFFA of Würzburg read a paper on "The Treatment of Congenital Dislocation of the Hip." He considered the two methods of reduction, namely by cutting down on the joint, and the bloodless method, which he described as the modern and, when possible, the preferable way. This latter is applicable only to about the age of ten. He reported a series of 127 cases, most of which were controlled by means of the Röntgen-rays. He exhibited a number of cured patients.

LORENZ of Vienna confirmed Hoffa as to the age up to which success might be hoped for by the bloodless method, and added that in cases of double congenital dislocation, two or three years might be taken off. The younger the patient the better the prognosis; after a certain age a stiff joint is the most to be hoped for. In the last three years he has performed the bloodless operation 360 times, in the last third of the cases the result being controlled by the Röntgen-rays. He advised strongly the bloodless method, and reiterated what Hoffa had said, that if it fails the other remains to be done anyhow.

DELHMANN of Breslau exhibited a skiagraph of a hip-joint on which the bloodless operation had been performed two years ago. There was a new bony outgrowth on the margin of the acetabulum, which it seemed would tend to hold the head of the femur better in place.

MIKULICZ of Breslau said that the Röntgen-rays have taught him that the anatomical result is not always as perfect as he previously thought it was. He considers all the ordinary methods of performing the bloodless operation of equal value and believes the non-success in some cases to be due, not to the method employed, but to the peculiarity of the case. In his opinion many of the dislocations take place during birth, and these are the easiest to reduce. In the precongenital conditions the difficulty lies usually in some peculiarity of the joint capsule. In the case of very young children a specially designed apparatus applied to the part often brings about the desired result. In other points he agreed with Hoffa and Lorenz.

Delhmann, Heusner, Höftmann, and Lange exhibited mechanical appliances to aid the reduction by the bloodless method, and to facilitate the application of the bandage.

NARATH of Utrecht reported six cases of fracture of the femur coming under his observation, caused by the operation.

BENDA of Berlin reported and detailed three cases of "General Miliary Tuberculosis in Association with Tuberculosis of Bone." KUETTNER of Tübingen reported cases of tubercular osteomyelitis of the long bones, on account of the rarity of this form in comparison with acute osteomyelitis. BUENGNER of Hanan spoke on tuberculosis of the symphysis pubis and showed the analogy between that and tubercular sacroiliac synchondrositis. The affection is more common in females than males, and is seen in adult life. It may attack one or both bones. The manner of spreading and the form that the purulent collection assumes has caused it more than once to be diagnosed as hernia. SUDECK of Hamburg considered the anatomy and etiology of coxa vara. The majority of cases he thinks due to frequently repeated slight traumatisms which take effect on young growing bone more easily than on fully developed bone. He also reported a traumatic case of bending of the neck of the femur.

In a paper, entitled "Surgery of the Gastro-intestinal Tract," KROENLEIN of Zurich reported a case of traumatic pyloric ulcer. The man, forty-eight years old, and up to this time perfectly healthy, received a violent blow over the stomach. For months he suffered with excruciating pains in the stomach and frequent attacks of vomiting. On account of the little nourishment he was able to take and the consequent loss of weight laparotomy was performed.

A large ulcer completely surrounding the pylorus was found. This end of the stomach was resected, the patient recovering fully. The speaker called attention to the importance of the case from its medico-legal accident aspect.

REHN of Frankfort a/M. reported a very singular case. He operated on a twenty-five-year-old servant-girl for severe peritonitis, in which it was necessary to resect part of the intestine. The operation was successful and the patient recovered and went about her work. Four months later she began to complain of pain in the abdomen and constipation; finally symptoms of complete intestinal obstruction came on and a second laparotomy was performed. Within the intestine causing the obstruction was a gauze compress. That it had been accidentally left behind at the first operation and had lain there for four months without a symptom was highly improbable, yet only one other explanation remained and that was that she had swallowed it! He also exhibited a preparation of an umbilical hernia, the contained intestine having in it a gall-stone.

THIRD DAY, APRIL 7TH.

LEXER of Berlin opened the proceedings by reading a paper on "Surgery of the Gastro-intestinal Tract," and showed sections of a persistent omphalo-mesenteric duct which he had found lined with a mucous membrane exactly similar to that at the pyloric end of the stomach.

KOENIG, JR., of Berlin, reported a case in which laparotomy had been performed three times, the first time for ulcer of the stomach with persistent hematemesis, the ulcer situated near the pyloric orifice being removed. The resulting cicatrix caused obstruction and a second laparotomy with gastro-intestinal anastomosis was performed. Obstructive symptoms again manifested themselves and the case coming under his care, he found on operation a stricture of the new pylorus. The stomach was once more resected and a new gastro-intestinal anastomosis performed. The patient, whom he exhibited, had completely recovered.

BRAUN of Göttingen reported a case of repeated laparotomy for perforation of a duodenal ulcer eleven months subsequent to a gastro-intestinal anastomosis. He considered the cause of the ulcer to be irritation due to overflow of the acid gastric juice. Hahn and Kausch of Berlin each reported a similar case. Von Beck of Karlsruhe reported a case of gastro-intestinal anastomosis by means of the Murphy button. Three months later violent epigastric pain developed and on opening the abdomen the button was found in exactly the same position in which it had previously been placed. He also reported a case of complete intestinal obstruction in which on laparotomy the cause was found to be a drinking-glass that had been forced high up into the rectum. Koerte of Berlin detailed a case of gastric ulcer of traumatic origin, similar to that reported by Krönlin. He also reported seven cases of intestinal obstruction by gall-stones. In the majority of them the diagnosis was determined before operation. Hadlich described a unique case of intestinal obstruction in which the intestine was found completely divided and ending in two blind pouches. The separation had taken place gradually and was the result of new-formed tissue bands. Gersuny of Vienna described peritoneal adhesions which are frequent on the sigmoid flexure and can lead to considerable disturbance. They are easily seen, though rarely found, because not sought for. They owe their origin probably to small hemorrhages into the serous membrane and it is not unlikely that similar adhesions may form on the appendix causing obliteration or stricture of its lumen.

GRASER of Erlangen spoke on acquired diverticula of the intestine. Numerous investigations, especially after injection of the intestinal vessels, lead him to conclude that they are the result of heart insufficiency. They are especially frequent on the sigmoid flexure, the loose areolar tissue of which predisposes to their formation. Persistence of these diverticula may lead to acute inflammation and the production of peritoneal adhesions. Hausemann of Berlin said he did not believe cardiac failure to be the cause of these diverticula. He believes their formation to be due to a congenital tendency in certain individuals, which predisposition is still inexplicable.

RENVERS of Berlin then read a paper on "Appendicitis," treating the affection from a clinical standpoint. He said that it might occur in the course of an ordinary intestinal catarrh and the patient recover without surgical interference. He believed it possible, therefore, to treat some cases medicinally and expectantly. Even suppurative conditions, he contended, might occasionally under very favorable circumstances cure spontaneously, though the prognosis without operation is unfavorable. Relapses indicate operation.

EWALD of Berlin described the masked chronic form. He said the symptoms are indefinite, oftentimes rather general, and only with difficulty can a proper diagnosis be made. Here it is especially difficult to decide on operation, the condition apparently standing on the boundary line between the clinician and the surgeon.

SONNENBURG of Berlin spoke on the necessity and time of operation. Chronic cases producing protracted ill-health, or acute cases in which the inflammatory symptoms do not disappear by the fifth day require operation. In suppurative cases two operations come into consideration: the opening and drawing of the pus-sac, an operawhich is not dangerous but leaving a possibility of return of the symptoms, or the complete removal of the appendix, which is more serious but is radical in its effect. He recommends the latter operation in cases in which all the arrangements for the operation have been perfected. The necessity for operation during intervals between attacks depends on the particular seriousness and conditions of individuals.

RIESE reported several cases in which patients developed disease of the kidney in the course of typhlitis, with a probable causal connection. DUHRRSEN of Berlin spoke on simultaneous disease of the appendix and the female pelvic organs.

GUSSENBAUER suggested that the name offered by Nothnagel be employed instead of appendicitis, namely, "scolicoiditis." ROTTER of Berlin said that Sonnenburg had expressed the opinion of the majority of German sur-

geons in his statement of the time for operation. But he did not believe that the removal of the appendix is indicated except in those cases in which its removal could be accomplished without too much difficulty. KUEMMELL of Hamburg said that he does not operate at all in light cases, in moderately severe cases only upon a secondary rise of temperature, and in general peritonitis always and immediately. He believes the pulse to be the best indicator of the condition. REHAR of Frankfort a/M. confirmed Sonnenberg on practically all points. KOERTE of Berlin remarked that Sonnenburg was not so quick with the knife as he formerly advised.

"Bowing of the Neck of the Femur" was the title of a paper by SPRENGEL, who presented two patients, one before, the other after operation, the condition in both being due to traumatism. He agreed with Kocher that the condition is due to a loosening of the epiphyseal cartilage, and exhibited skiagraphs and two preparations demonstrating this. He mentioned the medico-legal importance of differentiation between boring due to injury and that due to constitutional conditions. The number of operations for the conditions have been so far too small to draw conclusions from.

KOCHER of Berne mentioned the possibility of either a gradual or sudden boring. HENLE of Breslau reported favorable results in four cases in which the patients had been operated on in Miculicz's clinic.

BUNGE of Königsberg read a paper on "Treatment of Old Dislocations of the Elbow-joint." He advised against resection. He claimed excellent results in the Königsberg clinic without it. The joint is freely laid open and all soft tissues preventing reduction are cut through until reduction is possible. He has frequently found small pieces of bone broken off at the time of the dislocation to be the interfering objects; frequently, too, transverse fractures of the lower end of the humerus which had united obliquely. To prevent the formation of adhesions passive motion is instituted early and kept up a long time.

NEUBER of Kiel, in a paper on "Club-Foot," said that in cases in which the tendo-Achilles is to be cut he had given up the old procedure of subcutaneous division and now did it through an open wound. He thought he was better able to avoid secondary contraction.

WEHR of Lemberg read a paper on "Treatment of Heart-injuries," and detailed experiments on animals in which portions of the heart-wall were removed and the wound sutured. In the case of human beings he recommends a free opening of the chest by a skin and bone flap. Hemorrhage is to be controlled by the fingers.

FOURTH DAY—APRIL 8TH.

"Surgical Diseases of the Kidney" was the title of the first paper, read by WILMS of Leipsic. He spoke on mixed tumors of the kidney, but added little or nothing to our present knowledge. He explained their origin on Cohnheim's theory, but whether this misplaced tissue is capable of developing of its own accord, or requires something external to start it, he was unable to say. He mentioned the question of the mechanical theory of tumors, but no satisfactory conclusions were arrived at.

JORDEN of Heidelberg discussed the etiology of perinephritic suppuration. He said that it is usually the result of hemotogenous infection by pyogenic germs into the loose non-resistant tissue of that region, the microorganisms gaining entrance to the blood from a tonsillitis, a furuncle, or other seemingly innocent source. A frequent consequence of this perinephritic suppuration is suppuration in the kidney itself on account of the intimate connections between the vessels of the perinephritic tissue and kidney capsule. He reported a case of abscess of the kidney found on operation to be single. This was opened and drained, complete recovery following. During the course of the abscess the second kidney showed symptoms of nephritis, but as the patient recovered after operation these entirely disappeared. He also reported a somewhat similar case in which operation was not performed, and the abscess which was at first limited to the kidney infected the surrounding tissue. He, therefore, advised operation as soon as the diagnosis of abscess is made.

KROENLEIN of Zurich exhibited an interesting specimen of a cystic kidney removed from a pregnant woman without interfering with pregnancy. KUESTER of Marburg condemned the removal of a kidney for cystic degeneration because invariably after a shorter or longer period the disease attacks the other kidney. He thought it might be permissible to cut off a portion of the kidney but not more than that.

"Surgery of the Bladder" was the title of a paper by MODLINSKI of Moscow. He detailed his operation for complete removal of the bladder in cases of malignant growth, or when the bladder-wall is riddled with small tumors. He makes a new bladder from the lower part of the rectum.

VON MANEGOLDT of Dresden, in a paper on "Surgery of the Larynx," described his operation for laryngeal strictures and perforations caused by tubercular or syphilitic ulcers, and operative interference for tumors. To close a perforation or open up a stricture he transfers a piece of cartilage with its perichondrium from a costal cartilage. He detailed several successful cases.

BRAUN of Altona read a paper on "Skin-grafting." He said that after careful histological study of healed skin-grafts made after Krause's method, he found the principal constituents of the graft remaining, namely, the elastic and connective-tissue elements.

HENLE of Breslau confirmed Braun's findings from investigations on animals. VON ESMARCK of Kiel said that what has been called Krause's grafts had been described and used twenty years ago by Wolfe, an Englishman. KRAUSE contended that the transferrence of non-pediculated grafts had been carried out one hundred years ago by an Italian, but without much success. Now that he (Krause) instituted a successful method for preparing them, it was with justice that Mickulicz had designated them as Krause's grafts.

In a paper on "Skiagraphy of the Thorax" LEVY of Dorn insisted on the necessity of employing dry plates

twice poured in order to obtain good pictures; further, that the skiagraph should be taken during deep inspiration while the patient holds his breath.

Sultan of Göttingen claimed that the Murphy button is liable to cause perforation on account of its weight and that the absorbable buttons so far made are too rapidly absorbed. He presented a button in two parts, made of decalcified bone, joining together by a metal clasp and covered with rubber to prevent rapid absorption.

Hollaender of Berlin read a paper on "The Treatment of Lupus with Hot Air." He demonstrated some successful cases. He differentiated two forms of the disease, a rapid and a slow form.

During the afternoon session on the third day a ballot was cast for president for the next year. Professor von Bergmann of Berlin was elected.

REVIEWS.

International Clinics. A Quarterly of Clinical Lectures on Medicine, Surgery, etc., with specially prepared articles on Treatment and Drugs by professors and lecturers in the leading medical colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by Judson Daland, M.D., of Philadelphia; J. Mitchell Bruce, M.D., of London, and David W. Finlay of Aberdeen. Vol. IV., Series 8, 1899. Philadelphia: J. B. Lippincott Company.

This number of the "International Clinics" bears out very well its claim to an international character. We note clinics from Vienna, Berlin, Jena, Leipsic, Paris, London, Dundee, Aberdeen, Glasgow, and Edinburgh, as well as from various cities in this country. Dr. Thomas Oliver of Newcastle-on-Tyne (England) contributes an interesting clinic on scurvy and purpura. Despite general knowledge of its causation scurvy still sometimes develops even in patients of the better class, especially in children, and makes not infrequently a difficult diagnostic problem. Its relations to and differential diagnosis from purpura are very fully discussed. Dr. Oliver adopts Ralfe's explanation that scurvy is due to "some distinct alteration of the equilibrium between the inorganic and organic acids and bases in the blood whereby such neutral salts as chlorids become relatively increased at the expense of the alkaline salts or those alkaline salts become absolutely decreased."

From Professor Ziehen of Jena (Germany) there is a very suggestive clinic on the demonstration and significance of tendon-reflexes. He says, among other things, that "the absence of *any* tendon-reflex means a break in the nervous reflex arc on which it depends and hence means an organic lesion of some part of the nervous system." There is but one tendon-reflex in the arm according to him and this though usually called the triceps tendon-reflex is really an anconeus reflex. For reinforcement of tendon-reflexes where they seem to be absent Professor Ziehen suggests a cold bath before any prognosis or diagnosis is founded on their condition.

Professor Oppenheim of Berlin contributes a clinic on hemiplegia alternans inferior and hemiplegia alternans superior with two very striking illustrative cases. In the first case with deviation of the head to the right and eyes to the left (dissociate deviation of eyes and head) the lesion is in the upper (cephalic) portion of the pons. In the second case the left cerebral peduncle was affected.

Dr. A. Pearce Gould of London gives a very practical clinical account of his experience with Trendelenburg's method of treating varicose veins which he has applied in forty-three cases. The operation consists in the double ligature of the internal saphenous vein in the thigh. The procedure where Trendelenburg's sign is present is as satisfactory, Dr. Gould says, as it is simple of execution and free from ill effects.

Professor Rosenheim of Berlin, whose work on gastro-intestinal diseases is well known contributes a clinic on chronic constipation, in which he succeeds in making this threadbare subject interesting and almost says something new. The following quotation is suggestive of a certain iconoclastic spirit in the clinic: "Nothing is more absurd to my mind than the prejudice some physicians have as to the food their patients should not take; anything that disagrees with themselves their patients must not take; anything that tradition has set down as hard of digestion patients with gastro-intestinal trouble must avoid." Professor Rosenheim has had cases of indigestion with loss of appetite and constipation improve on sauerkraut, and he advocates the greatest dietetic liberty, each individual being a law unto himself.

The Pathology and Treatment of Sexual Impotence. By Victor G. Vecki, M.D. From the Author's Second German Edition, Revised and Rewritten. Philadelphia: W. B. Saunders, 1899.

According to the preface, this book produced in the original German "some commotion in the ranks of the young and old fogies, who were indignant that any one refused to worship their superannuated gods." The reason for this is, we suppose, certain statements under the physiology of the sexual act. Dr. Vecki does not accept the ordinary views as to the infrequency and insufficient vitality of spermatozoa after repeated coitus. A series of microscopic observations have shown him that in vigorous, healthy men coitus, after weeks of abstention from the act, is not accompanied by the ejaculation of seminal fluid teeming, as has been said, with abundant and lively spermatozoa, but that, on the contrary, they are comparatively rare, many show no manifestation of life, and others are by no means active. Repeated coitus is followed by an abundance of young, very active spermatozoa.

Observations on the fluid of seminal emissions, though often made within the hour after the event, rarely showed many spermatozoa, and the few present were, as a rule, not especially active. Spermatozoa seem to degenerate while in the seminal vesicles, and it is only after these are emptied that really active germinal particles are to be found in the seminal fluid. The importance of this

for certain forms of sterility is evident. This theory, too, gives a new biological significance to nocturnal emissions that occur normally in the continent. Nature is getting rid of germinal material that is no longer in proper condition to fulfil its function perfectly, not merely wasting, as has been taught, precious reproductive elements.

In the treatment of functional sexual impotence, Dr. Vecki has found suggestion and suspension of good service. The suspension treatment introduced by Matschutkowsky for tabetic patients is known frequently to have restored their sexual potency after it had disappeared for some time. Dr. Vecki has employed it with a certain success in simple impotence from other causes than spinal trouble. The suspension is made by means of the apparatus devised by Sayre for putting on the plaster jacket.

A TEXT-BOOK OF PATHOLOGY. By ALFRED STENGEL, M.D., Instructor in Clinical Medicine in the University of Pennsylvania. Eight hundred and forty-five pages, with 372 illustrations. Philadelphia: W. B. Saunders, 1899.

DR. STENGEL has succeeded in producing a work on pathology that will be found most helpful to the clinical pathologist. The author traverses the entire field, excepting the skin and special-sense organs. Part I. is devoted to general pathology, and here the etiology of disease, disorders of nutrition and metabolism, disturbances of the circulation of the blood, retrogressive processes, and inflammation and degeneration are taken up in succession, and given brief but clear and satisfactory consideration. The remaining chapters are devoted to progressive tissue changes, to bacteria, and diseases due to bacteria and parasites. The last two of these chapters are altogether the most satisfactory of this part of the book, and the author is to be congratulated on the clear and succinct way in which he has presented this subject.

The second part of the volume is concerned with special pathology, in which diseases of the various systems and tissues are taken up in succession. The chapters on diseases of the blood, the circulatory systems, and lymphatic tissues are particularly thorough, though brief, and up to date.

It may truthfully be said that this volume is everything that it pretends to be: A brief, trustworthy exposition of the practical side of pathology, put down in a straightforward way without redundancy of words or obscurity of thought. We congratulate the talented young author on the completion of such an enduring evidence of industry.

NOTES ON SURGERY FOR NURSES. By JOSEPH BELL, M.D., F.R.C.S., Edin., Consulting Surgeon to the Royal Infirmary. Fifth Edition. Edinburg: Oliver & Boyd, 1899.

IT is scarcely more than necessary to do more than call attention to the new edition of this excellent manual of instruction for nurses in the practice of surgery. The early appearance of the fifth so closely after the fourth edition, speaks for itself. The little book contains all that a nurse need know for the successful practice of surgical nursing, and excels in this respect that it does not contain a mass of useless material which is too frequently a part of hand-books written for trained nurses. An appendix on the relation of nurses to the general public has been added to the present edition.

THE TREATMENT OF WOUNDS; ITS PRINCIPLES AND PRACTICE, GENERAL AND SPECIAL. By L. S. PILCHER, A.M., M.D., Surgeon to the Methodist Episcopal Hospital in New York. Illustrated. New York: William Wood & Co., 1898.

THIS is a thoroughly revised and rewritten edition of a work published by the author some fifteen years ago. In the revision he has made those changes and amendments which time has rendered essential in an exposition on the healing of wounds—changes which affect methods rather than principles; for the elaboration of the simple surgical technic of the present day involved only a revision of the cumbersome technic of a decade and a half ago.

The present work is divided into two parts,—that dealing with the healing of wounds in general, including a discussion of asepsis and antisepsis and of the various dressings, and that which treats of the methods to secure the healing of wounds in special parts and organs of the body. Surgical emergencies are also considered in some detail and their treatment outlined. The author does not differ in any essential detail from the accepted teaching of the day in the development of which he has had an important part. The book may be commended for study to those who not only wish to read a work on operative surgery, but on the underlying principles of the surgical art as well.

This work is quite profusely illustrated, but some of the engravings are old and correspondingly crude.

THERAPEUTIC HINTS.

For Phalangeal Necrosis. — When, upon incision of a felon an area of necrotic bone is found it is advised by SPUSTER to introduce and apply to the bone a bit of gauze wet with the following solution:

℞ Tinct. iodi, Tinct. krameriæ, aa . . . *m.* lxxx
Iodi pur. . . . . gr. iss
Potassii iodi . . . . ʒ ss
Glycerini . . . . ʒ i.
M. Sig. External use.

A wet dressing is then applied. By the following day the improvement will be marked, and the process in the phalanx will soon subside.

Substitute for Salicylate of Soda.—To patients who suffer from unpleasant symptoms after taking this drug, such as headache, nausea, and ringing in the ears, a mixture of the salicylate of lithia and sulphate of quinin can be given with benefit. No symptoms of intolerance will appear:

R Lithii salicylatis . . . ʒ iiss
Quininæ sulphatis . . . ʒ ss-ʒ i.
M. Div. in pulv. No. XX. Sig. Four powders a day.—*Decoopman.*

ORIGINAL ARTICLES.

THE LIMITATIONS OF CONSERVATIVE SURGERY ON THE FEMALE GENITAL ORGANS.[1]

BY GEORGE BEN JOHNSTON, M.D.,
OF RICHMOND, VIRGINIA;
PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY IN THE MEDICAL COLLEGE OF VIRGINIA.

MUTILATION of human parts is abhorrent. Every organ has a right to exist until pathologic processes destroy its function, put it beyond repair, or constitute its presence a destroyer of health or a menace to life. Conservatism in pelvic surgery contemplates repair of diseased but redeemable structures, with abatement or removal of morbid conditions, restoration of function, relief of suffering and saving of life. The mere recovery from operation does not constitute success. The test should be relief of symptoms. Surgical discretion is a rare gift. Clean hands, operative skill and a good technic are common. Thus, unnecessary ablations continue because they can be safely accomplished and because unripe operations lack that discernment and judgment without which one is unable unerringly to decide when radical methods should give place to milder ones.

Conservatism must accomplish all that radicalism can, and more, in restoring the integrity of parts without sacrifice. Failing in this, or when extended beyond safe and legitimate bounds, conservatism may become rank radicalism. It is desirable, therefore, to fix its limits as accurately as possible, seeing how variable are the conditions involving its application. Every discreet surgeon enters the pelvic cavity prepared to alter his preconceived plan if unexpected conditions arise. In the selection of a final method in such cases as admit of conservatism he will be governed by (1) the age of the woman; (2) the nature of the malady; (3) the extent of the lesion and the existence of complex pathologic states; (4) the patient's physical condition; and (5) the probable necessity of a second grave operation.

Age of the Patient.—To a woman during the child-bearing period the preservation of the uterus and at least one tube and ovary (or even a portion of the latter) should be accomplished if it can be safely done. Nothing but positive necessity can justify the unsexing of such women. They constitute the peculiar charge of conservative pelvic surgery, and a greater latitude is allowed on account of the importance, for every reason, of their generative organs. Here such measures as carry with them the likelihood of failure and even some risk to life may be resorted to in their behalf. To one approaching the menopause the argument in favor of conservatism is less forcible, but even here it is most desirable to avoid the sudden cessation of the menstrual flow, if it can be avoided. To one past the menopause the ovary alone seems (on account of its internal secretion) to be important, save for the minor consideration of the mechanical advantage of preserving the uterus.

The Nature of the Malady.—It is obvious that no attempt at conservatism should be made in cases of malignant neoplasms, tuberculosis, or suppurative diseases of the tubes or ovaries due to the more malignant pyogenic organisms.

The Extent of the Lesion and the Existence of Complex Pathological States.—Even when most extensive involvement of an organ exists there may remain a small unaffected portion whose preservation would be desirable, but the difficulties connected with identifying and isolating such a healthy portion, in the presence of extensive disease, are great and often determine in favor of radical procedure. Not infrequently upon exploration of the pelvis it is found that the condition for which operation was undertaken is so complicated by other pathological states that the mode of procedure originally contemplated must be abandoned for more radical measures. Thus uterine fibroids may give rise to conditions of the tubes and ovaries necessitating their removal. In such a case little would be gained by saving, at the expense of a tedious operation, a uterus which would at best be a functionless organ.

The Patient's Physical Condition.—Conservative measures, as a rule, involve more extensive manipulations than do radical procedures, hence the latter must at times be adopted where the local conditions would suggest conservatism but where the patient would be unable to stand the prolonged anesthesia and the shock incident to tedious operative measures.

The last of the above considerations—the possible necessity of a second operation—can best be illustrated by one of several cases which have recently come under my observation, and the like of which is constantly met with by pelvic surgeons.

Mrs. X., aged forty-seven years, mother of four

[1] Read at the Centennial Anniversary Celebration of the Medical and Chirurgical Faculty of Maryland, April 26, 1899.

children. After birth of the last, sixteen years ago, without any acute illness she became a confirmed invalid, unable to undergo any exertion and confined to bed most of the time, her longest walk being from her bed to a lounge. Four years ago she consulted a surgeon who discovered a lacerated cervix and perineum, which he repaired. Her symptoms not improving, one year later she again placed herself under his care and was treated for six months with local applications, but without benefit. Two years ago she consulted another surgeon who performed a laparotomy and removed a cyst of one ovary, a hematoma of the other, six myomata (by six separate incisions), and performed a suspension of the uterus.

These conservative measures not affording relief, I was called to the country to see her last August. Upon examination the uterus was found fixed by the operation of suspension, the ovaries and tubes matted together by dense adhesions, and all of the pelvic organs exceedingly painful. I advised radical operation and this was consented to. Upon exploration of the pelvis, after abdominal section, the omentum for about the space of a hand's breath was found adherent along the line of the previous abdominal incision. The uterus was firmly suspended by a strong false ligament and adherent to both the bladder and rectum. It contained three fibroids. Tubes and ovaries were bound down by dense adhesions. The right ovary, from which the cyst had been previously removed, contained several cysts of various sizes, and the left contained a hematoma the size of a hickory nut. Both tubes were the seat of follicular hydrosalpinx. I proceeded to break up the adhesions and performed an oophoro-salpingo-hysterectomy.

This patient made a perfectly satisfactory recovery. On the seventh day after operation she volunteered the statement that she realized that the cause of her illness had been removed and that she felt she was cured. At the end of the third week she was out of bed and one week later she was able to walk better than at any time since the beginning of her illness, sixteen years ago. She is now cured.

In considering the desirability of conservatism in any given case, account must be taken of the relative importance of ovaries, uterus, and tubes. Of these structures the ovary occupies the first place, for the reason that its removal renders uterus and tubes functionless, while, on the other hand, removal of the latter leaves the ovary robbed of its prime function but serving other useful ends. Next in importance stands the uterus, but only, so far as we know, when at least a portion of an ovary can also be preserved. Efforts to preserve tubes alone are not desirable, since these structures are functionless in the absence of ovaries and uterus.

Though only within very recent years has it been conclusively demonstrated that the internal secretion of the ovary is of great importance in the female economy, and strongly suggested (though not proved) that the function of menstruation is more than a monthly inconvenience, still not even these most convincing arguments against the unnecessary removal of the organs concerned are stronger pleas for conservatism than is the moral question involved and the often lamentable mental condition following the unsexing of a woman. This latter consideration is more powerful than ordinarily considered, for women are naturally loth to express themselves freely in matters bearing on sexual relations.

Admitting the wisdom of and justifying the attempts made to defend and restore every pelvic structure presumably capable of regeneration, I may lay down some rules which will fix the limits of our efforts to restore to function and health in the common maladies coming to our notice.

The Ovary. Hematoma.—When large, painful and producing reflex nervous symptoms and occupying the bulk of a single ovary, removal of the organ is required.

Graafian Cysts.—If these be numerous and apparently involve the entire ovary ablation is to be practised. Their removal by dissection means many cavities to be closed by much suture material, the possibility of blood clots, supplying foci for infection, and, later on, painful cicatrices and no amelioration of the symptoms produced by the cysts.

Abscess.—If large and centrally located its removal intact is demanded. Its incision and drainage mean possible direct infection and peritonitis, the probable invasion of the parts sought to be saved with recurrence, a failure to rescue any useful portion of the gland. The urgency of complete removal is enhanced in the presence of systemic infection.

Dermoids.—Unless both ovaries are implicated, dermoids should be treated by complete removal. Even when both organs are affected it may be safer to be radical, inasmuch as these tumors are prone to destroy the organ and likewise to set up an inveterate form of local peritonitis with the formation of painful and dangerous adhesions, which inflammation is only cured by ridding the patient of the diseased parts.

The Tubes.—The uterine tubes should be amputated in (1) extra-uterine pregnancy, whether ruptured or unruptured, if the tube is much enlarged and altered; (2) in kinks and strictures if these are numerous, decided, and accompanied by dense adhesions, because having established by operation the perviousness of the lumen under such conditions, it cannot by any means at our command be maintained and may be followed by either hydro- or pyosalpinx; (3) in hydrosalpinx of either the follicular or flowing varieties, for the reason that the naked eye cannot define the limits of the former, and the latter will yield to no other treatment. In simple hydrosal-

pinx, if the tube is greatly distended, its walls much thinned and in the presence of adhesions; (4) in pyosalpinx in every instance where the infection is other than gonococcal and in these if the abscess cavity is large and the tube walls much impaired. Indeed, attempt to save a suppurating tube is rarely justifiable.

The Uterus.—I shall speak only of the application of operative measures to fibroids. Myomectomy was a great advance in the treatment of fibroids. It seems horrible to sacrifice an otherwise normal uterus on account of the presence of removable fibroids, yet unnecessary hysterectomies continue. Perhaps the most difficult problem in determining between conservatism and radicalism presents itself when the surgeon comes to deal with fibroids. There are two conditions, which, if existing, lead to a speedy conclusion. The presence of a limited number of only subserous tumors at once indicates the removal of the tumors only. On the other hand, if the tumors are deep-seated, or embrace the bulk of the uterus, or if they are very large, nothing is to be accomplished by hystero-myomectomy.

The doubtful cases are those in which the tumors are interstitial and small. Even here, when few and well defined, myomectomy may be undertaken with reasonable hope of success. The difficulty of distinguishing *every* nodule is very great, and where the number is large the numerous and deep incisions required for their extirpation render the operation for their complete removal tedious, dangerous and uncertain. I therefore contend that in every case at all doubtful, *except when they occur in young women*, hysterectomy is preferable to incomplete myomectomy. Overlooking and leaving a single nodule may destroy the permanent effect of the operation and require a second of a more thorough kind. The presence of complications, such as the coexistence of pathologic conditions in two or more organs, usually places the case beyond conservatism, as may the existence of disease in remote organs.

While conservatism properly applied is both wise and humane, to be tolerated it must accomplish what it seeks to do. In its application, the soundest judgment, the ripest experience and consummate skill must be present. The difficulties which encompass it are great:

1. It often entails prolonged effort, thus increasing the liability to shock.

2. Extensive manipulations which denude the peritoneum, thereby increasing the risk of infection and setting up post-operative adhesions and, maybe, intestinal obstruction. By dealing with open pus-cavities, grave danger of infection occurs. It often requires many wounds, which mean much hemorrhage, numerous cavities to be repaired, foreign suture material left behind to accomplish these repairs, the possible formation of blood-clots, which furnish foci for infection, a likelihood of secondary hemorrhage, perhaps painful scars and almost certainly, when many points have been subjected to operation, post-operative adhesions.

3. The bruising of tissues incident to harsh methods of controlling hemorrhage, thereby impairing the recuperative powers and thus endangering the success of the undertaking.

4. Finally, the ever-present prospect of a second operation.

THE USE OF FORMALDEHYD GAS AS A DISINFECTANT FOR DWELLINGS, VEHICLES, AND HOUSEHOLD GOODS.[1]

BY WILLIAM H. PARK, M.D.,
OF NEW YORK;
ASSISTANT-DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES OF THE DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK; ADJUNCT PROFESSOR OF BACTERIOLOGY AND HYGIENE IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

FORMALDEHYD is now such a well known substance that it will be necessary for the purposes of this paper to only review in the briefest way its properties before discussing its practical use as a gaseous disinfectant. At ordinary temperatures it is a gas having the chemical formula CH_2O, and possessed of an extremely pungent odor, very irritating to the mucous membranes of the eyes and nose. It is an unstable compound, for its molecules tend to combine and produce other substances having utterly different chemical and physical properties. Thus three molecules combining together form trioxymethelene or paraform, a white crystalline body almost inert, but which by heat is decomposed again into formaldehyd gas.

Formaldehyd is usually manufactured in large quantities from methyl alcohol by allowing its vapor mixed with air to come in contact with platinum or other substances heated to redness. For disinfection purposes, however, this has not proven either a very practical or a very economical method, and it is now almost universally obtained from a thirty-five to forty-per-cent. solution in water, called commercially formalin, or from its solid form, trioxymethelene.

Formaldehyd has the important property of uniting with nitrogenous products of decay thus forming true chemical compounds which are odorless and sterile. It is thus a true deodorizer. It has also a peculiar action upon albumen which it converts into an insoluble and indecomposible substance. It is from this power of combining chemically with the

[1] Read at the Ninety-third Annual Meeting of the New York State Medical Society, held at Albany, January 31, and February 1 and 2, 1899.

albumenoids forming the protoplasm of bacteria that formaldehyd is supposed to derive its destructive power against bacteria. Formaldehyd is comparatively non-toxic to the higher forms of animal life and considerable quantities of it have been inspired without fatal effect.

If we consider now the practical application of formaldehyd gas for purposes of disinfection we find that its destructive action on micro-organisms depends upon a number of factors, the chief of which are its concentration in the atmosphere surrounding the bacteria, the length of time of the contact, the existing temperature, the accompanying moisture, and the nature of the organism.

The necessary concentration of the gas in the atmosphere to kill the micro-organisms varies with each species, for some resist chemical agents much more than others; and also with the freedom of access of the gas to the bacteria, for if they are under cover or within fabrics a greater amount of gas must be generated than if they are freely exposed. For purely surface disinfection when the less resistant bacteria or other organisms are to be destroyed six to ten ounces of formalin of full strength to 1000 cubic feet suffices. For the destruction of the more resistant but non-spore bearing forms, such as typhoid fever or tubercle bacilli, at least three times the smaller amount of gas specified above should be generated. The gas penetrates through fabrics with difficulty, and to pass through heavy goods the concentration of the gas must be increased tenfold and moderate heat added.

The Value of Moisture. — At first it was thought by many that formaldehyd gas acted more effectually in a dry atmosphere, but further investigation has proven that although it does destroy bacteria with the amount of moisture usually present in the air yet it acts much more powerfully and certainly when additional moisture is present and best when present up to the point of saturation.

A fairly high temperature, but one still below that which would injure delicate fabrics, increases not only the activity of formaldehyd gas, but also its penetrative power, and for heavy goods some heat is essential. The production of a partial vacuum in the chambers containing the goods before the introduction of the formaldehyd gas still further assists its penetration.

The length of exposure necessary for disinfection depends upon the nature of the bacteria producing the disease for which disinfection is carried out, the penetration required to gain access to the bacteria, the concentration of the gas used, the amount of moisture in the air, the temperature of the air and the size and shape of the room. For surface disinfection in rooms when as much as twelve ounces of formalin is used for each 1000 cubic feet five-hours' exposure is amply sufficient, most bacteria being killed within the first half hour. For the destruction of micro-organisms protected by even a layer of thin covering, double the formalin and double the time of exposure should be allowed, and even then the destruction of many species of the more resistant non-spore bearing bacteria cannot be counted upon under the conditions met with in ordinary rooms. If absolutely complete disinfection is demanded, where penetration is required, the goods must be placed in special chambers where moderate heat can be added and all leakage of gas prevented.

Various forms of apparatus can be properly employed to liberate formaldehyd gas for purposes of disinfection. As each of these is lauded by its maker as the best, it may be of interest to give the results obtained by us from those in most common use.

1. *From Wood Alcohol.*—A number of lamps have been devised, all very much on the same principle, though varying somewhat in mechanical construction, which bring about the incomplete oxidation of methyl alcohol by passing the vapors mixed with air over incandescent metal. Although disinfection can be carried out by the best of these lamps, in our experience none of them is satisfactory or economical. They are amply sufficient for deodorization.

2. Commercial formalin is mixed with double its volume of water and placed in a suitable apparatus and boiled. The addition of water is for the purpose of diluting the formaldehyd and thus preventing its change into paraform, and also to add moisture to the air and aid the activity of the formaldehyd.

3. *From Formochloral by the Trillat System.*— This system consists in heating, under three atmospheres, a solution of formaldehyd gas in water mixed with thirty per cent. of calcium chlorid, known as "formochloral," to a temperature of 135° C. (255° F.). It is claimed for this method of producing the gas from formochloral that the polymerization of the formaldehyd is prevented, which would otherwise take place if a solution of formaldehyd were evaporated under ordinary conditions, and that thereby the whole of the formaldehyd is obtained in the gaseous state. The addition of any neutral salt aids the process, it is said, but calcium chlorid is the best. The formalin used for making the mixture should be free from methyl alcohol, otherwise, according to Trillat, this will combine with an equal quantity of formaldehyd, to produce methylal, a body having no disinfecting power, and thus cause

a loss of formaldehyd. The results with this apparatus have been satisfactory, but not more so than by other methods. The apparatus has the disadvantage of being expensive and heavy.

4. *From Formalin by the New York Sanitary Construction Company's System.*—This method consists in heating the ordinary commercial formalin to a temperature of 1000° F. or more in an incandescent copper coil or chamber and allowing the vapors to pass off freely. It is claimed for this method, in which the solution of formaldehyd is slowly introduced into an incandescent tube kept at a very high temperature, that the degree of heat is supplied necessary to break up the polymerized products formed, and thus a loss of formaldehyd is prevented. A further action of the intense heat in the copper tube on the solution is to convert the methyl alcohol contained in commercial formalin into formaldehyd gas by partial oxidation, thereby preventing the formation of methylal and increasing the amount of formaldehyd.

The apparatus consists of a closed receiver of copper holding about a gallon, a coil of copper pipe attached at one end to the bottom of the receiver, and, like the preceding apparatus and the one to be described later made by Lentz, at the other by means of a suitable connection (rubber tube with gutta-percha or metallic endpiece) with the room or apartment to be disinfected; and a heating lamp or Bunsen burner. In operation the desired quantity of formalin is placed in the receiver and the receiver is closed. The lamp is lighted and the coil brought to a red heat. The valve is then opened and the solution contained in the receiver is allowed to pass down and into the coil in a fine stream. Upon coming in contact with the heated metal, the formaldehyd solution is instantly decomposed and the gas liberated. The apparatus is fitted with a handle by which it may be carried, and weighs about 15 pounds, when filled. The receiver need not be refilled until the contents are exhausted. Six to twelve ounces of formalin are sufficient to disinfect 1000 cubic feet of space. The results with this apparatus, so far as our observation goes, have been as good as those obtained by any other means. The apparatus is rather expensive and slow in operation and is somewhat liable to get out of order.

5. *From Trioxymethylene or Paraform by Schering's System.*—This system consists in heating the solid polymer of formaldehyd, trioxymethylene, in a lamp specially contructed for the purpose by the Chemische Fabrik auf Actien in Berlin. The trioxymethylene for convenience is used in the form of compressed tablets or pastils. Each pastil contains the equivalent of 100 per cent. of formaldehyd gas, according to the manufacturers, and weighs one gram.

The mode of using the apparatus is very simple. The disinfector is placed upon a sheet of iron on the floor of the room to be disinfected. From 100 to 200 pastiles can be evaporated at a time in the apparatus. For the production of greater quantities of formaldehyd vapors, several of these outfits must be used together. The lamp is filled with alcohol, about four times as many cubic centimeters of the alcohol being employed as there are pastils to be evaporated. The wicks should project but little above the necks of the burners, or the apparatus may get too hot and ignite the pastils. The vessel is charged with formalin pastils, and the disinfector placed over the lighted spirit lamp. The lamp is allowed to burn out in the closed room. Seventy-five pastils are considered to be sufficient for the disinfection of 1000 cubic feet of space. Lately a small steam boiler has been added to the apparatus for the purpose of furnishing sufficient moisture with the gas. The results obtained by us in superficial disinfection when from 150 to 200 pastils have been used to each 1000 cubic feet have been good. The great advantage of the method is in its small initial cost and in the ease of employing the apparatus and the avoidance of the danger of deterioration which is present to some extent in formalin.

6. *From Formalin to Which Glycerin Has Been Added.*—A very convenient apparatus of somewhat greater cost than that of Schering is prepared by Charles Lentz and Sons of Philadelphia. To the formalin is added 10 per cent. of glycerin and the mixture is simply boiled in a suitable copper vessel, the steam and formaldehyd gas passing off by a tube similar to that used by the Sanitary Construction Company and Trillat Systems. In our experiments, which have not been very extensive, the addition of the glycerin has not seemed to add much to the effectiveness of the formalin.

With a slightly greater amount of formalin than that used in the high temperature autoclave and heated-tube methods the results seem to be equally as good. The apparatus is very easy to use, rapid in action and not liable to get out of order.

CONCLUSIONS.

As a result of the investigations undertaken in the Department of Health Laboratories on the use of formaldehyd as a disinfectant, and a consideration of the work of others the conclusions reached may be summarized as follows:

1. *Disinfection of Infected Dwellings.*—Exposed surfaces of walls, carpets, hangings, etc., in rooms may be superficially disinfected by means of formal-

dehyd gas, all apertures being tightly closed, when employed in the proportion of 12 ounces of formalin or 5 of paraform to each 1000 cubic feet, the time of exposure to be not less than four hours, and the temperature of the apartment not below 52° F. Under these conditions non-spore bearing bacteria are entirely or almost entirely destroyed when freely exposed to the action of the gas. Spore-bearing bacteria, such as anthrax bacilli, are not thus generally destroyed. But these latter are of such rare occurrence that in house-disinfection they may practically be disregarded, and if present, special measures can be taken to destroy them.

The penetrative power of formaldehyd gas at ordinary room temperature, even when used in double the strength necessary for surface disinfection, is extremely limited. Articles, therefore, such as bedding, carpets, upholstery, clothing, and the like, should when possible be subjected to steam, hot air, or formaldehyd disinfection in special chambers constructed for the purpose. If not, they must be thoroughly exposed on all sides. Diphtheria bacilli are fortunately among the most easily destroyed bacteria.

2. Disinfection of Bedding, Carpets, Upholstery, etc.—Bedding, carpets, clothing, etc., which would be injured by steam may be disinfected by means of formaldehyd gas in the ordinary steam disinfecting chamber, the latter to be provided with a heating and vacuum apparatus and special apparatus for generating and applying the gas. The gas should be used in the proportion of not less then tenfold the amount used for surface disinfection, the time of exposure to be not less than eight hours, and the temperature of the chamber not below 110° F.

In order to insure complete sterilization of the articles they should be placed so as to allow of a free circulation of the gas around them; that is, in the case of bedding, clothing, etc., these should either be spread out on perforated wire shelves or loosely suspended in the chamber. The aid of a partial vacuum facilitates the operation. Upholstered furniture and other articles requiring much space should be placed in a large chamber, or better, in a room which can be heated to the required temperature. The most delicate fabrics, furs, leather, and other articles which are injured by steam, hot air at 230° F., or other disinfectants, are unaffected by formaldehyd.

3. Disinfection of Books.—Books may be satisfactorily disinfected by means of formaldehyd gas in the ordinary steam chamber as above described, and under the same conditions of volume of gas, temperature, and time of exposure. The books should be arranged to stand as widely open as possible upon perforated wire shelves set about one or one and one-half feet apart in the chamber. A chamber having a capacity of 200 to 250 cubic feet would thus afford accommodation for about sixty books at a time. Books cannot be satisfactorily disinfected by formaldehyd gas in houses and libraries, or anywhere except in special chambers constructed for the purpose, because the conditions required for their disinfection cannot otherwise be complied with. The bindings, illustrations, and print of books are in no way affected by the action of formaldehyd gas.

4. Disinfection of Carriages, etc..—Carriages, ambulances, cars, etc., can be easily disinfected by having built a small, tight, brick building, in which they can be enclosed and surrounded with formaldehyd gas. Such a building is used for disinfecting ambulances in New York City.

5. Advantages of Formaldehyd Gas over Sulphur Dioxid for the Disinfection of Dwellings.—Formaldehyd gas is superior to sulphur dioxid as a disinfectant for dwellings, first, because it is more effective in its action; second, because it is less injurious in its effects on household goods; third, because, when necessary, it can easily be supplied from a generator placed outside of the room and watched by an attendant, thus avoiding, in some cases, danger of fire. Apart from the cost of the apparatus and the greater time involved formaldehyd gas generated from commercial formalin is not much more expensive than sulphur dioxid, *viz.*, 20 cents to $1 per 1000 cubic feet against 10 cents with sulphur.

Formaldehyd gas is the best disinfectant at present known for the surface disinfection of infected dwellings. For heavy goods it is far inferior in penetrative power to steam and dry heat at 230° F., but for the disinfection of fine wearing-apparel, furs, leather, upholstery, books, and the like, which are injured by great heat, it is, when properly employed, better adapted than any other disinfectant now known.

The experimental work upon which these conclusions are largely founded was done in conjunction with Dr. Arthur A. Guerard, and Dr. Robert J. Wilson, Assistant Bacteriologists, New York City Health Department.

OTOLOGY; ITS RELATION TO GENERAL MEDICINE.

By G. GRIFFIN LEWIS, M.D.,
of Syracuse, N. Y.

The family physician, as a rule, is the first to be consulted in incipient ear trouble, and as a great many of the cases require immediate attention it behooves him to be somewhat familiar with the aural

symptoms; and to know how to meet them. The busy practitioner has little time to devote to the study of otology; in fact, as a rule, there is no branch of his profession which he dislikes or neglects more. This is a fact much to be regretted, for there probably is no class of diseases which, if neglected or improperly treated, will result so disastrously to the patient as those of the ear. This statement is emphasized by the vast number of patients with preventable deafness who present themselves to the specialist with a bad purulent discharge from the ears which has existed since childhood.

The great majority of ear diseases have their incipiency in infancy and early childhood and many of them are closely connected with certain general diseases, especially the acute exanthemata, and for this reason they are all the more liable to be overlooked both by the medical attendant and the parents who are mostly concerned about the general affection without any suspicions of a local one. In the consideration of my subject I shall endeavor to be as brief as possible in my reference to those aural affections which the general practitioner is called upon to treat, and will omit entirely any reference to the treatment of those diseases which require the attention of the aurist.

Hereditary tendency, age, occupation, and habits, are strong factors in the causation of all forms of ear disease, but the occurrence of the large majority of such diseases, especially during infancy and childhood, can be ascribed to some one of the infectious or febrile diseases. Many a case of permanently impaired hearing may be traced to the failure of the medical attendant or parents to recognize the existence of ear trouble during a siege of acute febrile disease. At such a time, when one's resources are taxed to the utmost in combating the systemic trouble, he is not apt to direct special attention to the condition of the ear and, ordinarily, it is not until convalescence begins that the aural symptoms are noticed. During the course of any of the acute febrile or infectious diseases frequent and thorough inspection should be made of the ear, the nose, throat, and nasopharynx, even though there may be no aural symptoms complained of by the patient. The latter organs are the starting-points of many cases of incurable deafness, the mucous membrane of these being involved in nearly all the acute infectious and febrile diseases. The extension of this catarrhal condition to the Eustachian tubes, unless properly treated, will almost invariably cause middle-ear trouble. The rhinitis associated with scarlet fever or measles has an especially virulent effect upon the middle ear and particularly so when either one is accompanied by nasopharyngeal diphtheria. The latter disease may extend through the Eustachian tubes into the tympanum, causing ulceration and destruction of tissue. In some cases, when the micro-organisms invade the labyrinth, severe and even total deafness may result. Paralysis of the palate is also of frequent occurrence and this interferes with the proper ventilation of the tympanum, sooner or later producing a hyperemia and catarrh of the middle ear. Ear disease may also originate during an attack of smallpox, chickenpox, whooping-cough, or mumps.

Of the acute febrile diseases which enter into the etiology of aural affections influenza ranks first, being accompanied in many cases by an intense aural hyperemia entirely disproportionate to the conditions usually seen. Deafness to a certain degree is very common during an attack of typhoid fever and, unless it receives early and proper treatment, is quite likely to be permanent. In pneumonia and bronchitis middle-ear trouble may result from the passage of the infectious germ through the blood current and its lodgment in the tympanic mucous membranes, or by the condensation of air in the middle-ear brought about by excessive coughing. The syphilitic, rheumatic, tubercular, and strumous cachexiæ, predispose to and unfavorably influence diseases of the ear. Syphilis induces catarrhal swelling of the mucous membrane of the middle ear and the auditory nerve becomes secondarily affected. Aural diseases of rheumatic origin are usually chronic or have a tendency to occur frequently. Oft times they are accompanied by no general rheumatic symptoms until weeks or months after the aural lesion has become manifest. The almost incurable progressive deafness accompanied by tinnitus aurium is most frequently of a rheumatic nature. In tuberculosis the most common ear trouble is a chronic, persistent, and destructive suppuration of the tympanum. Lesions of the ear are as common with kidney trouble as lesions of the eye. In Bright's disease a change in the tension of the labyrinth may be brought about by interference with the general venous circulation. Eczema of the auricle and furuncles of the external auditory canal are of common occurrence with diabetic patients. Intracranial diseases, such as brain fever, meningitis, cerebral tumors, abscesses, or hemorrhages, may diminish or destroy the hearing by direct damage to the auditory nerve or by causing anemia, congestion, or hemorrhage within the labyrinth. Cerebrospinal meningitis ranks first as a factor in the etiology of acquired deaf-mutism. Insanity seems to claim an almost exclusive companionship to hematoma of the auricle and the appearance of the latter makes the prognosis of the former very grave.

Whenever disease of any nature is accompanied

by nose and throat complications one should not forget the possibility of ear trouble arising and should at once secure freedom of respiration and perfect cleanliness of the nasal mucous membrane.

That certain drugs exert a specific influence upon the organ of hearing is a well-known fact. These changes constitute anemia or hyperemia of the labyrinth or tympanum, which nearly always passes off after a time but if the drug influence is pushed to any great extent structural changes are brought about in the labyrinth and more or less permanent deafness results. Quinin is particularly liable to affect the ear, and the habit of prescribing large doses of it to break up a cold in the head cannot be too strongly condemned. During an attack of coryza there is almost always more or less congestion of the middle ear which is greatly increased by the administration of quinin. Salicin and salicylic acid, with its salts, stand next to quinin in their influence upon the ears. Alcohol and tobacco used to excess may, through their influence upon the mucous membrane of the nose and throat, exert a deleterious effect upon the ear. This is especially the case when tobacco is taken in the form of a snuff or when the smoke is exhaled through the nose.

Certain pathologic conditions, especially in females of a neurotic or hysteric type, may produce alterations of function within the organ of hearing; thus otalgia is frequently the result of oral irritation caused by cutting, crowding, or caries of the teeth, inflammation of the gums, ill-fitting plates, etc. Nasal douches or syringes, either anterior or posterior, should never be used, as they are liable to force fluid through the Eustachian tubes into the tympanum. This fact has been particularly impressed upon the mind of the writer by a very severe attack of acute otitis media brought upon himself by the use of a certain douche which of all douches is considered the least harmful. Snuffs, either powder or liquid, should for the same reason be condemned.

Regardless of the fact that in nine-tenths of all aural diseases the pathologic process is on the inner side of the impervious drum membrane, "ear-drops" are being constantly prescribed for all forms of ear disease. It would be a difficult task to enumerate all the irritating substances that are being inserted, with all solemnity, into the outer ear passages; in fact, it sometimes seems that there are but few fluids which have not been used in this way. Perhaps the most commonly used domestic remedy is sweet oil and laudanum. If warm when inserted the heat for a few moments may slightly ease the pain, but the alcohol of the laudanum is irritating to the membrane, while the oil becomes rancid, irritates, and serves as a culture for aspergillus. The same is true of all greasy substances so frequently put into the ear. Glycerin, which is one of them, robs the mucous membrane of all of its moisture and excites inflammation.

Perhaps the most common form of treatment adopted by the majority of practitioners for nearly all forms of ear disease is the use of the Politzer bag. All honor to Dr. Adam Politzer for giving to the profession this very easy and valuable method of inflating the middle ear, but I am of the opinion that if he could have foreseen the manner in which it was destined to be misused and the immense amount of harm that would result from its misuse, he would have hesitated long before making his discovery known. In many cases Politzeration is a dangerous procedure; for instance, in unilateral deafness, think of the wisdom of subjecting the well ear to such treatment, for it is impossible by this method to confine the air-pressure to one side. Many a case of deafness is produced or made worse by the stretching of the drum membrane due to over Politzeration. Rupture of the tympanic membrane is sometimes the result of too forcible a compression of the air-bag. This is particularly liable to happen when a patient is recovering from an attack of acute otitis media and the perforation in the membrane has just healed over. Attacks of mastoiditis may result from Politzeration during an attack of acute otitis media before perforation of the membrane and when the middle ear is partially filled with pus. Inflammation of the tympanum may also be produced by a mucopurulent discharge being forced through the Eustachian tubes from the nose. The same objections contraindicate Valsalva's method of inflation, though in a less degree.

Syringing out the external auditory canal in proper cases is a valuable procedure, but, unless done properly, may do considerable harm. The canal should be straightened by drawing the auricle upward and backward, and the current of water should be directed against the various sides of the canal, thus preventing too much force from being exerted against the tympanic membrane. The water should be of a proper temperature, and the canal should be thoroughly dried afterward. The prolonged presence of water in the canal, even at the temperature of the body, is liable to cause trouble. This fact is emphasized by the vast increase in the number of aural cases during the swimming season. For the same reason the practice of prescribing the syringe for the patient to use or have used at his own home certainly seems unwise. Blisters and poultices, over or in the region of the ear, are certainly of limited usefulness and considerable harmful potency. Poultices or hot water used to excess dur-

ing an acute inflammation of the middle ear soften the membrana tympani and hasten its rupture. If used after perforation they favor the growth of granulations, and have been known to cause facial paralysis.

Having so far dwelt principally upon the causes of ear disease, I will briefly refer to the remote affections and symptoms which are secondary to or dependent upon such diseases. Considering the rich supply of nerves in the external and middle ears, and the free anastomosis of these nerves, it is not to be wondered at that pathologic changes within these parts may give rise to remote symptoms. Thus, through the trigeminal and pneumogastric nerves, branches of which supply the external and middle ears, the stomach, lungs, or diaphragm may suffer from reflex irritation brought about by hardened cerumen, foreign bodies, etc., in the external auditory canal. Ear disease, by reflex irritation of the pneumogastric nerve through the medium of the trigeminal, is capable of establishing and maintaining an irritable state of the digestive apparatus. Cases of cough arising from aural reflex are not uncommon. They are usually spasmodic and persistent in character, so whenever a cough of that nature does not respond to the usual treatment an examination of the ear will often reveal the cause and the removal of the irritation will effect a cure. Hiccough is frequently dependent upon aural irritation. The writer has in his care at the present time a patient with catarrh of the Eustachian tubes, who, on several occasions has been awakened from sleep by a very severe and rapid hiccough, which is relieved by Valsalva's method of inflating the middle ear.

Eye symptoms, such as nystagmus, strabismus, paralysis of the superior oblique muscle, or contraction or dilatation of the pupil may also result from aural irritation. Brain complications resulting from neglected ear disease are quite common. Abscesses of the brain, meningitis, phlebitis, sinus thrombosis, epilepsy, facial paralysis, and vertigo are some of the possible results of neglected purulent inflammation of the middle ear and the etiology in many such cases is first discovered in the post-mortem room. Statistics show that more than one-half of all brain abscesses are caused by ear disease and that not far from two thousand deaths occur annually in Great Britain and four thousand in the United States from this result. Bergman asserts that the history of otorrhea, past and present, together with persistent sleeplessness and a temperature remaining steadily at about 99° F. are sufficient indications for opening the cranial cavity for the purpose of exploration. Irritation in the external or middle ear or any condition which will produce an alteration of intralabyrinthine pressure may cause vertigo which is often mistaken for stomachic vertigo or the so-called bilious epilepsy. Woakes of London claims that all vertigo is essentially auditory in its location and that when it exists where there has been no prior ear disease it is due to reflex impressions.

Earache is a very common complaint, especially in children, and although the majority of the subjects recover without the aid of a physician the prompt and proper treatment in many instances is of vital importance to the patient. A large percentage of the permanently deaf may trace the beginning of their infirmity to an earache, which, being regarded by their parents or guardians as the merest trifle, was consequently allowed to go without the proper medical attendance. Pain in the ears nearly always means inflammation, and especially is this true if the hearing is impaired. In most instances it is caused by an acute congestion within the middle ear but may be due to some abnormal condition in the external auditory canal, such, for instance, as furuncles, impacted cerumen, and foreign substances. In exceptional cases it may be reflex from a decayed tooth or a hypertrophied tonsil. In any case the first thing to do is to locate the seat of trouble, which may be done by a thorough inspection of the parts, ascertaining whether or not there is any redness, bulging, or retraction of the drum membrane, any soreness in the external auditory canal, or any tenderness accompanying pressure upon the tragus or over the mastoid bone. Thorough inspection of the nose, throat, and teeth should also be made. If the hearing is not interfered with the pain in all probability is of a neuralgic origin.

The proper treatment to pursue in these cases of otalgia, when not of a neuralgic origin, is first, the application of leeches in front of the tragus. In very young children a small blister in the same location may be substituted unless the case is a severe one. Heat applied over the ear, or a hot boracic or carbolic solution instilled into the ear, will often act like magic in lessening the pain and aborting the congestion but care should be exercised not to continue the hot instillations longer than really necessary as too much moist heat will soften the tissues and make them an easier prey to the inflammatory process. Inflation of the tympanic cavity is advisable in many cases when there has been no formation of pus in the cavity. Sometimes the instillation of a warm solution of cocain, or atropin and cocain mixed, will allay the pain and abort the attack. Should these remedies fail to relieve paracentesis of the drum membrane should be performed at the

most dependent part. This procedure will immediately relieve the pain, prevent spontaneous rupture, and favor the evacuation of pus, which otherwise, through one of its several means of communication, might produce septic inflammation of the brain or mastoid cells. The puncture, under favorable circumstances, will heal up within a few days, with a complete restoration of hearing, while a spontaneous rupture would take much longer or may never heal at all, and in either case usually leaves the hearing more or less impaired. Following the puncture or rupture of the drum membrane is a mucous discharge, which if neglected or improperly treated will become purulent and have an offensive odor. The treatment of such discharges comprises cleanliness, drainage, and the removal of diseased tissue, this being accomplished by properly syringing out the ear with a warm antiseptic solution followed by the instillation of a saturated solution of boracic acid and an occasional and gentle inflation of the tympanum. If this treatment does not effect a cure all granulations should be removed and astringent solutions used. Insoluble powders should not be blown into the ear as they may occlude the perforation and cause mastoid trouble, and for the same reason the patient should not be allowed to wear cotton in the ear.

Foreign bodies in the external auditory canal, in the majority of cases, are best removed by the syringe, care being taken to direct the current of water against the walls of the canal instead of against the substance itself. Inspection should also be made after each syringeful has been injected in order to ascertain the effect. A camel's-hair brush dipped in glue and brought in contact with the foreign substance and allowed to dry will often be of service in its extraction. Instruments should not be used until these means have failed, as, especially in the hands of the inexperienced, they may do great damage to the drum membrane and to the walls of the canal. In many cases more damage is done by the attempts at extraction than by the presence of the foreign body itself. Several cases have been reported in which the substance has been shoved through the drum membrane into the tympanum, producing middle-ear inflammation followed be cerebral disease and death. Unless the attending physician has the proper means at hand for removing the foreign substance, and is quite sure of success it is better for the patient to leave it alone in spite of the urgent demands of the parents or friends until such a time as the proper means and skill can be secured. Foreign bodies in some cases may remain in the ear for an almost indefinite period without exciting any local irritation and sometimes even without the patient's knowledge. Children often place foreign bodies in their ears and say nothing about it for fear of punishment, and they may not be discovered for months afterward. It is always well in such cases to examine both ears. Not long age a sister from one of our charitable institutions brought a little girl to me with a stone crowded into the external auditory canal of the right ear. Upon inquiry as to how it got there, the answer was that another little girl threw it in. Knowing such a thing to be impossible, and suspecting that it had been inserted by the patient herself, I asked her if she had anything in the other ear, to which she replied "No." Inspection of the left ear, however, revealed the presence of a substance which proved to be a wad of paper literally covered with hardened cerumen. It must have been in there at least several months. Insects frequently get into the external auditory canal and often cause intense pain. The best method to pursue in such cases is first to pour in some warm sweet oil, and then after a few moments syringe it out.

Impacted cerumen does not occur in ears otherwise healthy but in the majority of cases is the consequence of a chronic, non-suppurative inflammation of the middle ear, or of some irritation transmitted by the trigeminal nerve to the tympanum and auditory canal, therefore, it is not sufficient in these cases simply to remove the cerumen but to look for the cause of it. Impacted cerumen may be very easily removed by the syringe, the surgeon being particular after its removal to thoroughly dry the canal and inflate the tympanum. If it is too hard to remove in this way it may first be softened with a solution of bicarbonate of soda.

CLINICAL MEMORANDUM.

OBSTINATE HEMATURIA DURING PREGNANCY.[1]

By WILLIAM BYRD YOUNG, M.D.,
OF BON AIR, TENN.;
PROFESSOR OF GYNECOLOGICAL AND ABDOMINAL SURGERY IN THE SEWANEE MEDICAL COLLEGE, UNIVERSITY OF THE SOUTH.

Mrs. H., aged twenty years, weight 157 pounds. Early in January, when she was about three-months pregnant, I prescribed without seeing her, elixir of buchu, juniper, and acetate of potash for painful and frequent micturition, which gave relief. Up to this time she had always been in good health. About three weeks ago, when she was possibly six-months pregnant, I was called in to see her on account of her having noticed blood in her urine. At first the percentage was very small. She was also suffering from pain in her back, and violent headache. Thinking possibly the hemorrhage was uter-

[1]Read before the White County (Tenn.) Medical Society.

ine I made a vaginal examination, but found no blood coming from this canal. However, to make the diagnosis doubly sure I sterilized a soft rubber catheter, and drew off the urine, which contained a large percentage of fluid blood. The urine was loaded with albumin. After having applied heat and nitric acid it could scarcely be poured from the test-tube. Supposing this was due to the blood present in the urine I allowed a specimen to stand twenty-four hours and then tested the supernatant fluid, which showed a very high percentage of albumin. During two or three days she did not pass one pint per day. Her feet, hands, and face were but little swollen. I prescribed 15 grains of gallic acid, and 15 drops of tincture of iron, every four hours, alternating the two. For the headache I prescribed bromid of potash, 20 grains, every hour. Hot baths twice a day were ordered, and she was told to drink all the water she could. Her diet was restricted to milk and soup.

All the symptoms improved during the next forty-eight hours, with the exception of the hematuria, which grew steadily worse until at least two-thirds of the fluid she passed from the bladder was blood. The color of the fluid grew darker from the first until at its worst it looked exactly like freshly drawn venous blood. The reaction of the urine was neutral. The specific gravity for several days ranged between 1018 and 1024. At the end of about forty-eight hours her headache became very violent, and she grew exceedingly restless. The next time I visited her she was on the verge of an eclamptic convulsion. I at once gave her a hypodermic injection of morphin, and one hour later, one drop of croton-oil in a capsule. Within a very short time her bowels began to move, and in the next ten hours they acted perhaps ten or fifteen times. The discharges were free and watery. This seemed to relieve her and she obtained a few hours of refreshing sleep. The gallic acid and iron were continued night and day up to the afternoon of the third day without affecting the hematuria in the least. As it was increasing, and the patient growing anemic, with a pulse of 110, and a temperature of 99° F., I decided to discontinue the gallic acid, and gave her 10 drops of fluid extract of ergot every four hours, alternating with the iron, which I had gradually increased until she was taking 25 drops at each dose. She never vomited any of the medicine.

During the afternoon and night of the third day there passed from the bowels considerable fluid, very much like that coming from the bladder, only it appeared to be about the consistency of thin sorghum. The following morning I asked for a consultation, and Dr. Snodgrass of Sparta was telephoned for. After examining the patient he agreed with me and we continued the same treatment up to Wednesday the sixth day, when I ordered the ergot to be given every six hours instead of every four, because the patient stated that she had not felt the child move in the womb since Sunday. The urine was no better until Thursday morning, when it began to clear up, and by Friday morning it looked almost normal, and did not contain so much albumin. Thursday morning I discontinued the ergot entirely, but continued the iron. Saturday morning the urine began to look bloody again, and remained so until Monday morning, when the patient miscarried. The quantity of urine did not increase much until after the delivery. The delivery was normal, the placenta and membranes coming away very nicely in about twenty minutes. The child was dead. It was very poor, the skin was flabby, wrinkled, and distinctly discolored, being of a dark pink. The cord was black, but no clots were in it. The fluid that escaped on severing the cord was dark and closely resembled the discharge from the bladder. From the hour of delivery every symptom began to grow better except the pulse. This remained at about 100 or 115 for several days.

There are several points of considerable interest in connection with this case. First, did the ergot kill the child? Second, was the hematuria relieved during Thursday, Friday, and a part of Saturday by the ergot, or was the cessation due to the death of the child? third, did we do right in giving the ergot? In the language of the gamester, we had to play for what was in sight, because no authority on the subject could we find. After searching diligently through all the journals and text-books at my command I failed to find one word on the subject, except the following report of a case under the head of "hemophilia," in the "American System of Obstetrics:" "Large, well-formed pallid woman, twenty-three years old. Three abortions, with profuse hemorrhage, within the first three years of her marriage. During the fourth pregnancy frequent severe nose-bleeding; in the fourth month *continuous hematuria*, then epistaxis. Premature labor at the beginning of the eighth month. Death from anemia one month later." In the MEDICAL NEWS of May 4, 1889, Barton Cook Hirst, M.D., gives a short report of a case of hematuria in pregnancy. This is the only mention of the subject I could find in the journals. Dr. Hirst's case was in some respects similar to mine. The woman, twenty-six years old, was six-months pregnant. The hematuria appeared suddenly, but did not increase nor become alarming, although it continued until the woman was confined, after which the urine began to clear up, and on the third day the blood had quite disappeared. There was no report of symptoms of eclampsia, albumin, no scarcity of urine, no persistent headache. The author says: "The explanation of this case, as of the majority in which bloody urine appears during pregnancy, is very likely to be found in bleeding hemorrhoids of the bladder, produced by the pressure of the large gravid womb on the pelvic veins." The only thing he says in regard to the treatment in such cases is the following: "The treatment in such a case can be little more than expectant until pregnancy is terminated, unless, in a rare event, the quantity of blood is alarming." There was poor consolation in such reports to men under the trying ordeal through which Dr. Snodgrass and I were passing.

The Consumption of Coffee.—The average annual consumption of coffee in the United States during the decade 1870 to 1880 was 792,000,000 pounds; in the next decade it was 1,326,000,000. In 1898 it was 1,580,000,000. The enormous increase in the use of this stimulant is another indication of the high tension life we are leading nowadays.

NEW INSTRUMENT.

AN IMPROVED URETHROSCOPE.[1]

BY FERD. C. VALENTINE, M.D.,
OF NEW YORK;
PROFESSOR OF GENITO-URINARY DISEASES IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE.

IT is too late in the scientific day to urge need of urethroscopy upon a learned society like this. Arguments in favor of making the urethra as accessible to sight and to operation as the external surface of the body would be as superfluous as diatribes against remedies advertised to "cure all urethral discharges." The question of urethroscopy now reduces itself mainly to the choice of instruments.

Three forms of urethroscope are in use. The simplest, of which the Klotz tube is the best type, requires a coordination between the head-mirror and the tube, which is difficult and requires much practice. Moreover, the reflected light cannot be as clear at the distal end of the

FIG. 1. FIG. 2. FIG. 3.

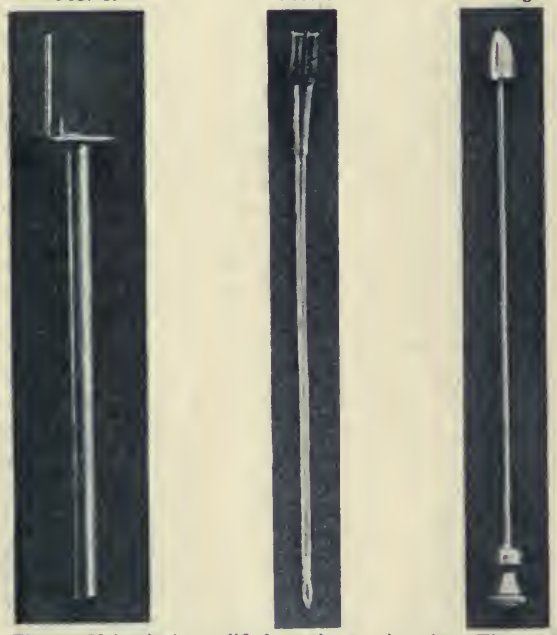

Fig. 1. Valentine's modified urethroscopic tube. The small spur on the disc is for attachment of the light-carrier, the large spur for that of the megaloscope.

tube as it is at the visual end. Here a glare obscures vision. obliging the operator to look through a disturbing zone of more intense light, into one, six inches beyond, not by any means as clearly illuminated. The wonder is that Klotz has been able to do so much and such good scientific work with this instrument. The second class of urethral illuminators are those that use light projected directly into the urethra. The best of these is indisputably the Otis urethroscope. But it is a costly and somesome complicated instrument, for whose use one must needs have as much skill as its talented inventor. In the third class, the Nitze-Oberlaender urethroscope hitherto stood alone. A little incandescent wire is carried into the depths of the urethra, bringing the source of illumination almost directly into contact with the sites to be examined. The advantage is too manifest for discussion; it is simply in obedience to the physical law that requires intensity of illumination for accuracy of vision. The objections to this apparatus are, first, its cumbersomeness, entailed by the continuous current of water required to keep the lamp cool. Secondly, the minute lamp readily burns out, and entails difficulty for its replacement, especially if it occurs in the midst of an examination. Thirdly, the size and weight of the apparatus, as well as its fragility, demand that it be kept stationary, necessitating a separate room for the purpose of urethroscopy. Fourthly, even if the canal be excedingly large, the light must be removed from the tube to swab excess of secretion from the urethra and to make direct applications to diseased spots. Fifth, the apparatus is expensive, almost prohibitive to the majority of beginning practitioners.

The urethroscope I have the privilege of showing overcomes all the objections cited. Previous to describing it I may be allowed a moment to do an act of justice regarding its origin. While Dr. Henry Koch of Rochester and I were fellow-students in Berlin, I often discussed with him my thought of a sufficiently small but encapsu-

FIG. 4.

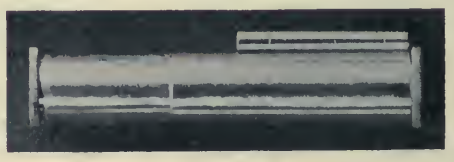

Fig. 4. Valentine's megaloscopic attachment for the urethroscope. Magnifies sixteen times.

lated electric light that would make urethroscopy easy and available to even novices in genito urinary work. I failed innumerable times to get manufacturers and workmen to make the light small enough for the purpose. Dr. Koch deserves the credit of having found and encouraged Mr. W. C. Preston of the Electro-Surgical Instrument Co. of Rochester to carry out my ideas on the subject. Under my directions the instrument has grown to its present conditions.

The apparatus consists of a small box containing four dry cells. These suffice for at least 350 deliberately performed, thorough urethroscopies. The price of a new set of cells is one dollar, making the cost of each urethroscopy less than one-third of a cent. The sources of electric light for other urethroscopes are either dip-batteries or accumulators. When they are exhausted from use or non-use, they require at least a day for recharging. The battery of my instrument can be replaced within five minutes. The tubes I use are similar to Kollman's modification of the Oberlaender tubes. Their burnished ends make it possible to examine the urethra from behind forward and from the front backward without giving the patient the slightest pain. The disc at the visual end of the tube is larger than those of other urethroscopes. A

[1] Presented at a meeting of the New York County Medical Society, held April 24, 1899.

small spur serves for attachment of the light-carrier, a large spur to hold a megaloscope, without which many minute urethral lesions would escape unaided vision. The light is encapsulated, making it possible to uninterruptedly examine all parts of the urethra and to perform all intra-urethral operations under the guidance of the eye. With a view to ascertaining whether under any circumstance the light might produce discomfort by its heat I have left it in the urethra as long as forty minutes. Not even the most sensitive patients complained of the slightest disturbance.

The entire apparatus is too simple to require any further description. A mere glance at its parts shows the purpose of each. I shall now have the honor of proving my assertions, through my assistants Dr. W. H. Prioleau and Dr. T. M. Townsend, who will show you the urethras of several patients as plainly as if the urinary channel were an open plain upon the hand or any other part of the surface of the body.

THERAPEUTIC NOTES.

The Subcutaneous Use of Mercury in Syphilis.—Lederman (*Therapeut. Vade-mecum Haut. und Geschlechts Krankh.*, Berlin, 1898) advises the subcutaneous method of mercurial treatment in syphilis in preference to the percutaneous, or method by inunction, on the grounds that it can be controlled with greater exactness, being entirely in the hands of the physician. It is more certain and rapid in its effect. Sublimate forms the most practicable soluble salt of mercury in use; injections of 1 c.c. (*m.* xv) of the 1–1000 solution daily for forty days will usually effect a cure. Larger doses can be given at longer intervals. One c.c. of the 2½-per-cent. solution twice a week for sixteen injections is also used, but the author does not recommend the use of five-per-cent. solutions. The more concentrated solutions are placed deeply within the muscles. In the majority of cases the injection is said to be painless, and it causes only a slight infiltration which slowly disappears. Neisser and his pupils use the insoluble salicylate of mercury in ten-per-cent. suspension in liquid paraffin. Cure is effected by eight ½-gram (gr. viii) injections at three-day intervals, followed, if well-borne, by six 1-gram injections at six-day intervals, 10 or 12 grams of the suspension being used altogether. Neisser uses a needle of special design which he allows to stand in aseptic liquid paraffin, and cleans the site selected for the injection with 1–1000 bichlorid or two-per-cent. lysol solution.

Drugs in Diabetes Mellitus. — This affection (Hare, *Practical Therapeutics*) is the result of disordered function, and is not a disease *per se*, but is a symptom of several disease processes. Therefore, we vary the use of drugs according to the patient's condition, the quantity of sugar in his urine, and the cause of his diabetes. If there is rheumatism we must use a combination of potash and salicylic acid, using of the latter from 10 to 15 grains three times a day. For gouty subjects the iodids and colchicum are combined—and if this combination proves ineffectual, arsenic with lithium citrate or carbonate must be employed. Arsenic alone is used in all forms of diabetes, and should be given in fairly large, constantly repeated doses. Opium is used oftener than any other drug; we cannot explain the manner in which it acts. Morphin, grs. ¼–½, three times a day, or codein, from 1 to 5 grains, three times a day, are the alkaloids to be employed, of which large ascending doses must be given. Some patients take 7 grains of morphin, or from 20 to 30 grains of codein, three times a day. These alkaloids are given best one hour after meals. Of course patients who take such doses must be carefully watched. Jambul is an uncertain remedy. The dose is from 5 to 30 grains, once to thrice daily, and gradually increased until 1 ounce has been given in twenty-four hours. If cachexia comes on, iron, strychnin, bitter tonics, and the lactophosphates of lime and sodium are to be used to support the nervous and circulatory systems. Plethora, produced by high living and little exercise, must be treated by restrictive diet, moderate exercise, and purgation to relieve engorgement. Thirst should be allayed by the use of acidulated or non-purgative alkaline waters. In all cases the well-established rules as to diet must be observed.

For Pannus. — Ohlemann ("Ocular Therapeutics," 1899) recommends Guthrie's ointment in the treatment of trachomatous pannus:

℞	Argenti nitratis	gr. xii
	Liquoris plumbi subacetatis . .	gtt. viij
	Petrolati	ʒ ii.

He advises also that if corneal ulcers complicate healing they should be scraped with a sharp spoon, and further treated with an iodoform ointment of the following formula:

℞	Iodoformi	gr. viiss
	Vaselini	ʒ iiss.

The Treatment of Acute Gout. — The limb should be placed horizontally, or in a position slightly elevated above the level of the body (Luff, in "Gout, Its Pathology and Treatment"). By means of a cradle the bed clothes should be raised from the affected part about which should be arranged warms packs of cotton wool saturated with a lotion, composed of sodium carbonate, ʒ iij; belladonna liniment, ʒ ij; tincture of opium, ʒ j, and water up to ʒ viij. A small portion of this lotion is mixed with an equal part of hot water, and this mixture is then poured on the wool arranged around the joint. The whole is then covered with oiled silk, and remains unchanged for eight hours. An initial dose of from 30 to 40 minims of wine of colchicum is followed by a mixture of from 10 to 20 minims of the wine with from 40 to 60 grains of citrate of potash, which mixture is given three times a day. Or the colchicum may be given in the citrate of potash as an effervescing mixture, using 30 grains of potassium bicarbonate to 20 grains of citric acid in each dose. The colchicum must not be pushed to the degree of producing extreme depression. After the inflammation subsides the doses of this drug are diminished until it is dispensed with. From 3 to 4 grains of blue mass are given on the first night, followed the next morning by

Epsom salts. Salines, containing sodium, should be avoided, for they diminish the solubility of sodium biurate. We must aim to relieve portal congestion rather than to produce powerful purgation. As anodynes, chloral, sulfonal, or trional, may be used. Or a full dose of extract of hyoscyamus, with blue pill may be given at night. Opium or morphin should be avoided. As to diet: For the first day or two, milk, with arrowroot or bread, or milk puddings made with rice, sago, or tapioca, or tea made with boiling milk instead of water, or weak tea with cold toast, thinly buttered, may be taken. The drinking of hot or cold water, or a mineral water (free from sodium salts) should be encouraged. The milk diet should be continued until the acute inflammation has subsided, when the patient may return to a more liberal diet, being careful not to take anything indigestible. Alcohol is contraindicated, except when there is a weak heart and a feeble irregular pulse. Beef teas and meat extracts and essences must be avoided at all times. They irritate the kidneys and interfere with the elimination of uric acid.

The Best Method of Prescribing Potassium Iodid.—The best method of administering iodid is doubtless in the form of an aqueous solution, in which one drop represents, approximately, one grain of the salt. To prescribe the two, ounce for ounce, results in a solution measuring eleven fluid drams, and one drop of this necessarily contains considerbly less than one grain of the iodid. To overcome this PROFESSOR HYNSON, quoted in *The Bulletin of Pharmacy*, makes the following suggestion: Dissolve 480 grains of the salt in 5½ drams of hot water, and then make up the solution to 8 drams with water. This always results in a solution representing one grain in each minim, and, approximately, in each drop. — *American Therapeutist*.

Rheumatic Joints Rubbed with Ice. — EWART (*La Semaine Med.*, April 12, 1899) says that if a rheumatic joint is not relieved of its pain by hot applications and the internal use of salicylates, that it should be rubbed with a piece of ice wrapped in flannel. This can be done by the patient himself. An almost immediate relief of the pain, and a delicious sense of coolness in the joint follows the application. It can be repeated two or three times a day if necessary. The cold friction also exerts a favorable action on the course of the disease.

Ecthol in the Treatment of Erysipelas.—DR. ROBERT C. KENNER reports twenty-two cases of erysipelas successfully treated by ecthol. This drug contains the active principles of *Echinacæ angustifolia* and *Thyja occidentalis*. The dose for an adult is a teaspoonful every two to four hours. In connection with this internal therapeusis he emphasizes the importance of abundant nourishing food and local treatment. For the latter he advises a solution of potassium acetate, 15 grains to the ounce of water, applied every hour or two.

The Soda Treatment of Diabetic Coma.—HERZOG (*Berl. klin. Wochenschr.*, April 3, 1899) places great confidence in the early administration of large doses of soda in diabetic coma. If possible the soda should be given before the coma develops. By attention to the reaction of the urine to ferric chlorid, and by watching for an increase in the amount of ammoniates, or of oxalates, the approach of danger may be known. Even when the symptoms of coma come on, it is still worth while to begin treatment with the soda, using from 3 to 10 drams of the bicarbonate daily. Herzog also advocates the subcutaneous use of either normal salt solution, or of a solution of bicarbonate of soda, 3 to 5 per cent., the injections to be frequently repeated. An excessive use of the soda may cause diarrhea, symptoms of heart failure, and bloody urine, but the experience of Naunyn, no less than that of the writer, shows that it may clear up an attack of coma, either temporarily, or in some instances, permanently.

Dionin as a Cure for Morphinism.—FROMME (*Berl. klin. Wochenschr.*, April 3, 1899) has found that dionin, a hydrochlorate of morphin ethyl ether, is serviceable as a substitute for morphin in those who are in the habit of using that alkaloid. There have been numerous attempts to find some drug which would take the place of morphin, and prove less harmful than it is to the user. Opium, bromids, and various narcotics have been tried with indifferent success. Cocain has been found to be far worse than the drug which it has been used to supercede. Codein has perhaps given more satisfaction than any one remedy, but it has its limitations. The plan of treatment advocated is to withdraw the morphin gradually, though not too slowly, testing the reaction of the patient meanwhile, by varying doses of dionin, and also of inert solutions, such as soda phosphate, or chlorid, in order to see how much reliance can be placed on the patient's description of the effect of the dionin, as well as to determine his susceptibility to large or small doses. When the amount of morphin taken daily has been reduced to ½ or ⅓ of a grain, it is well to stop it altogether, and substitute the dionin for it. One grain of the latter may be sufficient to quiet the unpleasant symptoms due to the stoppage of the morphin, or it may require four or five times that amount, according to the circumstances. Experience has shown that it is better to give an injection without waiting too long, as quiet will follow a small dose given in the beginning of the restlessness, while a much larger dose may be without effect if one waits until the storm is fully developed. Dionin is readily soluble in water (1 to 10), and particularly in warm water, so that it is fitted for subcutaneous use. It is manufactured by Merck.

Eucain in General Surgery.—Howard Lilienthal (*Annals of Surgery*, May, 1899) advocates the use of local anesthesia, using by preference eucain, even in such operations as castration, colotomy, and colecystotomy. He reports cases illustrating its use in all of these operations. The patient suffered no pain and in some instances assisted in the operation.

COLD APPLICATIONS AND ICE-MASSAGE.

Esmarch's treatise on "The Use of Cold in Surgery" brought this therapeutic measure prominently into notice nearly forty years ago. Among the many additions to the practical side of medicine and surgery which must be attributed to Esmarch no one was nearer to the heart of the old veteran than the application of cold as an alterative and counterirritant in inflammatory processes as well as an allayer of pain. More recently the direct application of ice and of ice-massage in appropriate cases has attracted no little attention. In an article in the London *Lancet*, April 8, 1899, Dr. Wm. Ewart, Senior Physician to St. George's Hospital in London details some very satisfactory results from the direct application of ice by rubbing. His first experience with it was in a case of extremely painful rheumatoid arthritis of the hip, in which hot applications had utterly failed to relieve the pain. Hot air-baths had been tried and abandoned as ineffectual, and applications of dry heat in the form of hot sand-bags gave only temporary relief, which was followed by increased pain. The circumstance that the pain became worse after the hot applications suggested the use of ice. The treatment consisted in gently rubbing the hip, the gluteal region, and the painful knee with a small block of ice held firmly in the hand by means of a piece of flannel. The relief was immediate. Pain ceased very soon and after only a few minutes the patient's features relaxed and "he began to smile gratefully."

Dr. Ewart has found ice-massage of equally good service in other cases of rheumatoid arthritis and in pemphigus complicated by painful joint affections. He has proven its value as a means of relieving the severe pleuritic pain which commonly accompanies acute pneumonia of the base. In this last affection the relief of pain was immediate and the application was welcomed as a comfort. Relief is not always permanent, so that in special cases the frequency of the employment of the ice-massage will have to be arranged to suit the individual case. This method of employing ice seems promising and the approach of hot weather makes the use of ice cold applications generally much easier because there does not exist in the minds of patients and their friends during the summer so much prejudice and apprehension as to the catching of cold and production of chills.

TRENDELENBURG'S OPERATION FOR THE CURE OF VARICOSE VEINS.

There has always been, among general practitioners, a certain feeling of distrust of surgical intervention for the relief of varicose veins. Thrombosis and embolism have, after operation, occasionally thrust their unwelcome presence into the progress of the case to mar the convalescence and discourage the operation. In some cases the deep veins as well as the superficial set are dilated and tortuous so that seemingly successful operations often fail to bring relief. Finally the veins that enlarge in their functional endeavor to compensate for those that have been obliterated by the surgeon take on, at times, a varicose dilatation on the slightest indiscretion so that the old condition with all its annoyance recurs despite even extensive surgical measures.

Some eight years ago Professor Trendelenburg of Leipzig described a simple operation for certain forms of varicose veins of the leg which he had found very successful. As is well known in practically all cases of varicose veins of the leg if the patient be placed in a recumbent position and the leg

elevated the dilated veins at once collapse to more or less their normal size. Professor Trendelenburg pointed out that if pressure be then made over the internal saphenous vein in the thigh the patient may resume the upright position and the veins fail to refill to anywhere near the same degree as before; as soon as the pressure is removed the varices become once more distended. In all cases in which this condition of affairs obtains, where Trendelenburg's sign, as it is called, exists, Trendelenburg counseled operative intervention. His method consists in excising, between double ligatures, about an inch of the internal saphenous vein in the thigh. The rationalé of the procedure is to guard the varicosed veins of the leg from the pressure of the column of blood in the venous trunks above the point of entrance of the saphenous into the femoral vein.

So many operative methods had been tried for varices that the new suggestion was not received with any great enthusiasm. It has, however, been gradually working its way into clinical practice in a good many quarters. Dr. A. Pearce Gould, Surgeon to the Middlesex Hospital, England, details, in the January number of *International Clinics*, some most satisfactory results with the operation, and in the *Lancet* for April sums up his experience with the operation in fifty cases. In all of them marked relief from pain and discomfort followed the operation. The usual process of cure was a more or less rapid shrinking of the affected veins, in some cases to quite their natural size, in others to just short of that. In some of the cases thrombosis of the vein below the ligature occurred with subsequent obliteration, but in none of them did thrombosis occur above the upper ligature.

Patients were kept in bed only a week, that is, until thorough healing of the small incision necessary in the operation had taken place. In the annoyance caused the patient, the risks of infection involved, and the subsequent scarring, the operation is much more satisfactory than the more extensive or multiple excisions sometimes employed In none of the cases in which Trendelenburg's sign could be demonstrated was there a recurrence of the varices in anything like their former condition. Even when, in the absence of this sign, recurrence took place after operation patients were well satisfied with the results because of the relief that had been afforded them.

THE DANGERS OF ANESTHESIA AND HOW TO MEET THEM.

In general the subject of anesthesia has been studied too much from an exclusively theoretical standpoint. It is not, in any individual case, an ideal heart or respiratory center that is affected, but a particular patient with an organization peculiar to himself.

Professor Schrötter of Vienna, in talking recently at the German Medical Congress, an abstract of the proceedings of which appears in this number of the MEDICAL NEWS, of the development of cardiac insufficiency, said that a great deal depends in the matter of cardiac hypertrophy and dilatation on the idiosyncrasy of the patient, and the congenital strength of the heart muscle. As has now become the very general fashion in Germany he ignores the influence of the cardiac nervous mechanism entirely. This, however, is too restricted a view of the subject. There are congenital differences in nerve supply, as well as muscular conditions, that come in to complicate the problem. At least one pathologist has thought that in cases of sudden death from what might be considered heart failure, or reflex inhibition, he has found a pneumogastric nerve containing less fibers than are normally to be found in that nerve. The persistent irritation of the terminal fibers of the vagus in any organ seems at times to predispose to sudden arrest of the heart through its inhibitory mechanism. Especially is this true in chronic pulmonary irritation, as is produced even by chronic bronchitis. Hearts that are liable to suffer from neurotic conditions, even apart from any organic lesion, require more careful watching than others since the irritative excitability of their reflex nervous mechanism is such as to render them especially liable to sudden nervous arrest. In a word, the precautions necessary for safe anesthesia, include not merely a cursory examination of heart and lungs for organic disease, but demand of the careful anesthetizer considerable previous knowledge of the patient's pulmonary and cardiac history to enable him to anticipate accidents. Along this line, rather than in the employment of some new anesthetic chemical compound,

must come the improvement so long looked for in the mortality from anesthesia.

ECHOES AND NEWS.

Dr. Senn for Governor of Illinois.—Dr. Nicholas Senn is declared to be a candidate for the Republican nomination for Governor of Illinois in 1900.

Christian Science Did Not Cure.—Mrs. Charlotte Bargnet, sixty-seven years old, died at Mount Vernon, New York, on May 3d. She had been suffering for three months and had not during that time received medical attention. Instead, a Christian Scientist prayed over her. Coroner Banding of Mount Vernon has ordered an inquest.

Information Wanted by "The Jeffersonian".—*The Jeffersonian* Magazine, which is published monthly during the college year by the students of Jefferson Medical College, Philadelphia, desires to obtain a complete list of the alumni of the college and information concerning matters of personal interest to any of the members. Parties interested will please take notice.

Officers of the Association of American Physicians for 1900.—The election of officers resulted in the unanimous choice of the following gentlemen to serve for the ensuing year: President, Dr. E. G. Janeway; vice-president, Dr. William H. Welch; recorder, Dr. I. Minis Hays; secretary, Dr. Henry Hun; treasurer, Dr. J. P. Crozer Griffith; councillor, Dr. William T. Councilman.

Testimonial to Dr. McGauran.—At the last meeting of the New York Celtic Medical Society the members, through Dr. Francis J. Quinlan, who made the speech, presented to Dr. G. D. McGauran a magnificent service of silver as a testimonial of their high regard. Dr. McGauran goes to Lawrence, Mass., in consequence of his wife's health, where he will make his future home.

The New Skene Hospital.—Articles of incorporation of the society in Brooklyn known as the "Skene Hospital for Self-Supporting Women," were signed May 4th. It will be remembered that Dr. Skene resigned the presidency of the Long Island College for the purpose of assuming the management of this new enterprise. Dr. Charles Jewett has succeeded Dr. Skene as president of the college.

Special Train from New York to the Columbus Meeting.—The Committee on Transportation of the New York County Medical Association is arranging the rates, train service, etc., for the Columbus meeting of the American Medical Association to be held on June 6th, 7th, 8th, and 9th. Those intending to go and desiring to take advantage of such arrangements as may be made will kindly address, as soon as possible, Dr. Parker Syms, Chairman of Committee, 50 West 47th street.

Quinin Consumed by Americans.—The report comes from Washington that 125,000,000 grains of quinin have been consumed during the past year by American soldiers in Cuba, Puerto Rico and the Philippines. It is stated also that Americans generally are a race of quinin-eaters, consuming as they do one-third of the quinin of the world. The drug is used in the preparation of many patent medicines, tonics, bitters, cold cures, etc., and is dissolved in rum or spirits for external use as a hair-tonic.

British Medical Fortunes.—The *Lancet* corrects an impression which seems to have existed in England to the effect that Sir William Jenner's fortune of £375,000 was earned by him in the practice of his profession. As a matter of fact, a certain portion of this fortune was derived from trade and bequeathed to him by a brother. The *Lancet* names the fortunes left by eleven eminent English physicians and considers that a first-class brewer's fortune would be expected to amount to more than the aggregate total of these eleven medical fortunes or the brewer would be accounted a comparative failure.

Christian Science Treatment for Poisoning.—Dora England, twenty-two years old, of 105 Central Avenue, Newark, died in the Newark City Hospital on April 23d. She had been suffering from melancholia for several weeks. On the day before her death she took some Paris green. Her act was not discovered until two hours afterward when her mother, a devout Christian Scientist, called in Mrs. Van Houten, a Christian-Science leader in Newark, who spent much precious time in praying over the girl, until the mother in desperation called on Dr. J. T. Wrightson, who administered antidotes and sent the patient to the hospital. His efforts, however, came too late and the patient died.

Report Concerning "Embalmed" Beef.—The report of the Army Beef Court of Inquiry, appointed to investigate General Miles' charges regarding the food-supply of the army in the late war, was made public on May 7th. It finds that General Miles' statements concerning refrigerated beef are not sustained, and that the canned beef was good and fresh when delivered. The canned beef is considered, however, unsuitable for use as a field ration. General Miles is criticized for not promptly reporting to the Secretary of War his knowledge or belief that the food was unfit and caused sickness. General Eagan was sharply criticized for purchasing such large quantities of canned beef as he did. It is recommended that no further proceedings be held.

The Lenval Prize.—This prize, consisting of the interest on 3000 francs ($600) which has accumulated between one International Otological Congress and the next, was founded by Baron Léon de Lenval, of Nice, and will be awarded at the next meeting of the Congress, to be held in London, August 8 to 11, 1899. It will be presented to the author of the most marked progress bearing on the practical treatment of affections of the ear, or to the inventor of any new apparatus which is readily portable and improves considerably the hearing power of deaf persons. All persons desiring to compete for the prize are requested to communicate without delay with Mr. Creswell Baber, 46 Brunswick Square, Brighton, England, stating the facts on which their applications are based.

The Infectiousness of Colds.—The treatment of tuberculosis by fresh air and good diet is now thoroughly recognized as the most beneficial one, and everywhere sanatoriums conducted on these principles are springing up. But it should be remembered that if proper care is taken of children when young that there would not be the need of sanatoria there now is, as in many instances the seeds of consumption can be eradicated by judicious bringing up. It is a fact, both instructive and interesting, that in many of the coldest portions of the globe colds are unknown. Nansen and his men when in the Arctic regions, although they underwent exposure of every description, never suffered from colds, but no sooner had they set foot on their native shore of Norway than they one and all caught cold. The experience of other Arctic explorers is the same. It seems, then, probable that after all there is something in the theory that colds are infectious. —*Pediatrics.*

Hospital Accused of Overcharging.—The Commissioners of Accounts, in a report submitted to the Mayor of New York City on May 4th, state that the New York Post-Graduate Medical School and Hospital made heavy overcharges against the city during 1898. They recommended that the matter be placed in the hands of the Corporation Counsel. During the year 1898 there were 11,236 free-days treatment at the hospital. The Mount Sinai Hospital receives forty cents a day for free treatments and the New York Polyclinic Medical School and Hospital receives one dollar. By applying the former rate, the Commissioners find that the Post-Graduate Hospital charged $20,505 too much, and by applying the rate paid to the Polyclinic the excess is found to be $13,764. The Post-Graduate Hospital receives $30,000 a year from the city, but there is no stipulated rate for free-days treatment. It would seem, therefore, that the Commissioners have no legal grounds for complaint.

Effects of Intense Cold upon Intellection.—Exposure to extreme degrees of cold has a stupefying effect upon the brain. Nearly every one exposed to cold for a long time experiences a weakening of the will power, and often a temporary loss of memory. This fact probably in its greatest measure was observed by the French in evacuating Moscow. Among the recently discovered papers of a German physician who was one of the retreating party are accounts of this retreat, in which it is stated that the first effect of the cold was the weakening of memory, which affected healthy men as well as those who had already suffered the hardships of constant exposure and extreme fatigue. When the mercury dropped to 36 degrees below zero many soldiers could not name their accoutrements. Some of them forgot the name for food and perished from starvation. Very many could not remember their own names. Others showed decided symptoms of mental derangement and later became insane.

Typhoid in Army Camps.—At the session of the Association of American Physicians which was held in Washington on May 3d, Dr. Victor C. Vaughan, one of the three physicians appointed by the War Department to investigate the cause of the typhoid-fever epidemic in military camps during the war, read a paper which may be considered a preliminary report of that board. Surgeon-General Sternberg practically endorsed the conclusions reached by Dr. Vaughan. It was held that the spread of typhoid among the troops was due almost entirely to camp pollution, and that the principal agent in the distribution of the germs was the house-fly. The army surgeons, both volunteer and regular, are criticised for erroneously diagnosing mild cases of typhoid as malarial fever, and for their aversion to calling typhoid by its right name. Thus there resulted a lack of proper precautions to prevent the spread of typhoid. In Dr. Vaughan's opinion practically all the cases reported as malaria were mild types of typhoid. This opinion is based on the uneven distribution of the cases among regiments camped side by side, the unofficial statements of regimental surgeons, the results of blood examinations, the fact that the so-called malarias did not yield to treatment with quinin and the high rate of mortality which corresponded with that from typhoid and not from malaria. It is believed that typhoid fever prevailed in ninety per cent. of the volunteer regiments before they reached the Government camps, "So widespread is typhoid fever in this country," said Dr. Vaughan, "that in assembling a regiment of volunteers the probabilities are that one or more in the regiment will be found infected with this disease." It was found that the water-supply at the various camps was generally pure and wholesome.

CORRESPONDENCE.

RELAPSES OF MEASLES.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I have just read your article on "Second Attacks of the Infectious Fevers." The inhabitants of the village in which I live have just begun to recover from a very widespread epidemic of measles. The epidemic was of some interest, and I deem it worthy of reporting from the fact that it was very widespread throughout the village, and secondly, because of two cases of relapse similar to those reported by Felty from Vienna, which were unique in my experience, and similar incidents of which I had never heard before reading your article.

The first case I cannot vouch for since it did not occur in my own experience. I only saw the case during the primary attack. The patient was a boy of about seventeen years of age, and I saw him with a colleague during the height of the primary eruptive stage. It was a typical case of measles. I saw him no more after this, but it was reported to me that he got along nicely, made a good recovery apparently, the eruption entirely disappeared, and he was out again for about one week when the relapse occurred. The eruption returned though not so severely as at first, and he was again confined to his room.

The second case, which happened about one month after the first, and during the latter part of the epidemic, was that of a young girl about fifteen years of age. Her pri-

mary attack occurred some three weeks previous to her relapse. At that time the eruption with other typical symptoms of measles occurred. She then apparently completely recovered and went about her duties and pleasures with no indication of ill health. About three weeks after her primary attack she drank a glass of iced lemonade, and almost immediately afterward the eruption began to make its appearance on her face. It spread over her face, body, and arms, by the following day, and was accompanied by nearly all of the associated symptoms which go to make up a typical case of measles.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

MAYOR ASHBRIDGE RESCINDS HIS ORDER RELATIVE TO RESIDENT PHYSICIANS OF THE PHILADELPHIA HOSPITAL—OVARIAN CYST OF THIRTY-FIVE-YEARS' DURATION—OPERATION FOR PERFORATION IN TYPHOID FEVER—OBITUARY—HEALTH STATISTICS.

Philadelphia, May 9, 1899.

Mayor Ashbridge's order that hereafter none but residents of the city shall be appointed house physicians to the Philadelphia Hospital, which service is generally regarded as the most valuable training to be obtained in this city, has brought forth such a storm of protests that he has been compelled to rescind it. What possible motive could have induced him to promulgate this it is hard to say, for neither the patients nor the city at large would have their best interests served in thus closing the doors of famous old "Blockley" to general competition. There are many drawbacks to the city's endeavor to again become the preeminent medical center of this country, and to gradually limit the number of hospital appointments is not conducive to an increase in the medical student population which is now estimated at close to 2000. It is only too well known that many of the hospitals, notably, two of the largest, the German and the Pennsylvania, make no pretence of having competitive examinations for appointment, while others do so nominally only. If the Mayor is anxious to reform the prevailing methods at Blockley he might begin by dismissing from the Board of Examiners men who hold teaching positions in medical colleges, thus giving all graduates an equal chance, which is hardly possible under the present conditions.

Complaints have been frequent that men teaching along certain lines ask questions peculiar to their individual work and views, and that these complaints are well founded can be easily seen from a perusal of the questions asked in previous years, and especially those in 1898. It is to be hoped that this much-needed reform will soon be made so that "medical-school politics" will no longer be a factor.

At the last meeting of the College of Physicians, held May 3, 1899, Dr. De Forrest Willard read a report prepared by himself and Dr. S. M. Wilson of "A Case of Ovarian Cyst of Thirty-five-Years' Duration; Patient Dying of Influenza Bronchitis at Seventy-four Years of Age," in which Dr. Willard stated that its chief interest was in the long and unusually uninterrupted course as showing the length of time a woman can live when malignancy does not enter the case as a factor. The case was an evidence also of the conservative views on gynecology, held some thirty years ago, and it was not strange, therefore, that removal was not advised by Dr. Willard when he saw the case for the first time.

Dr. Willard tapped the cyst with relief to the woman for a period of nearly two years, when tapping again became necessary, and was resorted to quite frequently thereafter. At the post-mortem the intestines were found to be adherent to the cyst which sprang from the left ovary, and was so adherent to the belly-wall as to show how impossible removal would have been; the latter formed part of the anterior wall of the cyst.

At the same meeting Dr. William J. Taylor read a report of "Two Cases of Operation for Perforation in Typhoid Fever." According to Cushing's statistics he showed that ten per cent. of the fatalities in typhoid fever are due to peritonitis from perforation, and during the late war, ten per cent. of 2000 patients, or 200, might have been operated upon with some chance of success, but were not. Cushing's report is not strictly accurate, however, for Dr. Taylor knew of at least one soldier not mentioned, Dr. Willard's case, who had been operated upon though with a fatal result. The recoveries after operation are few, but twenty-seven per cent. is reported by Cushing as being a fair estimate. Of the two patients under Dr. Taylor's care, one was operated upon four hours, the other two hours after a diagnosis of perforation had been made. The first case occurred in a man of thirty-four who had had hemorrhages. At the time of perforation his temperature dropped from 102.6° F. to normal, his belly became distended, there was severe pain over the right side of the abdomen, liver dulness had disappeared, and his pulse was so weak as to be imperceptible. During ether anesthesia his pulse improved. A perforation in the ileum, the size of a lead-pencil, was found, and after repairing it and washing out the belly with sterile salt solution, an attempt was made to close the abdominal wound, but the patient died before this could be accomplished. Dr. Taylor's second case occurred in a man on the twenty-fourth day of the disease. The temperature fell from 103° F. to normal, pain and board-like rigidity of the abdomen were present, and liver dulness had not disappeared. After opening the belly evidences of septic peritonitis were found, and a perforation in the ileum eight inches from the cecum. The ulcer was invaginated, the abdomen washed out with saline solution and drainage instituted, but the man died twenty-one hours later from septic peritonitis.

Dr. Taylor doubts the wisdom of Dr. Keen's advice to wait for reaction, and would operate immediately after a diagnosis is made. He doubts the importance of the absence of liver dulness as a sign of perforation, but lays stress upon the importance of recognizing the preperforative stage and Finney's symptoms of pain, nausea, vomiting, and leucocytosis. He outlined the surgical technic of these operations, and stated that in his opinion the

only contraindication to operation is a moribund condition of the patient.

In the discussion which followed Dr. H. A. Hare said that he was surprised to find so much stress laid upon pain as an all important symptom, for many cases have recently been reported, especially by French physicians, in which pain was absent, and on the other hand, in many cases in which perforation has been excluded because of the absence of pain, death has been found at post-mortem to have been caused by perforation. He quoted two cases of his own in which pain was absent, and stated his belief that this is very likely to occur when the perforation is a minute opening. Dr. Hare agreed with Dr. Taylor as to the slight value to be attached to the presence or absence of liver dulness, and quoted a case where tympany over the liver was due to a distended colon. As to the preoperative stage, most physicians have all they can successfully accomplish in making a positive diagnosis of perforation after it has occurred.

Dr. Davis called attention to the difficulty of making a diagnosis of perforation before the surgeon considered it too late to operate, and cited some cases illustrative of this perplexing problem. He said he, for one, would be only too glad to know a way of determining the preperforative stage, and agreed with Dr. Hare as to the difficulty of determining perforation early.

Dr. Joseph J. Kirkbride, for more than twenty years physician in the Out-patient Department of the Pennsylvania Hospital, died last week aged fifty-seven years. He was the eldest son of Dr. Thomas S. Kirkbride, who for forty years was superintendent of the Insane Department of the Pennsylvania Hospital, or "Kirkbride's," as it was generally known. He graduated from the University in 1872, and was well known in medical and scientific circles, being a member of the Academy of Natural Sciences, College of Physicians, etc.

Another death of last week was that of Dr. D. L. Beaver, Reading's oldest physician, who died at the age of eighty-four. He graduated from the Pennsylvania Medical College in 1841, and practised continually for fifty-eight years.

The total number of new cases of contagious diseases occurring in Philadelphia during the week ending May 6th was 278, reported as follows: Diphtheria, 70 cases with 14 deaths; scarlet fever, 39 cases with 2 deaths; typhoid fever, 169 cases with 26 deaths.

OUR LONDON LETTER.

[From Our Special Correspondent.]

CONFERENCE OF FRIENDLY SOCIETIES—RESISTANCE OF RATS TO DIPHTHERIA—DEATH OF SIR WILLIAM ROBERTS—OFFICERS BETTER MEN THAN RECRUITS—RATIONALIZATION OF GERMAN SCHOOL SYSTEM—THE LONDON POLYCLINIC—LIVERPOOL SCHOOL OF TROPICAL MEDICINE—THE MODERN HIPPOCRATES.

London, April 31, 1899.

The twentieth annual conference of the Friendly Societies Medical Alliance has just been held at Leamington. This is the dragon which has been devouring the income and prospects of the English general practitioner at such an appalling rate of late years. It is, therefore, a matter of some gratification to note that the Chairman in his address expressed regret at the clashing which had occurred between the societies and the profession in certain districts, admitted that the agents of the Alliance had been at fault in some respects, especially as regards "touting" for new members, and stated that conferences were being held with the General Medical Council for the purpose of agreeing upon a harmonious and mutually advantageous course of action.

A system of medical attendance by the year, arranged in advance, has many things to recommend it if, indeed, it be not the ideal one, and there ought ultimately to be no more difficulty in fixing a yearly fee at a fair and reasonably remunerative rate than a daily or weekly one as at present.

Our bacteriologic brethren are hard at work all along the line trying to prove that resistance is an important factor in disease, and immunity either accidental or relative. One of the latest essays in this direction is that of Louis Cobbett, who has just reported from the Cambridge Pathological Laboratories a series of studies upon the immunity of the rat to diphtheria.

After a number of careful experiments he comes to the conclusion that this well-known immunity is "only relative" and that rats succumb to the poison if only sufficiently large doses are used. But as this dose was found to be necessarily from 1500 to 1800 times the amount fatal to a guinea-pig of twice the weight, in other words, that the rat's resistance is from 3000 to 3600 times that of the "normal standard" of the laboratory, the guinea-pig, it is obvious that to call this "relative" is a mere trifling with terms. One might just as well talk of the relative immunity of the human species to bread and cheese, because 3000 pounds of the compound introduced into the system would produce fatal results.

The death of Sir William Roberts has painfully affected the whole community. Upon all hands are heard tributes to his brilliancy, charm, and nobility of character, and regrets that he could not have been longer spared. Although within a year of the traditional "three score and ten" he was still so fresh, so vigorous, so keenly alive, both mentally and physically, that had it not been for the ruthless onslaught of that cruelest foe of humanity, cancer, he might have continued in his splendid service of the profession, of the race, for at least a decade or a decade and a half longer. By a strange and bitter irony of fate he, who had devoted the better part of his life to the study of the disorders of digestion, and relieved the gnawing, gastric pangs of thousands of other men, died at last of cancer of the stomach. Born in 1830, he graduated at University College, London, and settled in Manchester for the practice of his profession. His fame grew so rapidly that in less than ten years he was invited to deliver the Goulstonian lectures at the Royal College of Physicians and was elected a fellow. His subject was the "Digestive Ferments" and the brilliant success achieved was more than sustained by his second course, a few

years later, upon "Dietetics," at Owens College, these two courses being combined and incorporated in his now classical work, "Digestion and Diet." About 1880 he came to London and a few years later gave his famous Croonian lectures on the "Chemistry of Uric Acid, Gravel, and Gout." Then came his knighthood and all the "Blue Ribbons" of the profession, one after another, the Presidency of the College of Physicians, membership in the General Medical Council, the Opium Commission in 1893, and many other honors.

A recent report of the War Office gives a most interesting comparison between the physique of the officers and that of the enlisted men. It has long been the conviction of the writer that the popular and traditional impression as to the "sturdiness" of the lower strata of society and "punyness" of the upper was utterly mistaken, and that the "better classes" were better in physique as well as in social position. The measurements given in this report fully confirm this view, as the officers, on entering the army, average two inches taller, from two to five pounds heavier, and have two to three inches greater chest girth than the recruits. And this, too, in spite of the fact that the men average nearly two years older than the officers at enlistment. Generations of "breeding" of even unconscious selection and better environment tell upon the human animal just like any other.

The German Department of Education, with its customary sagacity, has made practical application of the valuable studies of Drs. Springer and Kemsies upon fatigue in school-children and has just issued a circular laying down the following admirable rules: (1) All scientific studies and heavy work to be pursued in the morning. (2) Not more than four hours systematic work per diem and three-hours' "nooning." (3) Subjects to be taken in "fatigue order," the heaviest earliest in the day, beginning with mathematics, foreign languages, and formal sciences, and ending with geography and natural history, the last study being regarded as actually refreshing, instead of fatiguing, and capable of preparing the children for another additional study period.

The formal opening of the Liverpool School of Tropical Medicine occurred on April 22d. Lord Lister presided and Sir Wm. Broadbent, Michael Foster, Clifford Allbutt, Sims Woodhead, and other celebrities were present. The school has been fortunate enough to secure, as its chief lecturer, Major Donald Ross of "mosquito" fame, and already has an income assured to it, chiefly by private subscription, of £1600 a year.

Meanwhile the Government bantling is preparing to climb into the marsupial pouch of the dear public and announces the receipt of two superb Royal donations of £200 from the King of the Belgians, and £1000 from the Secretary of State for India. So that the gap to be filled by private charity is now only $59,500.

The first clinical demonstrations at the new Polyclinic were held last week and were attended by some eighty or ninety practitioners and twenty consultation patients. The formal opening will be held May 1st and the lectures and laboratory work will begin two days later.

The death is announced of a prominent member of the profession, who is better known by his work than by name, Dr. Jukes de Styrap, author of the famous "Code of Medical Ethics."

The Government has at last announced its intention of bringing in an amendment to the Factories Act, restricting the use of lead glazes in accordance with the recommendations of Professors Thorp and Oliver, given in a former letter. So a check is at last to be placed upon the disgraceful "saturnalia" of the English potteries.

A NEW OPERATION FOR EXOPHTHALMOS—TREATMENT OF CONGENITAL TORTICOLLIS—CARE OF INFANTS DURING WEANING—OPERATIONS UPON THE INSANE—A NEW METHOD OF RESECTING THE SUPERIOR MAXILLARY NERVE—ON THE USE OF COLD BATHS IN MENINGITIS—RHUEMATISM OF THE SACROILIAC SYNCHONDROSIS—POISONING FROM ORTHOFORM AND FROM ANTIPYRIN—AN ATTACK OF SYPHILIS IN A MAN WHO HAD HEREDITARY EVIDENCES OF THE DISEASE.

At the Academy of Medicine, April 4th, CHAUVEL discussed a new operation for exophthalmos which has been brought forward by Roure. The conjunctiva is divided around the cornea, separated from the sclerotic, and brought together above the cornea by a purse-string suture. Some days later, when adhesions have formed between the conjunctiva and the sclerotic, the redundant portion of the conjunctiva is cut off. As a result of this operation in rabbits there was a considerable amount of exophthalmos. As exophthalmos is only a symptom, the operation would seem to have little application in man, except in those cases in which the eye has been displaced forward as a result of a traumatism.

At the meeting of April 11th, BERGER spoke of the treatment of congenital torticollis. He presented a patient ten years of age, upon whom he had performed section of both heads of the sternomastoid muscle, following the operation by massage and molding exercises, flexion of the head, twisting of the neck and pressure on the spine with the child in dorsal decubitus or suspended, until the torticollis had been completely overcome and the curvature of the spine almost entirely so. He laid stress upon the importance of the after-treatment in such cases. The trouble was due to a traumatism of the neck during delivery. The presentation was a pelvic one, and there was noticed upon the right side of the neck, some days later, a swelling, which disappeared little by little, leaving a vicious position of the head, which increased until the child was in the condition above referred to.

PINARD said that congenital torticollis was due to a hematoma in the muscle followed by retractions, which brought about the deformities. The real cause is, therefore, not congenital, but is the traumatism of the muscle produced during delivery. If this is recognized and treated at once the unfortunate consequences may be avoided. The speaker mentioned five cases in which orthopedic treatment was immediately instituted, and in which as a consequence the extreme contraction was prevented.

SAINT-PHILIPPE said that weaning is a period of danger for most children, because it is usually badly carried out, so that gastro-intestinal dyspepsia with diarrhea frequently results. Milk is often badly borne, and if so, it should be suppressed entirely and its place be taken by barley-water, thin gruels, or albumen-water, with a little brandy. At the same time massage of the whole body should be practised. Gradually the child is to be transferred to a more solid diet, and the system strengthened by warm salt baths, injections of salt solution, inhalations of oxygen, and the fresh-air cure.

At the Surgical Society, March 29th, PICQUE said that operations ought not to be performed upon insane persons unless there was a strong probability that a decided benefit would follow. Experience had shown him that 88 per cent. of the female insane had some form of genital trouble, and in many instances the relief of that lesion exerted a favorable effect upon the mental condition of the patient. He cited cases in which the melancholic delirium of a patient entirely disappeared after the removal of an ovarian cyst. In instances of this character the mental affection had accompanied or followed the lesion of the body, and the latter was known to the patient. In other patients the mental trouble had preceded the knowledge of the surgical condition, but the latter had aggravated the former. In such cases a cure of the mental malady may also follow surgical intervention. In a third group of cases the convalescence from a mental difficulty was hindered by a metrorrhagia, or profuse leucorrhea, etc. The relief of the latter condition hastened the recovery from the mental disorder. There are also well-marked cases of mental disease, in which the existence of pelvic disturbance is unknown to the patient, and unassociated with her delirium. In such cases the cure of the surgical lesion may have no effect upon the condition of the mind. Picque operated upon 17 insane persons and 1 hysterical one, and treated 4 others without operation. Of these 22 patients, 12 recovered entirely, both mentally and physically; 6 were benefited, 3 were not improved, and 1 died as a result of operation.

At the session of April 12th, POIRIER described a new method of reaching and resecting the superior maxillary nerve. Examination of fifty skulls, and numerous dissections showed him that the pterygo-maxillary fossa, through which the nerve runs, is always a little above the level of the zygomatic arch. His plan was, therefore, to enter this fossa by an incision made wholly above the arch so as not to cut away any portion of it. He advocated resection of the nerve, and not its avulsion, as less likely to cause subsequent neuralgia.

At the Medical Society of the Hospitals, April 7th, RENDU related the history of a young man who had died of cerebrospinal meningitis. At autopsy the sulci of the brain were filled with a thick yellow pus, almost like butter, containing in great numbers cocci in short chains. As death approached the symptoms were well marked. The head was thrown back, there was photophobia, and a constant incoherent delirium without convulsions; but in the early part of the illness, when the symptoms were those of stupor, headache and cervical pains, and diarrhea, the case was thought to be typhoid and the patient was treated with cold baths, which were ill borne.

NETTER said that it is rare to find a streptococcus in cerebrospinal meningitis. He knew of only two reported cases. It is the rule that cold baths are not well borne, according to his observations. Warm baths on the other hand, at 38° to 40° C. (100° to 104° F.), are acceptable to a patient with cerebrospinal meningitis, and relieve the pain and contractions. They should be given three times in twenty-four hours.

At the session of April 19th, GALLIARD mentioned three cases of rheumatism of the left sacroiliac articulation. In one patient the rheumatism preceded a pneumococcic meningitis without pneumonia; in the second case it developed after an intestinal paresis which followed typhoid fever, the rheumatic pain existing along the vertebral column, as well as in the joint; while in the third case the rheumatism was gonorrheal and lasted four weeks, with pains along the sciatic nerves.

At the Society of Dermatology and Syphilography, April 10th, BROCQ mentioned some accidents which followed the use of orthoform. He applied a solution of this drug for the relief of prurigo, and found that it produced in one case an active irritation of the skin. In another patient an ointment containing 5 per cent. of orthoform produced an eruption which lasted fifteen or twenty days, and was accompanied by considerable dermatitis. He dusted orthoform over the vulva and between the thighs of a young woman and produced not only local irritation, but a well-marked eruption of infiltrated nodules upon the face, body and limbs. In an infant he had observed symptoms of intoxication follow its use.

FOURNIER mentioned two cases of swelling of the end of the penis, with large discolored blotches due to the use of antipyrin.

JULIEN saw a young man of twenty-two years, with a chancre on his penis and a secondary syphilitic eruption obtained from coitus with a syphilitic woman. The patient presented numerous evidences of hereditary syphilis, such as absence of the nails, chronic glossitis, affection of the eyes, etc. His father had contracted syphilis six months before marriage, but his mother remained free from the disease.

SOCIETY PROCEEDINGS.

THE SEVENTEENTH GERMAN CONGRESS OF INTERNAL MEDICINE.

Held at Carlsbad, April 11 to 15, 1899.

[Specially Reported for the MEDICAL NEWS.]

THE President, PROFESSOR QUINCKE of Kiel, opened the Congress, after which Count Condenove, Governor of Bohemia, delivered a short address of welcome.

The first paper, entitled "Insufficiency of the Heart-muscle," was read by VON SCHROETTER of Vienna. He said that the reserve energy of the heart is of congenital origin, and on the amount of this depends the prognosis in valvular disease. With a functionally strong muscle, valvular disease may be borne for years without symp-

toms, but if the reserve force is small, insufficiency may manifest itself even when no anatomical lesion can be discovered. Moreover, as the heart experiences no feeling of weariness, it happens that many "who employ their muscles too much and their intellect too little" in the different sports realize only too late the irreparable injury to the heart-muscle. On account of its wonderful power of compensation the heart finally answers the increased demand and hypertrophies; but this is a pathologic condition, and always remains such, leading sooner or later to complete exhaustion of the organ. Besides an insufficiency due to overwork of a congenitally weak muscle, the speaker recognized one due to nervous causes, manifesting itself usually in tachycardia. He illustrated this by a clinical example of what is ordinarily called "broken heart." A woman, aged thirty years, felt so deeply the loss of her husband that her only wish was to follow him. Although up to this time she had been perfectly healthy, she now began to decline, developed symptoms of heart weakness, tachycardia, etc., and after a short period died.

MARTIUS of Rostock considered fatty infiltration and degeneration of the heart muscle less serious than ordinarily assumed. He insisted that the impulse of the heart against the chest wall takes place during closure of the valves. He called attention to the fact that normal, healthy youths show little or no apex impulse, while feeble hearts frequently produce a diffuse, well marked one. From this he concludes that the normal heart works without friction, that is, without striking the chest wall.

SCHOTT of Nauheim dealt especially with chronic heart disease of youth. He called attention to the common difference of the seat of lesion in youth and old age; in the latter period arteriosclerosis leads to affection of the aortic valves, while in youth these are rarely diseased. For treatment he employs baths, suitable diet, and regulated exercise.

HIS of Leipsic regretted our lack of knowledge in regard to the nervous mechanism of the heart. He described an unusual phenomenon that he recently observed: For about forty seconds the ventricles ceased to beat, the heart-sound, the impulse, and the pulse disappearing, but a rhythmical sound was evident over the auricles, and a venous pulse noticeable in the neck. The ventricular contractions returned, but the contractions of the auricles continued more frequent for some time.

POEHL of St. Petersburg described the products of cardiac exhaustion as belonging to the xanthin group, but said they are more readily oxidized. In some cases of heart disease the urine is excreted under a reduced osmotic pressure, and it is possible that mineral waters may increase this and so relieve the heart.

"Leucemia and Leucocytosis" was the title of a paper by LOEWIT of Innsbruck. He described two forms of ameba which he had discovered in the blood of leucemic patients, and which he considers to be the cause of the disease. The one found in myelogenic leucemia he designated "hemameba leucemia magna"; that of lymphatic leucemia, "hemameba leucemia vivax." Though unable so far to cultivate these parasites, he has succeeded in inoculating lower animals with the disease, the animals dying after several months with all the symptoms of the disease, associated with the invariable presence in the blood of the micro-organisms. On the ground of the parasite being an ameba he recommends a trial of quinin in leucemia, though his own experience with it is too slight to form conclusions.

MINKOVSKI of Strassburg regretted that so little is known of the connection between the chemistry of leucemia and its clinical symptoms. Renewed interest has lately been developed in the study of the formation of uric acid on account of the increase in leucemia and leucocytosis. The value of therapeutics has become more evident in the study of leucocytosis, since it is possible by different tissue extracts, products of bacteria, and drugs to increase or diminish the number of leucocytes. It will not be long before Virchow's saying of fifty years ago, "I demand a place in pathology for the colorless corpuscle," will also apply to therapeutics.

GOLDSCHEIDER of Berlin spoke of the importance of Löwit's discovery, but doubted the facts. GRAWITZ of Berlin reported some interesting experiments on leucocytosis in animals. KUEHNAM of Breslau described some renal changes in leucemia. KRAUS of Gratz said that he had observed in his cases of leucemia an increase in the fibrin factors of the blood. LOEWIT closed the discussion by saying that he had not given his methods for staining and inoculation in detail because they would shortly be published, and from the publication there would be less likelihood of misquotation and error. (At the beginning of the afternoon session he demonstrated the hemamebæ microscopically. They were situated within the leucocytes near the wall, and were stained red, while the cell itself was counter-stained blue.)

The next paper, on "The Diagnosis and Treatment of Aortic Aneurism," was read by SCHMIDT of Frankfort. He insisted that not enough stress had been laid on the Oliver-Cardarelli symptom "tugging" as an early sign, and also recommended the habitual use of the Röntgen-rays. Out of 54 cases that he had observed, 52 of which were in men, he found evidence of syphilis in but 16. In certain parts of Bavaria, he said, where women do the physical work of men, aneurisms are as frequent as among men. In the way of treatment he advised potassium iodid, rest in bed for about eight weeks, and the "starvation diet" recommended by Tufnell thirty years ago. In this dietary the food is cut down one-half, and water limited to 350 grams daily.

HAUSEMANN of Berlin stated that in sixty-four cases of aneurism in which he performed the autopsy he had found evidence of syphilis in but 12.

SENATOR of Berlin believed the Röntgen-rays necessary only in aneurisms of the descending aorta. He detailed a case in which he was following a French method, namely, injecting into the sac solutions of gelatin.

QUINCKE of Kiel thought that the connection between syphilis and aneurism, in view of the success attending the potassium-iodid treatment, is greater than the previous speakers had admitted.

CZERNY of Breslau in a paper on "Hyalin Degeneration," said that it results from the destruction of cell protoplasm. It can be produced artificially by inducing suppuration. In cases of cachexia it changes into amyloid material, and in these cases may also be carried in the circulation and deposited in and around the blood-vessels, especially of the brain.

In a paper on "Diseases of the Gastro-intestinal Tract" EWALD of Berlin described a form of appendicitis coming on with general gastro-intestinal disturbances without any local symptoms whatever. He detailed a case treated as hysteria for more than a year. The patient was finally operated on by Sonnenburg, who found adhesions, ulceration, and suppuration about the appendix.

PETERSON of Heidelberg gave the indications for surgical interference in cases of non-malignant disease of the stomach. ESCHERICH of Gratz and JACOBI of Berlin spoke on the virulence and peculiarities of the bacillus coli communis.

VAN NOORDEN of Frankfort, in a paper on "Diseases of the Kidney," insisted strongly against the common treatment of contracted kidney. He said that diets of milk and alkaline mineral waters tend only to overload the already diseased blood-vessels and oppress the heart.

In a contribution on "The Origin of Fat" ROSENFELD of Breslau claimed that carnivora possess very little fat because they practically only get whatever little happens to be on the meat, and albumen is not convertible; that ruminants, on the contrary, show much more fat, the carbohydrates being changed into fat. The fat of different animals differs in accordance with the kind of fat consumed and from what produced. Fish can be made to take on mutton fat by feeding it to them for a long time. He, therefore, believes that human fat, too, differs according to its mode of origin, the fat of the Eskimos giving the characteristics of fish fat, and that of Polynesians those of cocoa butter.

"A New Micro-organism for Syphilis." A paper with this title was contributed by NIESSEN of Wiesbaden. He has cultivated a bacillus from the blood of syphilitics, the inoculation of which, he claims, into monkeys and pigs produces symptoms similar to those seen in the human being, namely, a peculiar rash of the skin and mucous membranes, swelling of the lymph glands, and finally fatal disease of the nervous system.

SPITZER of Breslau, in a paper on "Uric-Acid Formation," claimed that his investigations point to the fact that uric acid is not produced in the muscles, connective tissue, or the kidneys, but probably in the liver or spleen.

WIENER of Prague and JACOBI of Berlin said that independently of one another they had reached the same conclusion.

In a paper on "Tetanus Serum" BLUMENTHAL of Berlin mentioned his earlier denial of the efficacy of tetanus serum. Experiments in the meantime, in which he had injected the serum directly into the brain, or into the cerebrospinal fluid of goats afflicted with the disease without effect, have strengthened his former opinion.

On the vote for the president for next year, Von Jaksch of Prague proved the choice of the Congress.

THE ASSOCIATION OF AMERICAN PHYSICIANS.[1]

Fourteenth Annual Meeting, Held at Washington, D. C., May 2, 3 and 4, 1899.

FIRST DAY, MAY 2D.

THE meeting was called to order by the President, DR. G. BAUMGARTEN of St. Louis, who opened the proceedings with the following introductory address:

In opening this fourteenth session my first impulse is to express to you my appreciation of the high honor you have conferred upon me. I can only excuse my acceptance of this office by my literal faith in the words of your first president, when he spoke of this Association as one in which no one will care who are the officers and who are not, and by the loyal interest I take in its welfare.

This Association was founded as one of a number of special societies cultivating special branches of medicine and it stands for specialization, subdivision of labor, and concentration of effort on the part of the investigator and clinical observer, but it differs from our allied sister societies in that it counteracts the disadvantages of specialization by allying the clinician with the pathologist, the bacteriologist with the chemist, and thus prevents one-sided devotion to mere technical training.

We count among our members those who direct their labor and acumen to the quest of the most intricate details, as well as the master minds who, trained in the appreciation of the smallest factors, yet survey all that upon which the light of science shines from a vantage ground.

It is incumbent on me to make the formal announcement that since last we met we have lost one of our master workers, Dr. William Pepper. This body, which owes so much of its early success to the tactful organizing efforts of Dr. Pepper, mingles its sorrow with that of the profession of all America, with the university and with his native city. He was one of the organizers to whom this Association owes its existence, and we remember with gratitude the kindly influence of his presence among us, one of the most interested of our members, ready in discussion, lavish of instruction, always competent and willing to give more than he received. May the Association long be spared another such loss!

The first paper, entitled

IDIOPATHIC DILATATION OF THE COLON*

was read by DR. J. P. CROZER GRIFFITH of Philadelphia. He said in part: Cases of dilatation of the colon may be divided into three classes: the acquired, the congenital, and the idiopathic congenital. In the first class I would place those cases that are due to habitual constipation, fecal impaction, acquired atony due to a debilitated system and narrowing of the bowel by pressure. In the second class may be included those cases due to congenital obstruction, or stenosis of the colon or rectum which causes distention to develop above it, and in the third class are the so-called idiopathic congenital dilatations which are dependent upon no discoverable organic

[1] All papers marked with an asterisk (*) will be published in ful in the *American Journal of the Medical Sciences.*

cause. A synopsis of all the reported cases of idiopathic dilatation will be appended to the paper, and I wish to give the notes of one case which has been under my own observation. R. S., born in June, 1894, and two years and eleven months of age at the time of the examination. He had been constipated from birth and very strong purgatives were required. When five months old marked distention began in the abdomen accompanied by more or less pain. He would sometimes go as long as a week without any movement and then have a diarrhea which was at times accompanied by even an increase in the gaseous distention of the abdomen. The condition persisted without change until November, 1896, when, because of his having swallowed a button the purgatives were discontinued for a week, and after this it was almost impossible to secure a movement of the bowels. Then a severe diarrhea set in, the patient's condition steadily grew worse, and though colotomy was performed his strength had diminished so much that he did not recover. Autopsy showed nothing abnormal in the abdomen except a constriction in the ileum.

In a few cases diarrhea has been a constant feature and not infrequently has it been a final event in the history of the case. As a rule, pain and tenderness have been absent, and the presence of hard fecal masses has been the exception. The treatment should be, first, hygienic and medicinal, and secondly, operative. For the latter purpose, colotomy, or resection of the bowel as suggested by Treves, may be resorted to.

THE RELATION OF IDIOPATHIC DILATATION OF THE COLON TO PHANTOM TUMOR*

was the title of a paper by DR. R. H. FITZ of Boston. The descriptions of such tumors show marked variation in their shape, size, duration, and in the nature of the associated symptoms. It is noteworthy in the history of the subject that of late years reports of cases of phantom tumor have almost wholly disappeared from medical journals. In the meantime a considerable number of cases have been published, the characteristics of which simulate those of phantom tumor, but the tumor proved to be a permanent enlargement of the colon. The affection is a cause of deformity, discomfort and danger. It occurs both early and late in life. The former variety is frequently called congenital, though the term infantile is more comprehensive, since a recognizable congenital cause occurs only in the few instances in which a malformation of the lower part of the colon or rectum has been found. It is considered probable that constipation is the chief factor in the production of idiopathic dilatation, both in the infant and in the adult. The two conditions, chronic phantom tumor and idiopathic dilatation of the colon, are considered identical. The symptoms are similar; in each the tumor subsides under anesthesia to return when consciousness is recovered, and the phantom tumor, after laparotomy has proven to be a dilated colon. The phantom tumor has no necessary relation to hysteria and idiopathic dilatation of the colon may occur in neurasthenic or hysterical persons. Finally cases of phantom tumor in medical journals have been replaced by examples idiopathic dilatation of the colon. The resection of the dilated sigmoid flexure is advocated in those cases where the condition has existed for so long a time as to indicate a permanent enlargement, and especially when associated with serious discomfort or suffering. Instances are given of the successful performance of this operation.

DR. OSLER: In the first of my cases the operation of colotomy was performed by Dr. Halsted and it is erroneously stated in Rotch's "Pediatrics" that the child died later. When last heard from the child was still alive. In a second case the operation for artificial anus was performed, all the symptoms disappeared and the child improved rapidly. In a third case I reported, a child aged seven months, lived for two years subsequently, and, at autopsy we found enormous dilatation of the colon with narrowing of the sigmoid flexure.

My fourth case illustrates that this condition sometimes disappears spontaneously. The boy, aged ten years, had great distention of the abdomen with perceptible sacculation. He had chronic heart disease and with the aggravation of this and the development of ascites the dilatation of the colon disappeared.

The very rapid improvement in the patients after colotomy, leads me to believe that the operation should be performed early and that it is much less serious than the operation proposed by Treves.

DR. JACOBI: In considering the cause of this condition I may suggest that there are in the intestinal tract possibilities of imperfect development of the muscular layers. I have not seen that condition of things in the intestine, but have seen it in the stomach where there was a local atrophy of the muscle and I can imagine that a similar condition in the colon would give rise to dilatation. Further autopsies will teach us more about it.

DR. JAMES TYSON of Philadelphia then reported a case of

PRESYSTOLIC MITRAL MURMUR ASSOCIATED WITH SYSTOLIC TRICUSPID MURMUR AND JUGULAR PULSE.

The patient was a woman, aged thirty-two years, and when first seen was in the eighth month of pregnancy. There was a history of illness eight years before, during her first pregnancy, and shortly after that an attack of rheumatism, apparently muscular. Following this she has had a winter cough and three months ago is said to have had pleuropneumonia from which she never entirely recovered. Since then she has been having an aggravated cough with dyspnea, weakness and loss of weight. On admission to the hospital her appearance was that of a consumptive, but physical examination showed only general bronchial catarrh. On inspection a jugular pulse was recognized coincident with systole of the ventricles and there was marked systolic thrill at the apex, which was in the fifth interspace, about an inch to the left of the mid-clavicular line. Auscultation gave at the apex a short, rough murmur, terminating abruptly in a loud, thumping, first sound, followed by a faint second sound and when the stethoscope was carried up into the pulmonary area the second sound became more intense and again less loud as the aortic area was approached. The presystolic murmur was a double one and the thumping sound was well heard in the axilla but less loud in the mitral

area. It was also heard at the angle of the left scapula behind. Just across the left parasternal line was a long, loud, blowing systolic murmur, most intense in the fifth and sixth interspaces. Nowhere and at no time was a mitral systolic murmur audible.

The patient was relieved of the bronchial catarrh by the use of potassium iodid and belladonna, and the extreme cardiac distress was diminished by hypodermic injections of morphin. When she went in labor cyanosis became very intense, and she had to be rapidly delivered by forceps. She was examined soon after labor with the following result: the jugular pulse had disappeared, the liver could be distinctly outlined, the presystolic thrill was still plain, and the pulmonary second sound strongly accentuated. The changes noted were due simply to recession of the diaphragm and subsidence of venous turgor, which followed emptying of the gravid uterus.

DR. JANEWAY: I have found that the presystolic mitral murmur in about one-third of all cases can be heard behind, near the angle of the scapula. This is opposed to the rule usually stated. Anyone who has had a great deal of hospital experience has watched cases of mitral stenosis with well-characterized murmurs and has had those cases go out of the hospital, to return again later as cases of mitral insufficiency and much uncertainty has been brought about in this way, but when the autopsy was held a mitral stenosis was found where the last clinical history gave mitral insufficiency.

DR. GRIFFITH: I am very glad to hear Dr. Janeway speak as he has, for I made this point in a paper read here three or four years ago. No reference to the fact is made in the text-books, that in cases of mitral stenosis the murmur can so frequently be heard much beyond the ordinary limits.

A CASE OF MITRAL STENOSIS WITH FEVER (NON-MALARIAL) OF RELAPSING TYPE*

was reported by DR. F. P. HENRY of Philadelphia. He said: My patient was a young, unmarried woman, pregnant, highly chlorotic, with well-marked, though well-compensated mitral stenosis and fever which might be styled recurring, relapsing, or intermittent, but certainly not malarial. Inference that the fever was dependent upon the heart lesion is based upon the fact that no other cause could be found. About ten days before admission she began to feel weak and complained of headaches, pain in the back and neck, with occasional nausea, vomiting, and epistaxis. The menses had been suspended for two months. Physical examination revealed nothing abnormal except a presystolic murmur followed by the short, sharp first sound and a scarcely audible second sound. The heart was but little, if at all, enlarged. The temperature was normal for five days, when it began to rise, and two days later reached 101.4° F. The next day it was again normal, and remained so for six days, when it suddenly rose to 102° F. Six days later there was another ascent to 102° F., and this was repeated several times. On two occasions the rise in temperature was accompanied by a chill. Repeated examinations of the blood for the malarial organism gave negative results. Blood count showed red cells, 2,705,000 per cm.; leucocytes, 6000; and hemoglobin, 20 per cent. Urine was normal. The patient is living and free from fever, but that is not sufficient reason for believing that the fever was not etiologically connected with endocarditis.

DR. JOHNSTON: It seems to me the explanation of these cases must be found in what we know to be the cause of analogous conditions in malarial fever, or tuberculosis, namely—in the life history of an organism. I have recently seen a somewhat similar febrile case without the cardiac symptoms, and repeated examinations of the blood threw no light upon the condition.

DR. BOND: I would like to suggest that possibly this may be due to gastro-intestinal trouble.

DR. HENRY: There were no gastric disturbances at all.

The next paper, on

THE IMMEDIATE AND REMOTE EFFECTS OF ATHLETICS UPON THE HEART,*

was read by DR. ALFRED STENGEL of Philadelphia. He said, in part: For six years past I have been making examinations to determine the effects of athletics upon the size and efficiency of the heart and character of the circulation. The charts I shall exhibit will illustrate the changes in the outline of the heart as obtained by percussion, and auscultatory percussion, after exercise. It seems that in the beginning of exercise there is a temporary increase of the cardiac pressure and the phenomenon known as "second wind" is explained by recovery of the right ventricle after the preliminary over-distention incident to exertion. The details of a number of cases may be given to show that unfortunate results may occur from violent excessive exercise in young persons not under proper training, and also to show that there is a marked difference between those who are carefully and those who are insufficiently trained. There is more or less danger attending any sport, but I would lay stress upon the necessity for careful athletic training, not only for the athletic field, but for the general struggle of life. The effect of continued indulgence in severe sports is the development of some cardiac hypertrophy, and athletes who have thus enlarged their hearts frequently suffer symptoms of over-compensation, at least during some years after they have ceased to follow athletics.

I would suggest rigid medical supervision in college athletics and that young men be encouraged to continue some form of exercise after discontinuance of regular athletics.

DR. FOLSOM: From the cases I have seen I am inclined to think that a great many of the bad effects come from one of two causes: either a young man enters into athletics without a very good heart, or more commonly still these young men with big frames and strong muscles, but unaccustomed to severe muscular exercise, go into athletics without realizing that it is easier to strengthen the muscles of the legs and arms than the muscles of the heart.

DR. OSLER: I would emphasize one point in Dr. Stengel's paper, that is, the frequency with which he has found a systolic murmur in the pulmonary area of healthy

young athletes. I hope that statement may sink deeply into the minds of the gentlemen composing the army and navy board. Every year I have two or three young fellows come to me because they have been rejected by these boards upon the discovery of such a murmur, and such rejection is often an injustice. I would also like to issue a warning to men who have about crossed the line of forty to forty-five against trying to ride bicycles and climb hills with the boys. So long as they ride with men of their own age all right, but when they attempt to climb hills with young athletes look out for trouble.

DR. DOCK: It is not sufficiently borne in mind by many that athletes with apex murmurs may be capable of a large amount of hard work. I have noted this both in the case of football players and in some of the soldiers enlisted for the late war.

ON THE INTERPRETATION OF PULSE TRACINGS

was the title of a paper by DR. A. R. CUSHNY of Ann Arbor, Michigan.

When the dog's heart is exposed, and the ventricle is stimulated with single electric shocks, each stimulus that falls during the non-refractory period is followed by an abortive systole, which is sometimes sufficient to cause a distinct pulse in the arteries, but often fails to do so. The auricle is not affected by the stimulus and continues to beat in its usual rhythm. The next contraction of the ventricle after the abortive systole is induced by an impulse descending from the auricle as usual, and, therefore, takes place at the exact time at which a contraction would have occurred had there been no abortive systole. The interval between this beat and the last normal one is, therefore, exactly double the pause between two ordinary contractions. If a sphygmographic tracing be taken, the pulse appears to miss one beat, and the intermission is found to be exactly twice as long as the interval between two ordinary elevations of the tracing. If the auricle be stimulated instead of the ventricle the result at first appears the same, the ventricle contracts prematurely, owing to the artificial impulse descending from the auricle, and there is either a very small undulation in the sphygmographic tracing or a complete intermission. If the duration of this intermission be measured, however, it is found to be less than double the pauses between two ordinary pulsations. In this way the examination of the sphygmogram of the dog enables one at once to determine whether the stimulus was applied to the ventricle or to the auricle, for in the first place the intermission is exactly twice as long as the ordinary interval between two pulses, while in the second place it is invariably shorter. Some consideration will show that the first proportion is true for any intermission of the pulse that is due to disorder of the ventricle only, that is, such an intermission must be equal to twice the ordinary pause. Any intermission that is of shorter duration must accordingly be due to the disordered action of the parts of the heart above the ventricle, which determine the pulse rhythm.

In cases of heart disease hitherto examined the sphygmogram very often showed intermissions, which indicated that the ventricle alone was at fault, while in many others it was perfectly certain that the intermission was due to disorder of the rhythmic parts of the heart. In some cases the pulse was so irregular that no certain conclusions could be drawn in the matter. The accurate measurement of the pulse-tracings in irregularity of the heart thus affords a means of diagnosing with considerable probability whether the ventricle or the rhythmic part of the heart is at fault.

DR. M. ALLEN STARR of New York, then read a paper on

TABES.

Only two sets of neurons appear to suffer in this disease, namely, the sensory elements of the optic apparatus in the brain and the sensory elements of the spinal cord, whose primary centers are the posterior spinal ganglia and whose double branches extend to the surface of the body in the peripheral nerves, and to the medulla oblongata through the posterior columns of the cord. While in the ordinary disease the spinal and optic neurons seem to be the ones most vulnerable they are by no means uniformly involved together. In 300 consecutive cases of tabes optic atrophy was present in thirty only, and in twenty-five of these cases blindness was present many years before any other symptoms of tabes, except knee-jerk, developed. In fact, the cases in which optic atrophy is an early symptom rarely present the typical symptoms or the usual course of the disease. This leads me to separate the spinal type of tabes from the optic type, and to consider them both as degenerative diseases of the sensory neurons, but not the same disease. In the spinal type optic atrophy may appear late, and in the optic type spinal symptoms may eventually develop, but in their mode of onset, origin, and course, these diseases seem to be distinct from each other. This necessitates the careful study of each case in order to determine the proper treatment.

I want to call attention to the general anemic ill-nourished condition of these patients and direct special attention to treatment for building them up. Even admitting that from sixty to seventy per cent. occur in individuals who have had syphilis I consider it most important to begin with the tonic treatment, and to defer the use of mercury and the iodids until the patient is in a better condition for their administration.

DR. SINKLER: There is no question that attention to the nutrition is of great importance in these cases, but the best results I have seen followed removal to a different climate, especially a mild climate like that of Florida or California.

DR. THOMSON: I fully endorse Dr. Starr's method of treatment, especially the use of cod-liver oil, but in certain cases I find it useful to apply the actual cautery to the spine. Another favorite measure of mine is the red-pepper pack.

DR. FOLSOM: In regard to the use of the iodids it seems to me important to begin them as soon as possible, and I believe they are of service in the building-up process.

DR. BOND: I agree with the last speaker, for usually these patients tolerate the iodids very well.

DR. CAREY: Perhaps it may not be inappropriate to

make a suggestion as to the time at which iodids should be given. I think it is a common practice to give the iodids on a full stomach, while as a matter of fact the iodid of potassium should be given without any liability of its coming in contact with starches and should, therefore, be given one or two hours after meals.

DR. JANEWAY: Last year I spoke of the treatment of chronic syphilitic fever by the mixed treatment, that is, moderate doses of the iodid, from 5 to 20 grains, with $\frac{1}{32}$ to $\frac{1}{20}$ of a grain of mercuric iodid, and the tincture of cinchona. I have been using this also in some cases of tabes with good results.

DR. STARR: I believe that antisyphilitic treatment is indicated in most of these cases, but I believe the most benefit is derived from first building up the general health.

KERNIG'S SIGN IN MENINGITIS*

was the title of a paper read by DR. J. B. HERRICK of Chicago.

KERNIG in 1884 described a phenomenon which he thought was found only in affections of the pia mater and which was never lacking in inflammations of that membrane. If a patient with meningitis be made to sit up as on the edge of the bed, the thigh being, therefore, at right angles to the body, it is found extremely difficult to extend the leg because of the presence of a marked flexor contracture.

My own observations have been made upon nineteen cases with six autopsies. Kernig's sign was present in seventeen, and in the two cases in which it was absent a single examination was made only a short time before death and it was noticed at the time that there was a general laxity of all the muscles. In most of the cases the sign was not necessary to the diagnosis but in some it was of considerable value. In twenty-five healthy individuals examined, this sign was not found in any case and in one hundred patients ill from other conditions than meningitis it was present in two, absent in ninety-eight. It would seem then to be as pathognomonic as rose-spots in typhoid or murmurs in endocarditis.

ON ASTASIA-ABASIA, WITH A CASE,*

was read by DR. J. C. WILSON of Philadelphia.

This is the tenth case reported by American writers. The patient was a woman, twenty-four years of age, whose family history showed on the paternal side an epileptic uncle and an aunt addicted to the use of morphin, while on the maternal side were two uncles, dipsomaniacs. Some closer relatives showed nervous tendencies. On January 16th she was aroused from sleep by ringing of the door-bell and received an indifferent telegram. The next day on attempting to rise she found it impossible to stand or walk. She described her condition in the following terms, "My left leg feels as if it were made of cotton," an expression already recorded in other cases and "I feel like a combination of a child learning to walk and a drunken woman." There are abrupt movements of flexion of the knees, followed by rapid extension and contortions constituting compensatory movements of the upper extremities in order to obtain equilibrium. On attempting to stand her knees bent and she would sink to the floor. Careful examination in every way failed to throw any light upon the condition. Treatment consisted in rest in bed, valerianate of zinc, in 1-grain doses, four times daily, and massage with electricity to the legs and feet. At the end of two weeks when allowed to get out of bed she was given lessons in walking. Improvement was rapid, but in a short time distinct hysterical manifestations appeared and she had to be isolated again, so I look upon the condition as a symptom of hysteria.

A CASE OF FAMILY PERIODIC PARALYSIS*

was reported by DR. J. K. MITCHELL of Philadelphia. He said: The case I wish to report is that of a boy, aged eighteen years, who has attacks of paralysis occurring at frequent intervals. He may retire perfectly well, but awake in the morning helpless, paralyzed from head to foot with total abolition of skin, muscle and tendon reflexes, loss of faradic and galvanic contractility, unchanged sensibility, and unimpaired mind and speech. Five cases of a similar nature have been seen in his mother's family. The boy has been kept in the hospital occasionally for periods of six months, so that careful blood examinations and a careful study of the body excretions could be made in order to determine if possible the presence of toxins. Whilst this has not been entirely successful I am not inclined to look upon the case as purely hysterical, but rather believe it is due to auto-intoxication.

SECOND DAY, MAY 3D.

DR. W. W. JOHNSTON of Washington, D. C., opened the proceedings by reading a paper, entitled

THE CONTINUED FEVER OF EPIDEMIC INFLUENZA.

The onset of fever is sudden in all cases of influenza. Sometimes a short acute, catarrhal stage is followed by prolonged fever, but more frequently the attack is very mild in the beginning, but progressive weakness and increasing fever finally forces the patient to seek medical health. As a rule, the evening temperatures are ascending for from two to five days. Defervescence is gradual, resembling typhoid, and the normal point is reached at different dates. The common characteristic of the latter stages of influenza fever is the long-continued minor oscillations and very delayed disappearance of the evening rise, long after patients have resumed a more active life. The recognition of the nature of this fever is sometimes difficult and it may be taken for enteric fever or even acute tuberculosis.

The second paper, entitled

SOME REMARKS ON TYPHOID FEVER AMONG THE AMERICAN SOLDIERS IN THE RECENT WAR WITH SPAIN,*

was read by DR. V. C. VAUGHAN, of Ann Arbor, Mich.

In August, 1898, Dr. Sternberg appointed a board consisting of Major Walter Reed, U. S. A., Major E. C. Shakespeare, U. S. V., and the writer to study the causes and the spread of typhoid fever among the troops in the various camps within the United States. The members of the board have been and still are engaged in this investigation. The work is not completed,

but the board feels justified in formulating certain conclusions. We have visited all the large camps in the United States, making direct personal inspections, studying the water-supply, the quality and quantity of food, and its method of preparation, the nature of the soil of the camp, the space allowed regiments, the arrangement and size of the tents and number of men occupying each one, the location of sinks with reference to the mess-tent, the disposition of fecal matter, etc. Medical and other officers were called upon for testimony. Then followed a study of the records in the Surgeon-General's office.

The first striking point appeared in the first day's work at Camp Alger and consisted in the lack of scientific diagnosis of typhoid fever; most of the febrile cases were found to be diagnosed as malaria. At once competent men were asked for and furnished promptly by Dr. Sternberg to go to the various camps and make scientific examinations of the blood and apply the Widal-test in febrile cases. As a result of these careful examinations it can be stated that malaria was a very rare disease among the troops that remained in the United States, not one case being found at Camp Alger, for instance, and only one at Chickamauga. Our full report will contain in detail the evidence and reasons for saying that practically all the protracted febrile cases were typhoid. Not only was typhoid diagnosed as malaria, but it was covered up by other names. For instance, in one regiment the death-rate from indigestion amounted to fifteen per cent. of all the cases, and in another nearly all deaths were attributed to dengue.

The origin of typhoid in the large encampments is easily determined. So widespread is typhoid fever in this country that in assembling a regiment of volunteers the probabilities are that one or more men will be found to be infected with the disease, and about ninety per cent. of the volunteer regiments that went to Chickamauga were infected when they reached that place. How did it spread among the troops? The evidence concerning the possibility of water infection is for the most part negative. The most potent factor at most of the camps was camp pollution with fecal matter. The epidemic was not due in any respect to the sending of Northern men to Southern camps. In most of the camps fecal matter was deposited in pits which were open, and flies swarmed over it, and then, of course, walked over the food at the mess-tents. In many regiments fecal matter was deposited about the camp on the ground, and there were pieces of woodland near Chickamauga Park through which one could not walk without soiling his shoes. In many regiments paper soiled with fecal matter was blown about the camps. In fact, there was no adequate provision for disinfection of stools and prevention of infection.

DR. STERNBERG: It is certainly discouraging that after the lessons of the Civil War we should have had a repetition of camp infection by a disease that we recognize as due to filth. I had hoped for better things, that the profession in general would more fully appreciate the dangers, and I issued a sanitary circular describing the means of avoiding such an infection. The line officers were many of them inclined to consider all talk about cleaning the camp, about flies carrying infection, etc., as a fad of the doctors, and would not recognize danger until the epidemic had occurred. I am afraid that the doctors throughout the country do not pay as much attention as they should to the sterilization of the excretions from typhoid patients, and these are the doctors that made up our regimental surgeons. Typhoid invaded practically all the camps, even those in Northern States, where the regiments never left the home camp. I can only hope that the results of this war may be impressed upon the profession, and that we may devise some way of avoiding similar disasters in the future.

DR. WILLIAM OSLER of Baltimore reported

A CASE OF HEMACHROMATOSIS, WITH EXHIBITION OF PATIENT.

The patient is a man of good family history, who noticed about four years ago that he had begun to change in color. He is a vigorous, healthy man, but on examination last Saturday I found a well-marked hypertrophic cirrhosis of the liver with enlargement of the spleen. He has the long duration of the disease, the increasing bronzing of the skin, the enlarged liver, and has had recurrent attacks of purpura. Examination of the urine shows the presence of iron.

DR. W. H. WELCH of Baltimore presented

A CASE OF HEMACHROMATOSIS, WITH EXHIBITION OF SPECIMENS.

I have brought over the specimens from a case of this disease which have been very thoroughly studied by Dr. Opie. The patient presented extreme pigmentation of the skin, and examination of the various organs of the body have shown that they are all more or less pigmented and have undergone hypertrophic changes. Two kinds of pigment are present, the iron-containing and iron-free pigment, the latter being found principally in the heart muscle and in the walls of the small intestine.

OTITIS MEDIA IN LOBAR PNEUMONIA OF CHILDREN

was the title of a paper by DR. S. J. MELTZER of New York.

In the course of the last fifteen years I have observed a number of cases of lobar pneumonia in children at the beginning of which earache was the first and predominant symptom. All the cases had in common the following points: earache at the onset of the disease, lasting usually only one or two days, never outlasting the disease, and in none did it terminate in a discharge from the ear. With two exceptions the earache was on the same side with the pneumonia, and as far as I could ascertain in all cases there had been at some previous time an otitis media in the now aching ear. The literature shows that otitis media is a very frequent complication of catarrhal pneumonia in children, but I have found no mention of its being a complication of lobar pneumonia. In lobar pneumonia of children purulent otitis media is at least very rare, and I offer the hypothesis that the earache is possibly only a sympathetic pain of a chronically inflamed drum.

A paper, entitled

ENDOCARDITIS OF TONSILLAR ORIGIN, WITH A REPORT OF FIVE CASES,*

was read by DR. F. A. PACKARD of Philadelphia.

One of the most interesting questions in medicine at the present time is the etiology of acute articular rheumatism and each year there is a steadily growing assurance that it should be classed among the acute infections. I believe that the cases I shall report have been plain cases of acute tonsillitis and pharyngitis having no connection with rheumatism, and that the endocarditis arose as a direct consequence either of infection of the endocardium by micro-organisms, which gained entrance by way of the tonsils, or to structural changes in the mitral leaflets brought about by coagulation necrosis or through results of chemico-vital action of toxins produced by micro-organisms in the throat and absorbed by the inflamed tissues. It may be said that the tonsillitis and the endocarditis were simply "rheumatics," but there was no preceding or subsequent history of the presence of other members of the rheumatic group or of any of the ordinary rheumatic manifestations.

A CASE OF FATAL EPISTAXIS WITH A STUDY OF THE BLOOD*

was reported by DR. GEORGE DOCK of Ann Arbor, Mich.

This patient came to the hospital January 10th on account of severe nose-bleed. Five weeks before the nose had bled for four hours, "filling a wash-basin," and a week later there was another attack which lasted three hours. These attacks have been repeated several times and required plugging of the nares. There was a continuous oozing of blood into the posterior nares. Examination of the blood showed red corpuscles 1,120,000, leucocytes 13,300, and hemoglobin 25 per cent. There was general pallor of the eyegrounds, and on January 27th edema of the lungs developed and the patient died of the increasing dyspnea. Autopsy showed an endothelial carcinoma of the turbinated bones, secondary anemia, edema of the lungs, fatty degeneration and liquefaction of the heart muscle and hyperplasia of the liver and spleen. The serous membranes were the site of considerable hemorrhage.

The most important feature in the study of the blood was the presence of enormous numbers of enucleated red blood-cells and it is a most remarkable fact that in spite of the evidences of blood formation the actual renewal of the patient's blood did not take place.

The next paper, entitled

EXPERIMENTAL RESEARCH DISPROVING THE THEORY THAT PARAXANTHIN POISONING IS A CAUSE OF MIGRAINE,

was by DRS. FRANZ PFAFF and J. J. PUTNAM of Boston.

Careful analysis of the urine from a number of patients with the symptoms typical of migraine indicate that there is no increase of paraxanthin. In considering the work of Dr. Ratchford we are inclined to believe that the results obtained from experimentation with final fluids were due to the fact that ammonium salts were not thoroughly removed.

THE ACTION OF HEPATIC, RENAL, AND OTHER CELLS UPON PHENOL AND INDOL, UNDER NORMAL AND PATHOLOGICAL CONDITIONS

was the title of a paper by DR. C. A. HERTER of New York.

Two methods were employed in this research. In one given weights of the normal liver, kidney, muscle, brain, and blood were minutely divided and then brought into contact with a known quantity of phenol or indol in watery solution and allowed to remain for periods of time varying from one to several hours, when the entire mixture was subjected to distillation. It was found that the distillate recovered from the liver contained less phenol than that from any other organ, and much less than that from a control distillate, making it clear that a certain amount of phenol was in some way transformed by contact with living cells. The blood and brain was found to possess only a slight transforming action, the kidney to act energetically, but less so than the liver, and muscle tissue to occupy a position intermediate. Similar results were obtained in the case of indol.

A second method of study consisted in introducing phenol and indol intravenously, killing the animals quickly and subjecting the triturated organs to distillation. These experiments justify the conclusion that the cells of the liver are more active than those of the kidney, muscle, or brain in removing aromatic substances from the blood and in effecting their rapid transformation.

Another series of observations was made with organs of animals placed under different pathologic conditions, such as prolonged anesthesia, poisoning by alcohol, staphylococcus septicemia, etc. These experiments indicate that some pathological conditions are capable of distinctly reducing the ability of the liver-cells to transform phenol and indol, and it was also found that the liver-cells in cases of fatty and cirrhotic livers were incapable of exerting their normal activity.

The next paper, entitled

ON THE TOXICITY OF THE URINE,*

was by DRS. F. FORCHHEIMER and R. W. STEWART of Cincinnati.

The conclusions as to toxicity of urine can be only tentative for all the cases; but positive for the majority. Those methods which exclude bacterial activity absolutely after the urine is passed are followed by comparatively no mortality. It would seem that most of the toxicity of urine is due to the formation of toxins by means of the action of bacteria upon some body or bodies in the urine. We are not justified in stating that there is no other toxicity, except that due to bacterial activity, but we are justified in making the statement that all those investigations that have been made in which this activity has been overlooked are to be regarded as inconclusive.

PERFORATION OF THE STOMACH BY A FOREIGN BODY IN AN INFANT SEVEN WEEKS OLD*

was reported by DR. T. M. ROTCH of Boston.

The patient, a child of seven weeks, was attacked suddenly with abdominal pain and vomiting. Symptoms of peritonitis developed, and on the fourth day a laparotomy was performed and the abdominal cavity irrigated. Three days later the infant died, and on post-mortem examination a minute perforation of the stomach was found in which was a small thread.

REVIEWS.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS. By LEWIS A. STIMSON, B.A., M.D., Professor of Surgery in Cornell University; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. John's, and Christ Hospitals; Corresponding member of the Société de Chirurgie of Paris. With 326 illustrations and 20 plates in monotint. New York and Philadelphia: Lea Brothers & Co., 1899.

PROFESSOR STIMSON'S volumes on fractures and dislocations, issued some fifteen years ago, have been classical sources of reference in difficult cases. The present single volume is the fruit of his riper experience, and "although in one sense of the word," as the author says in the preface, "this work is a second edition of the volumes published in 1883 and 1888, it has been so largely rewritten that it is practically new." The former two volumes have been condensed into one, a happy change in these days of the printing deluge, and their contents brought thoroughly up to date, for, though fractures and dislocations are as old as the race and the general principles of their treatment have long been known, there is an up-to-dateness of the subject very necessary for the general practitioner if he would save himself the worrisome opprobrium of imperfect or too slowly progressive results.

The work is characteristic of its writer in the thoroughly practical treatment of the subjects that divide surgical opinions generally just at present. While the book was in press we quoted (see MEDICAL NEWS, February 11, 1899) one of these eminently practical, thoroughly conservative, yet progressive views as to the vexed question of the treatment of fracture of the patella. Here is a like valuable opinion as to massage in the treatment of fractures: "A somewhat exaggerated opinion as to the value of massage has found expression in certain quarters. . . . A calmer and more judicial appreciation of its merits and limitations has succeeded. It appears to be beyond question that by its systematic and skilful use in suitable cases the primary swelling is lessened and disappears more promptly, the circulation and skin more rapidly regain their normal condition, the atrophy of the muscles is less and more promptly disappears, and the joints more quickly lose their sensitiveness and regain the range of motion which is possible under the changed skeletal conditions." Time was when the surgeon was satisfied if he got good union without deformity. The length of disability inflicted on the sufferer from fracture was scarcely considered, but now the *tuto cito et jucunde* of the healing art has invaded even the treatment of fractures, and massage is evidently an important factor in this since it brings the advantages claimed for it by Professor Stimson.

The practical suggestions as to the method of massage, the leaving on of one molded splint while the manipulations are carried on if there is much tendency to displacement, and the suggestion as to the use of the rubber bandage under certain circumstances as an instrumental masseur, evidently emanate from a man whose knowledge of the subject comes from large clinical experience.

The summing up as to the value of ambulatory treatment is as satisfactory as that with regard to massage. A hint as to its introduction by an instrument-maker begins the section on the subject and is characteristically expressive. The real value there is in the method under certain circumstances is shown. These subjects of massage and the ambulatory treatment of fractures are questions that the general practitioner and student are interested in just now because they have been a good deal discussed in the journals and at medical societies. The true function of the text-book is to give definite, not dogmatic views, on such subjects so as to enable the practitioner who faces "a condition, not a theory," to draw his own conclusions.

We had hoped to find an equally interesting discussion of the subject of sprain fractures around the ankle-joint, on which the Röntgen-rays have given us some new light of late years. Perhaps the subject was not considered sufficiently settled as yet to be able to state definite conclusions.

The skiagraphic illustrations of the book are excellently reproduced; some of the best we have ever seen. The Röntgen-rays are of the greatest value in the diagnosis of fractures, yet they do not do away with the necessity for thorough clinical experience in the matter.

THE PRACTICE OF OBSTETRICS BY AMERICAN AUTHORS. Edited by CHARLES JEWETT, M.D., Professor of Obstetrics in the Long Island College Hospital, Brooklyn, N. Y. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

THIS new text-book on the obstetric art represents the combined work of some of the best known writers on midwifery and cognate subjects in this country. A careful inspection of their labors shows that, under careful editing, they have succeeded in compiling a book of no ordinary merit, some parts of which, indeed, are classical in their worth. As a work of reference, it cannot well be excelled, for the opinions of the writers are supplemented by those of others of great weight and authority in the obstetric world. It may be that this very feature may detract from the worth of the book for the use of students who are notorious for their indifference as to the authority which is not that of their teachers. A serious student, however, like a serious practitioner, will be the gainer for having read and digested this book.

It is impossible in a weekly journal to review in minute detail a work of this size. The chapter on the diagnosis

fferential diagnosis of pregnancy is a splendid logical writing and embraces some new features ickinson). The physiology of labor (Drs. Jewett uckmaster) is well handled and is free from the n which usually characterizes this subject. Drs. o and Bartley discuss the physiology of the puerper- including the care of the new-born child.

In the chapter on the pathology of pregnancy, the subtitles are: "Multiple Pregnancy" (Dr. Manton), "Anomalies and Diseases of the Fetal Appendages" (Dr. Etheridge), "Pathology of the Fetus" (Dr. Van Cott), "Abortion and Premature Labor" (Dr. Vineberg), "Ectopic Gestation" (Dr. Henrotin), and "Diseases of Pregnancy" (Dr. Etheridge). Dr. Henrotin's article on ectopic pregnancy may be cited as an example of the modernness of the book; there is no doubt expressed as to the operative treatment of this condition as the only one; there is no dodging the question as there is in some not very ancient books on this subject. The late Dr. Etheridge's article, too, shows an advance in this direction, that every conceivable ailment from which a pregnant or a non-pregnant woman may suffer is not included among the diseases of pregnancy.

Part VI., dealing with the pathology of labor, includes a consideration of the anomalies arising from disease, accident or the forces at work, and a very readable paper on eclampsia (Dr. Edgar), in which the author repeats his opinion that veratrum viride is of great service in this condition. Personally, we do not favor the view of regarding insanity arising during the puerperium as an entity distinct from similar conditions minus the influence of child-bearing; but the article by Dr. Hamilton gives due credit to heredity and this is some gain in the right direction.

The monograph by Dr. Williams on puerperal infection is alone an excuse for the publication of the book if one were needed. He advocates the immediate repair of even slight tears of the perineum as prophylactic of infection, although he does not advise the same treatment of slight lacerations of the cervix; he objects to a routine examination of the internal genitals after the conclusion of labor as favoring sepsis; curetting he recommends only when the contents of the uterus are not septic and when a general sepsis has not already supervened. Hysterectomy for puerperal sepsis is to be performed only when the process is limited to the walls of the uterus and intra-pelvic abscesses are, of course, to be opened. This paper for scientific clearness and accuracy and thoroughness is one of the best in the book and on the subject. The work concludes with a complete series of articles on obstetric surgery.

Profuse and handsome illustrations, many of them original, help to make the book attractive. Altogether, as a well grouped, scientific exposition of the art of midwifery as it is taught at the present day, this work by American authors stands easily among the highest.

ESSENTIALS OF MATERIA MEDICA, THERAPEUTICS AND PRESCRIPTION WRITING. By HENRY MORRIS, M.D., Fifth edition. Philadelphia: W. B. Saunders, 1899. SAUNDERS' question-compends have always been popular among medical students, Dr. Morris' little book no less than the others of the series. The new edition is marked by ample reference to the newer drugs and by an insertion of dosages in the metric as well as in the apothecary systems.

THERAPEUTIC HINTS.

To Facilitate Feeding in Infantile Stomatitis.—It is very desirable to diminish the sensitiveness of the inflamed surface in this condition so that nourishment will be taken regularly by the child, and for this purpose orthoform has been used with success. Ten to twenty minutes before nursing or feeding a sufficient quantity of the drug, very finely powdered, is spread over the affected surfaces by insufflation. Care should be taken to avoid the soft palate and the pharynx as the unpleasant taste of the drug is otherwise made perceptible. No ill effects need be feared, and the analgesia obtained enables the child to take its nourishment willingly.

For Dyspepsia with Deficient Muscular Action. — MATTHIEU considers bicarbonate of soda and ipecac to be most valuable for the stimulation of muscular action in the stomach. The soda should be taken an hour before meals, 45 grains at a dose, the ipecac in small doses ($\frac{1}{30}$–1 grain), repeated several times at half-hourly intervals after meals. The following formulæ are recommended:

1. ℞	Tinct. ipecac. . . .	ʒ iss
	Saccharini	gr. iss
	Menthol	gr. iv
	Spiritus (80 per cent.) . .	ʒ i
	Syr. simpl.	ʒ iv.

M. Sig. Two to four teaspoonfuls.

The menthol is added in order to control the nauseating action of the ipecac.

2. ℞	Tinct. ignatiæ . . .	ʒ iss
	Tinct. ipecac. . . .	*m.* xv
	Tinct. anisi	*m.* lxxx.

M. Filter. Sig. Six drops in Vichy.

The treatment should be continued for periods of 10 to 15 days, with intervals of rest of one week. As the muscular power increases the secretions are also affected favorably.

Toxicity of Orthoform.—Part of the praise heaped on this drug in its capacity of local anesthetic agent is based on the belief that no toxic effects can be ascribed to it. DRS. ALBERTIN, POLLESSON, and ROLLET of the Lyons Hospital have, however, reported several cases in which the application of orthoform to an extensive surface (as for burns) has been followed by symptoms of intoxication (headache, nausea and vomiting, fever, and erythema) which disappeared shortly after removal of the applied drug. The symptoms, while not severe enough to be dangerous, were very unpleasant, and sufficed to indicate to the physicians in charge that orthoform should be used cautiously and in small quantities.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.
VOL. LXXIV. NEW YORK, SATURDAY, MAY 20, 1899. NO. 20.

ORIGINAL ARTICLES.

SYPHILIS OF THE EYE AND ITS APPENDAGES.[1]

BY CHARLES STEDMAN BULL, M.D.,
OF NEW YORK.

IT is not possible, in the brief time alloted to this paper, to give any detailed account of the various syphilitic affections of the eye and its appendages. It has, therefore, been deemed wiser to refer very briefly to the rarer lesions of a syphilitic nature met with here, and to devote most of the paper to an account of the commoner syphilitic affections which are likely to be encountered by the general practitioner. To this end I shall begin with the anterior or superficial lesions; those which are recognizable by the naked eye without the aid of any instrument of precision.

Syphilis of the Eyelids.—In the eyelids we meet with four varieties of syphilitic lesions: (1) The chancre; (2) papules or tubercles, the so-called tubercular syphilide; (3) rupial ulcerations; (4) gummata. These all occur in both lids, more frequently the lower lid, and at both canthi; and usually involve the edge of the lid.

The chancre may occur on the edge of the lid, involving both skin and conjunctiva, though it is sometimes met with on the skin surface alone, or on the conjunctival surface alone, or very rarely on the conjunctiva of the eyeball. It probably originates by inoculation of the virus in the mouths of the excrepry ducts of the glands of the skin or mucous membrane. It begins as a small pimple with much itching and irritation. Then the summit becomes excoriated, the ulcer grows broader, but rarely deeper, and assumes a saucer shape. The edges are firmly indurated, and the floor is moist and covered with grayish-yellow débris. The base is distinctly indurated for some distance beyond the ulceration, and the lid may be much swollen. Induration of the neighboring glands is an almost constant symptom.

The two principal modes of contagion are unclean fingers, and the diseased mouth, lips, and tongue.

Diagnosis.—The resemblance of a chancre to a broken-down or ulcerated tubercular syphilide is often misleading. The latter has not the characteristic induration, and its edges are sharply punched out. A hordeolum has an acute course, is painful, its base is not indurated, and it heals rapidly after being opened. A chalazion has a narrow, deep opening, with soft edges, and no induration. Rodent ulcer and epithelioma have some points of resemblance to a chancre of the edge of the lid, but they occur, as a rule, late in life, have a red, granular surface, and the ulcer tends to spread along the lid, healing as it extends. Lupus may be confounded with a chancre, but is rarely confined to this site, and may be discovered elsewhere on cutaneous and mucous surfaces. Chancre of the lid is chronic and indolent, and is not very responsive to treatment. The induration is persistent and may remain for months after the ulcer has healed. It rarely leads to any serious loss of substance or distortion of the lid. Local treatment is of little or no avail.

Syphilitic eruptions of the eyelids are usually of the papular or tubercular variety. They are quite common on the skin surface, but are rarely met with on the conjunctival surface. They may occur at any age, and at almost any period of the constitutional infection. They may be confined to the skin, or may involve the entire thickness of the lid. They often ulcerate, the center of a papule or tubercle breaking down or sloughing. The papule may be of rapid growth and great size, but it does not extend deeply, and the destructive process is superficial. A tubercular syphilide extends more deeply and, in some cases, presents the appearance of a diffuse gumma. Microscopically, the two are one. The resulting ulcer is a deep, punched out cavity with mucous edges, irregularly crescentic in shape, and covered with a brownish-red deposit or crust. The tubercular syphilide originates in the corium or subcutaneous cellular tissue, and is painful on pressure. It may cause deep destruction and distortion of the lid. When healed the cicatrix has a central depression and peripheral pigmentation. It may be confounded with lupus, but the latter extends slowly, the nodules are softer and rarely suppurate, and the cicatrix is diffuse and white. From epithelioma it must be distinguished mainly by the results of constitutional treatment.

Gummata, when confined to the skin or edge of the lids, are not common. They are characterized by a dense, board-like hardness, and the skin becomes of a reddish-brown color. When nodular and

[1] Read before the New York Academy of Medicine, March 16, 1899.

isolated, they are one and the same with a tubercular syphilide. When diffuse, the whole lid is swollen. The process may be either acute or chronic, and usually other symptoms of syphilis are present. When the whole tarsus seems to be infiltrated, it has received the name of tarsitis syphilitica. The infiltration is chronic and indolent and is generally located in the upper lid. There is no pain and no secretion. The tumor is hard and resisting, the lid cannot be everted, and ptosis is present. The swelling is homogeneous, and the skin is not usually involved. The cure is never a complete one, for after the absorption of this dense infiltration, more or less deformity of the tarsus remains, and it has entirely lost its normal resistance.

Syphilis of the Conjunctiva. — Syphilitic lesions occurring primarily in the conjunctiva are not common, especially in the cul-de-sac or ocular conjunctiva.

Conjunctivitis.—In syphilitic patients we not infrequently meet with an obstinate conjunctival inflammation, with little or no secretion, which does not yield to the ordinary local applications, but does to appropriate constitutional treatment. It is very apt to accompany cases of obstinate syphilitic iritis.

Chancre.—The chancre of the conjunctiva, not involving the eyelid, is a very rare lesion. It has been met with in the cul-de-sac, where the palpebral conjunctiva is reflected over upon the eyeball; and also in the ocular conjunctiva near the corneal margin, and in the lacrimal caruncle.

Syphilitic Eruptions.—Papules or pustules of the conjunctiva appear as small, circumscribed, elevated, non-vascular spots of a reddish-gray or coppery color. They may appear singly, or several may develop close together and subsequently coalesce.

Mucous patches on the conjunctiva closely resemble mucous patches met with on other mucous membranes. They may ulcerate, and then appear as shallow, irregular sores, with a tawny surface and ill-defined base. They respond readily to treatment, and cause but little contraction of tissue. When the papules or pustules ulcerate they have a fatty-looking coating, irregularly eroded edges, and uneven base. They usually cicatrize rapidly, and if on the edge of the lid, the cicatrix appears as a tendinous white cord. The isolated occurrence of these superficial ulcers of the conjunctiva has been regarded as symptomatic of constitutional syphilis.

Gummata.—True gumma of the conjunctiva is the least common of all syphilitic lesions of the eye, and is always a late manifestation of the disease. It may be either circumscribed or diffuse. It appears as a small, discrete nodule in the conjunctiva, varying much in size, with a yellowish summit and a red base. It tends to disintegrate and ulcerate rapidly. If these gummata appear in the ocular conjunctiva, they may coalesce and form a zone of dense infiltration around the cornea, interfere with its nutrition, and cause ulceration or abscess.

Congenital Syphilis.—The poison of inherited syphilis does not seem to have any marked tendency to manifest itself either in the conjunctiva or eyelids, though patches of excoriation and actual loss of substance are occasionally met with in connection with similar manifestations on the face and scalp. The skin of the lids in syphilitic infants is usually thick and opaque, and the ciliary margins of the lids often show little pits and scars, the signs of former eruptions. We sometimes meet with well-marked instances of blepharo-adenitis of syphilitic origin, with patches of excoriation with sharply defined edges, and of irregular shape, near the canthi. The whole edge of the lid is then apt to be inflamed and swollen. No mucous patches or gummata are ever met with in these syphilitic children.

Syphilis of the Lacrimal Apparatus.—Constitutional syphilis rarely attacks the lacrimal apparatus primarily. The most frequent source of secondary affections of these organs is orbital periostitis, or periostitis of the nasal duct. Inflammation and ulceration of the nasal mucous membrane extends by contiguity of tissue to the lining of the nasal duct and thence to the lacrimal sac. Then follow more serious lesions of the nasal duct with the group of symptoms so familiar to all, of purulent discharge from the sac, stricture of the duct, phlegmonous inflammation of the overlying tissues, ending in abscess and the formation of a lacrimal fistula. Finally caries and necrosis of the nasal process of the superior maxilla take place, which usually permanently distort or obliterate the nasal duct.

Lacrimal Gland.—Inflammation of the lacrimal gland occasionally occurs from extension of the process from an orbital periostitis to the fibrous envelope of the gland and thence to the connective tissue framework of its interior. There is usually exophthalmos, severe pain, and a distinct swelling at the upper and outer angle of the orbit. The lacrimal gland has also been known to be the seat of a gummatous infiltration, a secondary process extending from the surrounding connective tissue. The symptoms are the presence of a tumor at the upper and outer angle of the orbit, displacement of the eyeball downward and inward, at times severe pain in the orbit, and extreme sensitiveness to pressure. The tumor not only extends backward into the orbit, but forward beneath the conjunctival cul-de-sac and upper lid, causing ptosis.

Lacrimal Caruncle.—The caruncle may become

inflamed in consequence of dacryocystitis or caries of the lacrimal bone, and may also be involved in a chancre, which has occurred at the inner canthus of the lids, or in the neighboring ocular conjunctiva. Gummatous infiltration of the caruncle has been described by Dr. R W. Taylor of this city. The caruncle becomes enormously enlarged, deep red in color, firm to the touch, and protrudes between the edges of the closed lids. Persistent antisyphilitic treatment causes a reduction in the growth and eventually atrophy of the caruncle.

Dacryocystitis and Stricture of the Nasal Duct.—This disease almost always extends from the nose, either through the medium of an inflamed and ulcerated mucous membrane or as a result of primary periostitis of the nasal duct or lacrimal bone. There is more or less epiphora, a sense of distention over the sac, then swelling with a discharge of mucus or pus from the puncta on pressure over the sac, phlegmonous inflammation of the overlying tissues, pointing of the abscess, ulceration and the formation of a fistula. It may be both an early and a late manifestation of the constitutional disease. The formation of a fistula should be prevented by an early incision of the cauliculi and sac and thorough division of the stricture of the duct, with the passage of a large-sized steel probe, while persistent constitutional treatment is kept up. If the disease has been of long standing, extensive disease of the superior maxilla is certain to be found, and it may prove impossible to open the caliber of the duct, on account of extensive disease of the bone, which may be either of a carious nature, or more rarely due to a hyperplastic process, with the formation of exostoses or periostoses in the orbital walls. Even here persistent antisyphilitic treatment often works wonders. Should the duct be found obliterated, it will be well to destroy the lacrimal sac by deep cauterization from the anterior surface, and allow the resulting cavity to close by granulation.

Chronic dacryocystitis with stenosis of the nasal duct is by no means an infrequent occurrence in inherited syphilis, and is due to disease of the bony walls of the duct, with periostitis and the development of exostoses.

Syphilis of the Cornea and Sclerotic.—The corneal lesions associated with *acquired* constitutional syphilis may be classified as follows: (1) Diffuse parenchymatous keratitis, which may involve either the center or periphery of the cornea, and which is always accompanied by iritis. (2) The true keratitis punctata in which numerous punctate foci of infiltration appear in the parenchyma of an otherwise transparent cornea, without iritis. (3) A later stage of the preceding, in which the punctate deposits are accompanied by a generally cloudy cornea and by iritis. (4) Gummatous degeneration of the cornea.

Parenchymatous or interstitial keratitis is far more frequently the result of inherited, than of acquired, syphilis. The acquired form is characterized by a cloudy opacity in the deeper layers of the cornea, consisting of a number of irregular, yellowish-gray spots, more or less closely connected together. These spots usually first appear at the center of the cornea and extend toward the periphery. In this cloudy parenchyma vessels are seen to enter at various depths. The deep circum-corneal ciliary injection is generally absent, and the subjective symptoms of photophobia and lacrimation are but little marked. The process is always slow, lasting not only weeks, but months and even years, and never ulcerates.

True *keratitis punctate* is characterized by the deposit of circumscribed gray spots in the parenchyma. There are no blood-vessels visible, and the intervening corneal tissue is transparent. These spots may disappear as rapidly as they appear, and they never suppurate. The iris does not seem to be involved in these cases.

Gummatous infiltration of the cornea begins at the periphery and extends a varying distance into the parenchyma. It closely resembles a tubercular syphilide, and usually breaks down and suppurates just as the latter does, and ends in perforation of the cornea.

All these varieties of keratitis belong to the late period of constitutional syphilis. They are all very chronic, but yield to persistent treatment. The local treatment consists of hot fomentation, atropin and cocain, and leeches to the temple

The Cornea in Inherited Syphilis.—Our knowledge of the form of keratitis occurring in the subjects of inherited syphilis, we owe mainly to Mr. Jonathan Hutchinson. Chronic interstitial keratitis here begins as a diffuse haziness at the center of the cornea of one eye, with little or no evidence of congestion. There is some irritability of the eye and dimness of vision. The opacity consists of dots in the parenchyma, which at first are distinct from each other. In the course of a few weeks the whole cornea has become more or less densely opaque by extension and confluence of these punctate deposits. The appearence of the eye in this stage has given rise to the name "ground-glass cornea." There is then developed a zone of ciliary injection, and there is photophobia and pain. After a varying period of weeks or months the other cornea is attacked and follows the same course. Vision may be reduced to perception of light. This is sometimes followed by a still more severe stage, in which the whole cornea

becomes scarlet from enormous development of vessels in the parenchyma. The clearing up of the opacity is always excessively slow, but in the course of a year or more the improvement is decided. Even in the most favorable cases, the vision is never quite entirely regained. Almost all these patients present a peculiar physiognomy, consisting of a coarse, flabby skin, pits and scars in the forehead, scars of old fissures at the angles of the mouth, a sunken bridge to the nose, and a set of permanent teeth peculiar for their small size, bad color, and crescentically notched edges of the central upper incisors. When interstitial keratitis and the notched "Hutchinson teeth" are met with in the same patient, the two symptoms are pathognomonic of inherited syphilis. Most of these cases occur in children between the ages of eight and fifteen years. This keratitis is rare in infancy and very rare in adult life.

Syphilis of the Sclerotic.—In this dense, fibrous membrane, syphilis causes two processes: (1) Episcleritis or scleritis, the two being different phases of the same lesion, and (2) gummatous infiltration of the sclerotic.

Episcleritis or Scleritis.—The symptoms are one or more patches of deep congestion on the eyeball, more or less infiltration of the superficial layers of the sclera and a corresponding elevation of the conjunctiva. The vascular injection is deep red or purple in color, and is very deep. There is dull pain and a sense of pressure in the eye. There may be complications on the side of the iris and ciliary body. The disease is very chronic, rarely ends in suppuration, and always leaves behind it a bluish or brownish discoloration. If very chronic in its course, the sclerotic becomes very much thinned from atrophy, and allows the choroidal pigment to become visible; and this always favors the development of staphylomata.

Gumma of the Sclerotic.—This is a purely localized infiltration, somewhat distinctly circumscribed. The growth is generally flattened, but sometimes attains a large size. These gummatous deposits usually occur in the course of the straight muscles of the eye, and are more frequent on the temporal side of the eye. They are moderately hard, sensitive to the touch, and very vascular. Persistent constitutional treatment will effect a cure, but with some distortion of the eyeball. Gumma of the sclera is always a late manifestation of the disease and rarely exists without the choroid or iris also being involved.

Syphilis of the Uveal Tract, Iris, Ciliary Body, and Choroid.—Syphilis may involve the entire uveal tract in one eye alone or in both eyes simultaneously or it may involve the iris or choroid alone. The ciliary body is probably never alone involved.

Syphilis of the Iris.—Iritis is one of the most frequent symptoms of constitutional syphilis. It is in the great majority of instances an early lesion, though it is met with as a late manifestation. As a rule only one eye is attacked at first, though the other soon becomes affected. It may be of three varities: plastic, serous, or gummatous. The first two varieties do not differ in their symptoms from iritis due to other causes. The sole variety of iritis absolutely indicative of syphilis is the iritis gummosa, and to this variety alone should the term "syphilitic iritis" be applied.

Symptoms.—In plastic iritis these are: deep ciliary injection forming a zone of short, deep, straight vessels around the corneal margin; turbidity of the aqueous humor; swelling and discoloration of the iris; more or less immobility of the iris; irregularity in the shape of the pupil; exudation in the field of the pupil, upon the capsule of the lens; photophobia; lacrimation; defective vision; pain, and increased tension of the eyeball. All of these symptoms may be present, though some are occasionally wanting.

In serous iritis, in addition to the above symptoms, there is a punctate deposit of exudation upon the posterior surface of the cornea. This form of inflammation usually involves also the ciliary body and choroid.

In iritis gummosa the real syphilitic iritis, in addition to the above symptoms, there may be seen in the iris one or more distinct, yellowish-red, nodular elevations, varying in size from a hemp-seed to a pea, either in the sphincter region, or at the periphery, which show a tendency to coalesce.

The prognosis is generally good in the plastic or serous varieties, but doubtful in the gummatous form owing to the tendency of the disease to extend to the ciliary body and end in atrophy of the globe.

Treatment.—The local treatment should consist of hot applications frequently repeated, atropin more or less frequently, leeches to the temples if the pain is severe, and dark glasses. Except in very bad cases, these patients need not be kept in a darkened room. The patient should be brought under the influence of mercurials as rapidly as possible and, if the lesion is a late manifestation, potassium iodid in large doses should be administered. If the attack has resulted in permanent adhesions between the iris and the capsule of the lens it may be necessary subsequently to perform iridectomy in order to allow the iris more play, and to prevent relapsing attacks of iritis and the dangers of subsequent glaucoma.

Syphilis of the Ciliary Body.—Cyclitis, like iritis, may be plastic, serous, or gummatous. It is a serious disease tending to destruction of the eye, and the prognosis is always unfavorable.

Symptoms.—These are usually ciliary injection, very severe pain, tenderness on pressure, diminished tension, diminished vision, due to exudation into the vitreous humor, and a plastic exudation between the posterior surface of the iris and the suspensory ligament and capsule of the lens. The aqueous humor is turbid, and there may be punctate deposits on the posterior surface of the cornea. In cyclitis gummosa the gummatous infiltration has a strong tendency to involve the sclerotic and iris. Here the prognosis is most unfavorable, the whole eyeball tending to shrink rapidly into phthisis bulbi. The treatment locally and generally is the same as for iritis.

Syphilis of the Choroid. — Syphilitic choroiditis may be divided into two classes: one which attacks the anterior segment of the choroid, and is usually connected with iritis and cyclitis, and that variety which is more or less closely confined to the posterior segment of the eye. Both these varieties are known as choroiditis disseminata. The first variety is usually called irido-choroiditis, is always of a severe type, with boring pain, rapidly failing vision, dense opacities in the vitreous, diminution of tension and, in bad cases, rapid atrophy of the eyeball, contraction of the vitreous, and detachment of the retina. The posterior choroiditis is almost always a chronic process, and always involves the retina, and hence, the disease should be called chorioretinitis. Ophthalmoscopically, the disease shows in reddish-yellow or yellowish-white patches of exudation of irregular shape and size, accompanied by a fine dust-like opacity in the anterior part of the vitreous. These patches soon tend to assume an atrophic aspect, and are then surrounded by a zone of pigment. There are several different varieties of this posterior inflammation, which are not easy to differentiate. In the anterior form of the disease the opacities in the vitreous are cobweb-like, or densely membranous, which are sometimes fixed and sometimes floating. The vision is always at once and materially affected.

Treatment.—The treatment consists in the local use of atropin to put the ciliary muscle at rest, occasionally, leeches to the temple; dark glasses, plenty of fresh air, and the bringing of the patient as rapidly as possible under the influence of mercury and potassium iodid. Should the optic nerve become affected strychnin is indicated. The disease is very obstinate in resisting treatment, and the vision is always permanently impaired, even in the most favorable cases, owing to the retina being involved in the degenerative process. The whole uveal tract may be involved in children as a result of inherited syphilis, and even intra-uterine iritis and choroiditis disseminata have been found in the newborn child. In some cases the writer has seen both pupils blocked by plastic exudation from an intrauterine iritis.

Syphilis of the crystalline lens, as a primary disease, is unknown. Opacities of the lens and its capsule are met with in syphilitic patients, but only as a result of inflammation of the uveal tract.

Inflammation of the vitreous humor, or hyalitis, never occurs primarily from constitutional syphilis. It is always due to cyclitis or choroiditis.

Syphilis of the Retina and Optic Nerve.—Inflammation of the retina alone, distinct from optic neuritis, is not a common lesion in constitutional syphilis. Associated with choroiditis it is one of the commonest symptoms met with.

Simple retinitis is a rare disease, diffuse in character, and its symptoms are mainly ophthalmoscopic. The fundus is indistinct, there being a distinctly defined mist-like, grayish opacity extending over the posterior zone, and like rays along the course of the blood-vessels. The outlines of the optic disc are blurred, and the disc is very hyperemic, owing to the presence of engorged veins. There is marked diminution of central vision, with a central scotoma in the field, which may be annular. There is night blindness; there are various photopsic manifestations, and sometimes there is photophobia. The prognosis is usually favorable and vision is restored under proper treatment, but the disease is subject to relapses. If the optic nerve becomes involved in the process the prognosis is unfavorable.

Sometimes the retinitis is of the exudative type, with patches of yellowish deposit all over the fundus, accompanied by hemorrhages. This does not differ from the same disease due to other causes, and the prognosis is much more unfavorable.

Central recurring retinitis is a very rare form of syphilitic disease. It is characterized by an opacity in or at the macula, and the appearance of small, white, punctate spots grouped around it. The disturbance of vision and the opacity at the macula appear suddenly, disappear in a few days, but recur in a few weeks. In subsequent attacks there occur irregular white streaks, radiating from the optic disc in all directions. The prognosis is rather unfavorable on account of the marked tendency of the disease to recur again and again.

Almost all cases of retinitis due to syphilis are associated with inflammation of the optic nerve and should be classed under the head of neuro-retinitis.

Syphilis of the Optic Nerve.—When the optic nerve is affected by syphilis, there may be marked ophthalmoscopic changes in the optic disc, or none at all. The visible ophthalmoscopic changes are of three kinds, *viz.*, papillitis or "choked disc," neu-

ritis descendens, and atrophy of the disc. When no ophthalmoscopic changes are visible, the symptoms are all subjective, and consist of, first, amblyopia or amaurosis; second, hemianopsia dependent on disease of some portion of the optic tract between the chiasm and the occipital lobe; third, a flittering scotoma. The optic nerve may be affected in some portion of its entire course independently, or secondarily, by propagation of the diseased process from the surrounding tissues. When both eyes are simultaneously affected, it is proof that the lesion has involved either the sheath of the optic nerve, or the nerve itself, or both.

Papillitis, or Choked Disc.—This is an inflammation of the intra-ocular end of the optic nerve. It is characterized by intense swelling of the optic disc due to general edematous infiltration, marked stasis in the retinal veins and ischemia in the retinal arteries. The edema extends a varying distance into the surrounding retina. Bilateral papillitis points to the existence of some intracranial process which has caused an increase of the intracranial tension and indirect compression of the optic nerve, but it does not indicate the nature of the lesion which has caused the increased tension. If the papillitis is unilateral, the lesion may be situated entirely within the orbit. The defect in vision does not always correspond to the ophthalmoscopic picture. There may be very little disturbance of vision and no defect in the visual field.

If taken in time the prognosis of papillitis, if the cause is intra-orbital, is fairly good under proper treatment. If the lesion is intracranial, the prognosis is always doubtful.

Neuritis Descendens.—This depends on inflammatory changes in the nerve substance itself, caused by an extension of an inflammatory process from the surrounding tissue to the sheath of the nerve, and thence to the nerve-fibers. This process may extend to the nerve-fibers from the central parts of the brain. Unilateral neuritis descendens points to a lesion in the corresponding nerve-trunk between the chiasm and the orbital end of the nerve. Bilateral neuritis descendens points to a lesion in the nerve between the chiasm and occipital lobe. The most common cause is some gummatous infiltration of the brain or meninges. Vision is first affected peripherally and the defect generally extends toward the center. Both papillitis and neuritis descendens may end in an atrophy of the optic nerve.

Atrophy of the Optic Nerve.—Three forms are met with: (1) Inflammatory atrophy due to papillitis or neuritis descendens. (2) Cerebral atrophy. (3) Spinal atrophy.

In inflammatory atrophy, the disc is an opaque, dirty yellowish-gray color, with blurred outline, and obscured by a mist. The arteries are very much reduced in caliber and surrounded by white streaks (perivasculitis). In cerebral atrophy, the disc is brilliantly white, the outline sharply cut, the lamina cribrosa very distinct, and the vessels but slightly reduced in caliber. In spinal atrophy the disc is bluish-white, the outline sharply defined, and the vessels but slightly reduced in caliber. This is the kind of atrophy met with in ataxy.

In those cases of optic nerve trouble with no ophthalmoscopic evidence of disease we must depend on the presence of functional disturbances to form an opinion as to the location of the lesion. If the loss of vision is confined to one eye, the lesion *may* be in front of the chiasm, though it may also be situated in the posterior part of the internal capsule, or even in the cortex. If it is in the internal capsule, there is also present contralateral anesthesia of the other cranial nerves.

In left lateral hemianopsia the lesion must be sought in the right optic tract. In right lateral hemianopsia, it is in the left optic tract, between the chiasm and the occipital cerebral lobe, and usually between the cerebral peduncle and the chiasm. In rare instances both retinitis and optic neuritis have been found in new-born children, the results of inherited syphilis of the intra uterine type.

Syphilis of the Ocular Muscles and Motor Nerves.—Pure myopathic processes due to syphilis scarcely ever occur in the ocular muscles, the lesion almost always involving the motor nerves or their nuclei, and this lesion may be located in the brain, or at the base, or in the orbit. In the latter case the cause is a lesion of the orbital wall, involving the origin of the muscles. Syphilitic paralyses of the ocular muscles are generally late manifestations, rarely occurring within the first six months. They may develop rapidly or slowly, and are obstinate in resisting treatment. Many never are cured. The lesion is usually a gummatous infiltration at the base of the brain, or endarteritis in the vicinity of the nuclei. Isolated paralyses of the eye-muscles are not infrequently the first symptom of general syphilis.

In about three-fourths of the cases it is the motor oculi which is affected, and the abducens in about one-fourth. A very frequent form of syphilitic paralysis is unilateral ophthalmoplegia interna, or paralysis of the sphincter iridis and of the ciliary muscle, and about three-fourths of such cases are syphilitic. Here the cause is endarteritis. Paralysis of the fourth nerve due to syphilis is very rare. Sometimes these ocular paralyses are very late symptoms, the constitutional disease has apparently been cured, and are then usually the forerunners of tabes.

Symptoms.—The most common symptom is diplopia, which may be either homonymous or heteronymous. If the third nerve is affected, in whole or in part, the images are crossed or heteronymous. If the sixth nerve is involved the images are homonymous. In the former case there may be a divergent squint; in the latter, a convergent squint. If there is a difference in the height of the images, the superior or inferior rectus is involved, and it is again the third nerve. If the entire trunk of the third nerve is involved, the eye is divergent, there is ptosis from paralysis of the levator palpebræ, the iris is widely dilated, and the accommodation is paralyzed.

The prognosis is fairly good, but the longer the paralysis has lasted the more unfavorable is the outlook for a cure. There are some rare instances of muscular paralyses due to inherited syphilis.

Syphilis of the Bony Walls of the Orbit.—Disease of the bony walls of the orbit is not a very common manifestation of syphilis. The lesions which occur here are: (1) osteoperiostitis; (2) gumma or syphiloma of the periosteum; (3) periostosis, hyperostosis or exostosis; (4) caries and necrosis. They are all late manifestations of the disease.

Osteoperiostitis may be acute or chronic. It is manifested by pain and swelling, generally around the orbital margin, and exophthalmos, if the lesion be deeply seated in the orbit, the protrusion being to one side instead of straight forward.

Gummatous periostitis or gumma of the periosteum is always a slow, chronic process, and involves generally the superior orbital margin, but cases have been met with where the syphiloma developed at the bottom of the orbit, in which case the most marked symptom would be the exophthalmos. Both these processes may end in caries and necrosis, in which case a fistulous opening is formed either through the conjunctiva, or through the tarso-orbital fascia and lid, and several sinuses may form and open at a long distance from the real site of the disease.

The varieties of chronic hyperplastic bone disease met with in the orbit are periostosis, hyperostosis, and exostosis. They are all of rare occurrence, and may go on without any signs of inflammation until the excessive development of bone tissue has reached an enormous size. The exostoses, however, are generally the result of long continued periostitis with suppuration. These diseases are interesting mainly from their rarity, for they respond but slowly or not at all to treatment. In rare cases, however, orbital exostoses disappear rather rapidly under treatment. Periostosis and hyperostosis have in a few instances been met with in young children, the subjects of inherited syphilis.

ETIOLOGY AND FREQUENCY OF SPORADIC PURULENT MENINGITIS.

BY L. NAPOLEON BOSTON, M.D.,
OF PHILADELPHIA;
BACTERIOLOGIST TO THE PHILADELPHIA HOSPITAL; INSTRUCTOR IN OBSTETRICS IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

THE records of post-mortems made at the Philadelphia Hospital from April 4, 1894, to October 26, 1898, show that during this time there were eighty instances in which some form of meningitis was present. The number of cases in each variety is as follows[1]: Leptomeningitis, 8; basilar meningitis, 9; pachymeningitis, 20; pachy- and basilar meningitis, 4; basilar and leptomeningitis, 3; complicating typhoid fever, 1; basilar (subacute) 2; chronic, 10; hemorrhagic of brain, 1; hemorrhagic of cord, 2; hemorrhagic tubercular, 1; tubercular, 6; purulent, 13.

The etiologic factors that may contribute toward sporadic cerebrospinal meningitis are many, and rarely the same as that of the epidemic variety; however, in most instances, sporadic cases of purulent meningitis are secondary to a similar infection elsewhere, as disease of the cranial bones, otitis media, mastoid, nasal, or ethmoid disease, erysipelas of the scalp,[2] traumatism, or by extension along the cranial vessels or nerves. Aside from these cases due to direct extension, there are cases of metastatic meningitis, which may be encountered accompanying pneumonia, rheumatism, dysentery,[3] endocarditis, empyema, puerperal sepsis, anthrax and scarlet, typhoid, and other fevers, where the exciting cause is carried through some of the circulatory channels; and lastly, cases due to no describable cause other than primary infection. It is the second and third varieties that I wish to illustrate by the following cases (Case I. is reported through the courtesy of Dr. John Guiteras, Pathologist, and Dr. David Riesman, Assistant Pathologist, and Case IV. through that of Dr. Frederick Packard):

CASE I.—S. S., male, black, aged thirty-one years, was admitted to the medical ward with the following history: cough, pain in left side, headache; had been expectorating blood-streaked material for some days. Physical examination disclosed all evidences of lobar pneumonia, affecting the base of the left lung. Conjunctivæ jaundiced; examination of urine showed presence of bile-pigment and albumin. Two days later he developed severe pain in the abdomen and head, followed by wild delirium, nystagmus, ptosis, and aphasia, which were soon followed by coma and death.

Autopsy showed extensive purulent meningitis, the exudate covering the entire brain, but more

[1] Classified from pathological diagnosis and notes.
[2] Analysis of 1674 cases of erysipelas showed meningitis as a complication in one instance (Anders).
[3] Two purulent cases complicated dysentery.

marked at the base and in the parietal regions. The spinal cord was not examined. There was consolidation of the left lung involving the entire lower lobe and a portion of the superior lobe (stage of gray hepatization). The kidneys were in a state of cloudy swelling. Other viscera showed jaundice and the usual changes present in febrile conditions. Cultures contained only pneumococci as did cover-slip smears from the meningeal exudate.

Case II.—F. C., female, aged thirteen years, was admitted to the nervous ward in a semi-comatose condition. Friends stated that her trouble began four days before admission by pain in the head, neck, and back. The head was retracted and drawn to the left, eyes turned to the right, pupils equal, reflexes absent in arms, not increased in lower extremities. Mild delirium with apparent consciousness at times. Temperature 101° F., on admission, fell to 100° before death, which took place a few hours later.

Autopsy revealed the presence of purulent meningitis, involving meninges of both brain and cord, forming almost a complete envelope of exudate which gave the brain a greenish-yellow tint. Several of the cultures from the meninges were sterile, but one from the brain showed bacillus cadaveris and staphylococcus pyogenes aureus; while one from the cord showed only diplococci. Cover-slip preparations showed bacilli and micrococci.

Case III.[1]—J. H., male, white, aged twenty-six years, was admitted with a history of having been seized with headache and vertigo some hours before. On entering the hospital he became unconscious. There was slight facial paralysis, rigidity of the right side; increased reflexes, and slight retraction of the head. Temperature 100° F. on admission, and there was a constant rise to 106° F. prior to death, which occurred two days later. Examination of urine showed a trace of albumin. No sugar, no casts.

Autopsy revealed an extensive purulent exudate infiltrating everywhere the pia mater and arachnoid of both brain and cord, giving to these organs a yellowish tint. Ventricles were distended with fluid and on puncture of meninges in lumbar region considerable fluid escaped. Exudate was also found to extend over roof of third ventricle. Cultures from the meninges of the brain were found to contain the colon bacillus. No cultures were made from the cord. Cover-slip preparations were found to contain bacilli. On section the meninges presented many bacilli and a few organisms which appeared as micrococci.

Case IV.—R. G., white, about middle age, was admitted to the hospital in an unconscious state. His condition was regarded as a unilateral cerebral lesion. He died ten days after admission. At autopsy a small area of apparently purulent meningitis about 1 cm. in diameter was found along the left fissure of Sylvius. There was also an area of softening in the right lenticular nucleus. Cultures from this localized area of meningeal inflammation showed the micrococcus tetragenus.

[1] A detailed report of case made by Dr. J. H. Lloyd, *Internat. Med. Jour.*, November, 1898.

CASES OF PURULENT MENINGITIS AT THE PHILADELPHIA HOSPITAL DURING THE LAST FOUR YEARS.

No. of cases.	Month.	Sex.	Age.	Color.	Nati'n'lity.
1	April	Male	6 months	White	American
2	June	"	1 week	"	"
3	October	"	13 months	"	"
4	"	"	26 years	"	"
5	April	"	64 years	"	Irish
6	June	"	26 years	"	German
7	March	"	31 years	Black	American
8	May	Female	7 months	White	"
9	August	Male	37 years	Black	"
10	October	"	52 years	White	German
11	January	"	26 years	Black	American
12	July	"	26 years	White	"
13	September	Female	13 years	"	"

In the accompanying table I have considered only those cases in which either the pathological diagnosis or notes pointed clearly to purulent meningitis. Cases in which there was doubt I have placed under other headings.

Strümpel states that cerebrospinal meningitis has continued in Leipsic since 1864, a few cases occurring each year. From a brief review of the literature I think the same can be said of Philadelphia since the epidemic of 1863, an account of which was given by Stillé. From the records of this hospital purulent meningitis is a rather common occurrence, being present in 16¼ per cent. of all cases in which any form of meningitis existed.

Cases IX., X., and XIII. were regarded by the pathologist as tubercular. In all cases in which the middle ears were examined the results were negative. Without a bacteriological examination it is impossible to say how many of these cases were purulent, but from the pathological notes I am disposed to believe that some of the cases classified as basilar were probably purulent. It is indeed certain that the pneumonia bacillus sometimes secondarily reaches the meninges and here excites purulent suppuration (Strümpel). The same author also regards this organism as an exciting cause when pneumonia does not exist. Holt, in an article on the bacteriology of the epidemic form of the disease, states that the diplococcus of pneumonia is the organism commonly found, but by no means the only one. "In sporadic cases also, it plays an important part." He credits Netter with having reported twenty-five sporadic cases, of which eighteen were due to the pneumococcus, four to the staphylococcus and streptococcus pyogenes, and various other bacteria in the remainder.

Here is probably the opportune place to speak of the relation between the epidemic and sporadic forms of this disease. Since the report of the Mas-

sachusetts State Board of Health, setting forth the investigations made by Councilman, Mallory, and Wright, we can no longer regard the pneumococcus as the cause of epidemic meningitis. These investigators have clearly shown that this form of the disease is produced by the diplococcus intracellularis. The majority of sporadic cases in which bacteriological examination had been made were found to be due to the pneumococcus. However, cases are recorded as being due to the tubercle bacillus, bacillus pyocyanus, bacillus meningitidis purulenti, bacillus anthracis, and typhoid, colon, and the various pus-producing micrococci. The writer is inclined to regard sporadic purulent meningitis as a condition capable of being the results of any pus-producing organism, and with rare exceptions, due to causes other than those involved in the production of the epidemic form. It has been suggested that all forms of purulent meningitis not due to the diplococcus intracellularis prove fatal.[1] This, however, can only be decided by careful bacteriological study of the meningeal fluid during life, and needs further investigation to throw any true light on the subject.

In Case I. no organism, other than the diplococcus of pneumonia, was present. The same organism being found in the lung is sufficient evidence to regard both the meningitis and pneumonia as due to the micrococcus of pneumonia. In Case II. there was a mixed infection. The diplococci found resembled closely in microscopic appearance the diplococcus intracellularis of Weichselbaum, yet its development on different culture media gave widely different reactions, resembling in this respect the organism commonly found in nasal secretions. Here the staphylococcus pyogenes albus may have played an active part in the process, and to what extent the diplococcus contributed toward the condition cannot be estimated. Cultures in Case III. showed only the colon bacillus, and cover slip preparations, made from the exudate, contained bacilli. Sections of the meninges were found to contain bacilli, and few apparent micrococci, which prevent determining positively that the case in question had for its sole cause the colon bacillus. Case IV. was regarded by the neurologist as one of syphilitic softening. The only organism which could have contributed toward the condition was the micrococcus tetragenus.

The City with the Lowest Death-rate.—The death-rate in Erie, Pa., was 10.87 in 1896; 10.94 in 1897, and 10.53 in 1898. The population of Erie was estimated by the Mayor, January 1, 1898, to be 57,000. It is doubtful if many other cities can show as good a death-rate for three consecutive years; but Toledo, with 150,000 inhabitants, had a death-rate in 1898 of 10.33.

[1] Report of the Massachusetts State Board of Health, 1898.

RECENT INVESTIGATIONS UPON MALARIA.[1]

BY W. S. THAYER, M.D.,
OF BALTIMORE, MD.

UP to the last year our ideas as to the manner of infection in malaria have been mainly speculative. There have been three chief hypotheses: (1) That the disease is acquired through the gastro-intestinal tract; (2) that infection takes place through the inhaled air; (3) that the poison may gain access to the body through the bites of insects.

The solution of this problem has been greatly delayed by our ignorance as to the form in which the malarial parasites exist outside the human body. Experiment and analysis of the evidence go to show that there is little to support the view that the disease may be acquired through the gastro-intestinal tract. Experiments by Mariotti and Ciarocchi, Marchiafava and Celli, Marino, Zeri, Grassi, and Feletti have shown that the administration of large quantities of water from highly malarious districts, by the mouth, by rectum, and by inhalations, as well as the actual ingestion of blood containing living malarial parasites, is incapable of causing infection.

And while in the absence of our knowledge of the form in which the parasites exist outside of the body it is difficult to positively disprove the possibility that the disease may be acquired by inhalation, there is no thoroughly satisfactory evidence in its support. On the other hand, it has been known for many years that inoculation, subcutaneous or intravenous, of the blood of an infected individual will transfer the disease. Some years ago Laveran advanced an hypothesis that infection might take place through the bites of mosquitoes. Since this expression of opinion several other similar diseases in animals, diseases due to hematozoa, have been shown to result from the bites of insects. Thus, the parasite of Texas-cattle fever, an organism in many ways similar to the malarial parasite, has been shown by Professor Theobald Smith to be transmitted by the bites of the cattle-tick (*Boophilus bovis*), while the Tsetse-fly disease or nagana is introduced through the bites of the Tsetse-fly. More recently Patrick Manson of London has been an ardent supporter of the idea that the mosquito might play an important part in malarial infection.

In all varieties of the malarial parasite certain forms upon reaching maturity fail to sporulate, but in many instances after five, ten, or fifteen minutes undergo a process of flagellation, which was early described by Laveran, the separate flagella breaking away often from the mother element, moving about rapidly in the blood with an act-

[1] Remarks made at the Centennial Meeting of the Medical and Chirurgical Faculty of Maryland, Baltimore, April 25–28, 1899.

ive serpentine motion. There has been much dispute as to the significance of these elements. Laveran believed that they represented a very important stage in the life history of the organism, while Dock first suggested that they might be bodies intended to preserve the life of the parasite outside of the human body. The Italian observers, as a rule, vigorously opposed these views, believing that flagellation was a degenerative progress.

Manson, who had demonstrated the fact that the mosquito forms an intermediate host for the filaria sanguinis hominis, ventured the hypothesis that this insect might play a similar part in connection with malaria. Surgeon-Major Ronald Ross, acting upon the suggestion of Laveran, observed the development of flagellate bodies in the fresh blood within the stomach of the mosquito. This single observation was not remarkable, inasmuch as the same is often noted when mature parasites are observed for a sufficient length of time outside of the human body. But afterward in carefully studying mosquitoes he observed remarkably large pigmented structures in the stomach wall of several insects which had previously bitten infected human beings. The pigment in these elements was so similar to that previously contained in the malarial parasite that the observer was impressed with the possibility that they might represent some extra-corporeal stage in the life history of the malarial organism. At this stage in Ross' researches the malarial season came to an end, and he was obliged to continue his studies upon the parasites of birds which, as is well known, are closely similar to those of human malaria. The results of these observations of Ross form the most important contribution to our knowledge of this subject that has been made since the discovery of the parasite by Laveran. If a certain variety of mosquito, the gray mosquito (*Culex pipiens*), be fed upon birds infected with the *proteosoma* (Abbé), there appear, two days after feeding, in the wall of the middle intestine of the insect, pigmented bodies similar to those just described. These structures gradually increase in size until at the end of the seventh day they have a diameter as large as sixty micromillimeters. They have a distinct capsule and contain a granular material showing at first a few pigment granules which afterward disappear. On reaching maturity they protrude from the surface of the mosquito's intestine into the body cavity. Shortly after this period rupture occurs, and a large number of small spindle-shape trypanosome-like bodies escape which enter the circulation of the mosquito. Ross further discovered that many of these accumulate within the cells of the veneno-salivary gland of the mosquito. The outlets of this gland unite into a common duct which descends to the extremity of the mosquito's proboscis. The discovery of these spindle-shaped bodies in the cells of the salivary gland instantly suggested to Ross a possible method by which infection might occur. And experiments showed that mosquitoes fed a proper length of time before upon infected birds were capable of transferring the disease to non-infected birds in almost every instance. Ross' admirable experiments, conducted with the parasites of birds, the nature and behavior of which is so similar to those of the malarial parasites that they have by some individuals been considered to be the same organism, abundantly justified the assumption that similar conditions might exist with the parasites of human beings.

At the same time, independently of Ross' work, Italian observers, Bignami, Grassi, and Dionisi, had come to the conclusion, from careful study of the etiological conditions of the disease, that the theory of infection through the bites of mosquitoes was by far the most probable hypothesis in connection with malarial fever in man. Grassi had gone so far as to narrow down upon two particular varieties of mosquito, the *Anopheles claviger* and the *Culex penicillaris*, as the probable varieties of mosquito which were capable of inoculating the disease. The ordinary house-mosquito, the *Culex pipiens*, that in which Ross had been able to cultivate the parasites of birds, Grassi believed to be harmless. Bignami, indeed, succeeded apparently in inoculating with malaria a human being who had voluntarily subjected himself to the experiment by subjecting him to the bites of these suspicious varieties of mosquito. Ross communicated the results of his experiments to the Italian observers, sending them specimens illustrative of the conditions observed, and during the months of November, December, and January, Grassi, Bignami, and Bastianelli succeeded in completely confirming all that Ross had found in birds upon the human being. They have shown that if examples of the *Anopheles claviger* be placed upon an individual infected with malaria in whose blood full-grown forms capable of flagellation exist, bodies almost exactly similar to those described by Ross appear on the second day in the stomach wall of the insect, undergo similar processes of development, and rupture, setting free the same small spindle-shaped bodies which accumulate in the cells of the salivary gland. The experiment has been rounded out to complete success in the case of the estivo-autumnal parasite. Three mosquitoes which ten days before had been allowed to bite an individual infected with estivo-autumnal malaria were placed upon a non-infected individual, the result being the development of a characteristic estivo-autumnal malaria.

The three mosquitoes were killed after biting this individual and full-grown bodies were found in the walls of the stomach, while the cells of the salivary gland were filled with the small spindle-shaped "sporozoids."

The result of these observations has, therefore, been a positive demonstration of one method by which malarial infection may occur, namely, through the bites of mosquitoes. Is this the only method? This is a question which as yet we cannot answer. From analogy with similar diseases, and from a careful study of the etiological conditions of malaria, the Italian observers are strongly inclined to believe that this is the case.

Are we to assume that the mosquito can acquire the parasite only by biting infected human beings? Is it not probable that there are other forms in which the parasite exists outside of the human body? These are questions which remain to be answered. It should be said that certain of the capsule-like bodies in the stomach wall of the mosquito do not give rise to these small spindle-shaped structures, but contain a smaller number of large brown spores which there is some reason to believe may be more resistant forms of parasite, and may possibly be transferred in some way to the mosquito larvæ.

An interesting point in connection with these discoveries is that they have completely supported Laveran in his original view that the flagellation of the malarial parasite was an important vital process and not as others had supposed, degenerative in nature. The first important observations tending to support this view were, as is well known, made by MacCallum two years ago. MacCallum showed that in certain parasites of birds, as well as in the human being, the free flagella penetrate other full-grown forms of the parasite in such a manner that there can be little doubt that the process is one of fecundation. In the birds' parasite, in which this process was first studied the fecundated form changed into the active "*pseudo-vermicule*" described by Danilewsky. This pseudo-vermicule has a sharp point and a steady forward motion as observed under the field of the microscope which enables it to penetrate into and destroy almost any object in its way. As soon as Ross discovered the pigmented bodies in the stomach wall of the mosquito he assumed that the parasite gained entrance into the walls as a pseudo-vermicule, the result of fecundation as described by MacCallum. The discovery of MacCallum, then, seems to supply the last link in the chain, inasmuch as it will be remembered that both Ross and the Italian observers insist that the presence in the blood of forms capable of flagellation is necessary to the development of the pigmented structures in the stomach wall.

In connection with this work, a few remarks concerning the observations of Professor Koch, which have been appearing during the last year, may not be out of place. Both in the reports of his studies in Africa and in a recent communication in the *Deutsche medicinische Wochenschrift*, in which he describes his studies in Italy, Koch has detailed observations confirming much that has been done by French, Italian, American, Russian, and German observers. The publications have, unfortunately, appeared in such a form as to give most readers the impression that the observations are original discoveries. They have been so regarded in many non-medical, and in some, particularly German, medical publications. It is but fair to say that Professor Koch's observations, while entitled to all the attention which is of course due to their distinguished author, are solely confirmatory in nature. Koch has not as yet made a single original observation in this field. Everything which he has described has been previously worked out and reported by others, and it is unfortunate, as Dr. Nuttall has elsewhere observed, that his publications should have taken such a form.

CLINICAL MEMORANDUM.

A SURGICAL SUGGESTION.

THE PURSE-STRING METHOD FOR TONSILLAR HEMORRHAGE.

By ROBERT H. M. DAWBARN, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL; SURGEON TO THE CITY HOSPITAL.

In a lecture upon tonsillar hemorrhage some little time ago, as reported by a friend and former student of mine, Professor Lefferts alluded to my method, suggested for use only in obstinate cases, of a purse-string suture about the tonsillar stump, tightened and tied; and he gave it a *coup de grace* by alleging that it is impossible of accomplishment—the patient meanwhile struggling, etc.

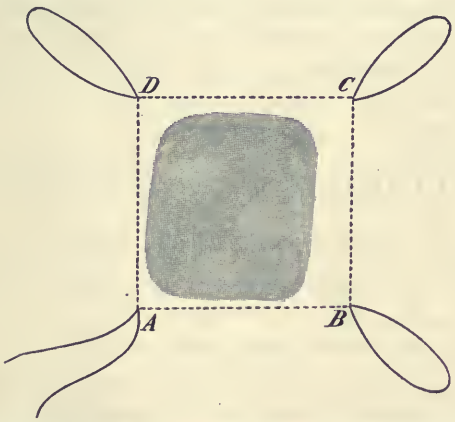
The fact is, however, that I have myself in one instance (*Medical Record*, December 17, 1892) used this impossible method successfully and did not find it even difficult. But my patient was, *of course*, asleep from anesthesia. Previous to and during the chloroforming the patient was gagged and the tonsillar stump was held between the forefinger on the stump and the thumb outside, on the angle of the lower jaw, so that little or no bleeding went on. Then the anesthetized patient was placed with the bleeding side uppermost, and by the aid of a forehead mirror and a large, semicircular needle, with needle-holder, the constricting purse-string was placed quickly and with ease, as the blood ran away by gravity from the surface I wished to see.

As the bleeding regularly comes mainly from one of the ascending two of the six tonsillar arteries it would seem sensible to begin with the lowermost of the four

stitches necessary (*A* to *B* in the accompanying diagram). Very possibly tightening this will be found to control the bleeding, and thus either render the other three stitches even easier of insertion, or perhaps needless. The silk purse-string thus tied around the base of the stump should remain in place from thirty-six hours to two days. The ends being left a little long will facilitate removal.

Regarding the cases in which this device may be needed it is admitted that although children may *almost* die from tonsillar hemorrhage they do not *quite* do so. This fact is, however, no excuse for trying every other plan which may perhaps succeed before using one so simple and safe and which must succeed.

It is in adults with tough, hard, hypertrophied tonsils that the ugliest cases of bleeding are found as a rule. Not every practitioner has a snare, which, it is admitted, would, if used slowly, be safer for the amputation in these adults than is the guillotine. To avoid the purchase of one more instrument by the overburdened general practitioner I would suggest as a new departure that when from the na-



The shaded portion represents the tonsillar stump. The letters indicate the order in which the needle is four times introduced, following the dotted lines.

ture of the offending tonsil he has reason to fear trouble, he would do well to place my purse-string suture *before* using the tonsillotome. To do this upon the adult and before any bleeding has occurred is certainly easy enough —and under minor anesthesia—the patient sitting upright in a good light. It is worth noting that eucain *B* is better than cocain when tonsillotomy is in question because the eucain does not contract arterioles and thus shrink the tonsillar mass so that the surgeon cannot remove as much as he otherwise would do. Anesthesia being accomplished, we now do the tonsillotomy and tighten up the suture previously applied in case bleeding justifies its presence as a precautionary measure.

On October 24, 1898, I had an opportunity to make use of the plan. The patient, Mr. A. L. O'B., a middle-aged dispensary patient, had a very large, hard, and chronically tender left tonsil, which for many years had annoyed him, inducing numerous sore throats and threatening quinsy each time, with great swelling and pain, but never actually suppurating. No trouble was experienced in passing the precautionary purse-string after applying for ten minutes a large compress wet in 10-per-cent. eucain *B* solution. It was with a pleasant sense of security against dangerous bleeding that the amputation was then performed. Perhaps the amount of blood that would ordinarily have been lost might not have jeopardized his life, but this patient was quite anemic and I preferred that he should not lose even a drop of his vital fluid needlessly; therefore, in this instance, I tightened and tied the purse-string before amputating the tonsil. Of course the result was an entirely bloodless operation. Enough morphin was subsequently employed to render the patient moderately free from annoyance by the suture, which was removed after thirty-six hours in this instance, eucain *B* being again applied before the stitch was cut and drawn out.

Regarding the depth to which the needle may safely go, this is considerable. The ordinary estimate is that the internal carotid is 1.5 cm. away from the base of the stump; the external carotid 2 cm.; and both rather behind the tonsil than transversely opposite to it. The late Dr. Hall, when professor of anatomy in the College of Physicians and Surgeons, New York, made some special dissections regarding these points, and taught that the external, not the internal, carotid is the nearer to the tonsil, and that in event of severe hemorrhage this will regularly come mainly from the ascending palatine branch of the facial artery.

There is no need for entering the needle deeply in the purse-string method. It is obvious that all we need is to have it far enough beneath the surface to avoid its cutting or tearing its way out while being tied. For the same reason the silk should be quite coarse, ordinary pedicle-silk by choice. It must, of course, be boiled first.

In conclusion I offer a diagrammatic sketch showing the placing of the four stitches in their proper order. Of course when the ends are pulled upon the three loops will all disappear beneath the surface.

MEDICAL PROGRESS.

Incision and Evacuation of Distended Intestinal Loops in Obstruction.—MAYLARD (*Brit. Med. Jour.*, April 8, 1899) says that he has obtained better results in his operative work in cases of intestinal obstruction since he has followed the plan of making one or more incisions into the distended loops of intestine and evacuating the contents before returning them to the abdominal cavity. It is easy to protect the peritoneum from infection by bringing the loop well outside before opening it, and afterward closing the incision with a Lembert suture before the loop is replaced. The handling of the intestine which this treatment entails seems to do good rather than harm, acting as a stimulant to muscular contraction and emptying the engorged blood-vessels. If peritonitis is present, the injection of about an ounce of sulphate of magnesia in solution should be made through the evacuatory incision after the bowel has been emptied of its fecal matter.

Resistance to Quinin of Certain Forms of Malaria.—CAMAC (*Johns Hopkins Hosp. Bull.*, April, 1899) says

that the temperature-chart after the administration of quinin will often enable a physician to determine whether or not a fever is malaria, and if so, of what type. It is desirable to know the character of the fever-curve before quinin is given. Fever which shows no sign of breaking after the administration of quinin every four hours for three days, is not malarial, and to give the remedy a further trial is not only useless but possibly harmful. If the fever yields earlier than the third day on moderate doses, it is likely to be of the tertian or quartan type, either double or single. In the estivo-autumnal type the temperature often fails to touch normal between the paroxysms. Its resistance to quinin has led Italian observers to speak of the gradual destruction of its parasite by quinin, as "fractional sterilization." In this form, naturally, the administration of the quinin should be continued longer than in the others.

Malaria with Typhoid Fever.—In a discussion on typhoid fever occurring among soldiers of the late war with Spain, DA COSTA (*Phil. Med. Jour.*, May 6, 1899) reported ten cases of typhoid fever complicated with malaria. There was no doubt about the clinical diagnosis, and it was in almost every case confirmed by the Widal test and by microscopical demonstration of the malarial parasite. In every case it was the tertian or estivo-autumnal organism which was present, generally the former. The majority of the patients had no chills before the typhoid developed, nor until late in the disease, possibly during a relapse. The chill was followed by marked temperature rise and sweating. The course of the fever was slow in all of these patients, lasting for more than four weeks. One case existed without chills. The practical conclusion is that one ought to examine the blood for malarial parasites in every case of typhoid with prolonged and irregular fever, or with chills, or with frequent relapses. In some of Da Costa's cases the malarial organism was not found at the first examination, but was found later. From 16 to 20 grains of quinin given daily for a few days was found to be sufficient to break up the fever. Smaller doses were then administered to full convalescence.

A New Method of Drainage after Suprapubic Cystotomy.—KACZKOWSKI (*Centralbl. f. Chir.*, March 18, 1899) has devised an apparatus which prevents the leakage of urine into the tissues after suprapubic cystotomy, and therefore materially hastens the time of recovery as well as adds to the comfort of the patient. It consists of an hour-glass-shaped balloon of rubber, through the center of which a catheter passes, and which has a little tube through which air can be forced into the apparatus to distend it. It is introduced immediately after the operation, and is blown up tight enough to prevent leakage around it. The catheter can be clamped or not as occasion demands. The use of this simple device is said also to prevent infection of the bladder from without. The inventor has used it in one case with perfect satisfaction.

The Cross-Suture of Tendons.—VULPIUS (*Klin. Ther. Woch.*, March 12, 1899), who has had a personal experience with some 70 cases of cross-suture of tendons, speaks in the most encouraging manner of this method of making good the loss of function occasioned by a partial paralysis. Over fifty of these cases occurred in patients suffering from paralytic flat-foot, or club-foot, either equinus or calcaneus. Some of the cases were simple, as those in which the extensor hallucis tendon was affixed to that of the tibialis anticus, while in some instances, parts of different muscles had to be sutured to the tendons of two or three paralyzed muscles. In other instances the sartorius was sutured to the tendon of the quadriceps; or the flexor carpi ulnaris to the tendons of the extensor longus digitorum. Such operations in the upper extremity are more difficult than in the lower, as the individual muscles are better developed and it is harder to educate them to an opposite use. A middle group of muscles, corresponding to that of the peronei is besides wanting. The necessities of each case must be studied, as one can not go by regular rules in this method of treatment.

Report of Progress in Dermatology.—GILCHRIST (*Maryland Med. Jour.*, April 8, 1899) gives a summary of the recent advances in dermatology. White has shown that ringworm of the scalp in Boston is generally (97 per cent. of the cases) of the small-spored variety. Under the microscope mosaics of glistening round spores 2 or 3 micromillimeters in diameter are seen clustered around the hair. Epilation, washing with Castile soap and warm water every morning, and the application of the following ointment will suffice to effect a cure in six months in most cases:

℞.	Sulph. flor. } aa Acid carbolic }	. . . .	3 i
	Naphthol	. . . . .	3 ss
	Adipis	. . . . .	3 i.

In the large-spored cases the spores are usually quadrangular with rounded corners. Treatment of these scalp cases is much more severe than in the small-spored variety, and one has to perform epilation and apply such drugs as mercury, chrysarobin, pyrogallic acid, and formaldehyd.

Unna's plan for the treatment of eczema of the palms and soles consists in the application every four to six hours of starch poultices to which a little boric acid has been added. A good deal of the sodden epidermis is removed by rubbing with a rough, soft, dry cloth between the changes of poultices. In about four or five days the palms become soft, smooth, and pliable. The following ointment is then applied:

R.	Acidi pyrogallici oxidati	. .	gr. v-xxx
	Lanolini	. . . . .	ʒ ss
	Ol. amygdal. } aa Aq. dest. }	. . .	3 ii.

A liquid soap which Skinner has found very useful in dermatological practice consists of oleic acid, 2 ounces; alcohol, 90 per cent., 3 ounces; solution of ammonia, a sufficiency, and water to 6 ounces. The ammonia is added drop by drop until the odor can faintly be detected. It is then allowed to stand for seven days and filtered through kaolin.

As a good general ointment for eczema the same authority recommends anhydrous wool-fat, ½ ounce; camphor, 30 grains; glycerin of subacetate of lead, ½ ounce, and coal-tar if indicated.

Suture of the Sphincter Ani Muscle in Cases of Complete Tear of the Perineum.—KELLY (*Johns Hopkins Hosp. Bull.*, January-March, 1899) draws particular attention to the control of the function of the bowel exercised by the sphincter muscle, asserting that a tear in this muscle will cause fecal incontinence. Even in cases in which the anus presents a normal appearance the surgeon should not fail to recognize that the sphincter may be ruptured and the torn ends separated by a considerable interval. Kelly's operation under such circumstances is intended to avoid the objections which have been raised to the operations of Emmet and Hegar. Hegar's plan is to suture the internal sphincter by fine silk and the external sphincter by fine catgut. What Kelly insists upon is the more thorough dissection of the ends of the sphincters, and the removal of all fibrous tissue. If in addition the external sphincter is separated from the overlying skin for a considerable distance, it will lie deeper after the sutures have been inserted, and hence danger from infection will be lessened. If the tear is in the external sphincter only, it is freed as described for a half inch or more, and the catgut sutures inserted but not tied. The rectal mucous membrane is then sutured, the suture line extending out over the skin. Then the sutures in the sphincter are tied, and afterward a silkworm-gut suture is inserted to take the tension off from the buried sutures in the sphincter. When the internal sphincter is also involved its ends are sutured by fine silk stitches which enter and leave through the mucous membrane of the rectum. Post-operative enemata of warm oil given through a soft catheter are recommended.

THERAPEUTIC NOTES.

Local Treatment of Pneumonia in Children.—CHASE (*Boston Med. and Surg. Jour.*, April 13, 1899) had an opportunity to study the value of external applications in the treatment of pneumonia in children. Most of the forty-five patients observed lived in tenement-houses. The surroundings were, therefore, not especially favorable. All but two were over a year old. Of thirty-nine who had lobar pneumonia, thirty-eight recovered. Six had bronchopneumonia, and of these four recovered. The effect of poultices was especially noted. These were made light, of flaxseed and cheese cloth, and covered with oiled silk or paraffined paper, and weighed not more than 6 ounces. They were placed on the affected part while the child was in bed, and removed in 30 or 40 minutes. Rarely were more than six or eight applied in twenty-four hours. Observation convinced him that poultices diminish pain, and have a soothing effect, often producing sleep; that they relieve dyspnea and reduce the number of râles; that they are rarely opposed by the children, and by adding to the comfort of the patient they maintain his strength and so facilitate his recovery.

Mustard paste was tried in a few cases and seemed also of benefit.

To reduce hyperpyrexia, the writer made use of cold sponging with water and alcohol. No case was observed in which a cold pack seemed indicated, but the cases were mild, and in no instance did the temperature reach 104° F., and remain there for six hours.

Emphasis is laid on the importance of fresh air, and of judgment on the part of the nurse to let the child remain quiet when it so desires, and to turn it when it becomes choked by secretion.

Treatment of Ozena by Citric Acid.—HAMM recommends insufflations of a mixture of equal parts of citric acid and sugar of milk, practised three times a day by the patient, in addition to a daily flushing of the nasal fossæ. He claims that the fetid odor is entirely removed by this treatment, even if pus and crusts continue to form, this favorable result lasting for some time. Secretion is also diminished.

Tribromid of Salol in Mental Diseases.—VIALLON has employed this drug as a sedative and hypnotic in the asylum at Dijon, and has found it comparatively valueless for acute cases of mania, etc., or for hysteria, but very useful for cases of chronic mania, general paralysis, etc., in which periods of excitement occur. Thirty grains given at 7 P.M., in soup or some other liquid, induces sleep, or at least a diminution of excitement. Viallon considers it superior to bromid of potassium for such cases.

Elixir of Terpin Hydrate for Bronchitis.—The following formula is recommended by CRINON:

℞	Terpini hydrat.	gr. lxxx
	Glycerini } aa	℥ iiss
	Spiritus }	
	Mellis despumat. . . .	℥ ii
	Tinct. vanillæ	*m.* lxxv.

M. Sig. Two to four tablespoonfuls a day.

For Burns of Small Area.—

℞	Europhen	gr. xlv
	Vaselini } aa	℥ i.
	Lanolini }	

M. Sig. For external use. Apply 3 or 4 times a day.

Dressing for Umbilical Cord.—In connection with the dry treatment of the cord, by which baths are delayed until healing is complete, the infant being bathed on the lap only, while care is taken not to wet the umbilical region, argilla (alumina) is recommended as an excellent cord-powder. It is applied twice a day until several days after the cord has become detached. Suppuration is said never to occur when this method is adhered to.

For Migraine of Hysterical Patients.—

℞	Ext. erythroxyli fl. . . .	℥ i
	Sodii bicarb.	gr. xl
	Sherry wine	ʒ iiss
	Oleosacchari limonis . . .	gr. lxxx
	Aq. melissæ	℥ iii.

M. Sig. One teaspoonful 3 times a day.—*Leyden.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

CHRISTIAN SCIENCE AND THE PRACTICE OF MEDICINE.

A NUMBER of deaths have recently occurred of people suffering from various disorders while under the treatment or rather the non-treatment of Christian Scientists. These have again attracted public attention acutely to this cult. Two of the deaths have been in the neighborhood of New York City, and it is a satisfaction to note that in each case the authorities have taken steps to bring the matter before the proper legal tribunals.

The failure to convict Christian Scientists in other cities in various parts of the country probably foreshadows a similar failure in these cases. The principles of religious toleration and freedom of conscience are so stretched by the judiciary of the country as to include under that guise this sacrilegious imposition on the community.

This is unfortunate. Meantime no better course presents itself than to continue to stigmatize all this unwarranted, fanatical sacrifice of life and health by citing before the courts as criminals all those concerned in this unchristian work, so that a suitable public opinion on this subject may gradually be developed. It is true that persecution usually proves only a means to further fetter the minds and opinions of fanatics, and often leads them to a more vigorous propagation of their ideas, which are by this means effectively called to public attention. In this case, however, the publicity given the acts of so-called Christian healers who, for monetary considerations, at critical moments take upon themselves all responsibility for the life and health of fellowmen will be productive of none but good results.

The recent order of the president of the New York Board of Health to the assistant sanitary superintendents of the various boroughs of Greater New York is very timely. The characterization of the healers as "evil-minded persons, who take advantage of their more ignorant neighbors professing that they are endowed with wonderful healing faculties," while not true of the rank and file of the followers of Christian Science has proved in almost every case that has come prominently before the public to be true of those who professed to have wonderful healing powers. Sordid motives have evidently been the mainspring of their pretended exercise of the curative faculties given them by a knowledge of Christian Science.

This is a commendable effort on the part of the New York Board of Health to solve an important and knotty legal and medical question. The manner of getting at it, too, is well advised since it is proposed that these assistant superintendents shall cooperate with the various medical societies of their districts, and shall consult with them as to the best means of accomplishing the permanent suppression of these practices. That the Board of Health is acting well within its powers is evident from the fact, so strikingly brought out in our recent investigation of this cult, that for Christian Scientists no such thing as contagious diseases exists, and that their failure to recognize these affections constantly exposes people to infection. The matter is an important one, also, for the followers in Christian Science. We sincerely hope that the united efforts of the Board of Health by the judicious use of the power it possesses, in cooperation with the various medical societies, will prove successful in suppressing this criminal imposition on the credulity of misguided people.

CLIMATE IN THE TREATMENT OF TUBERCULOSIS.

AN impression that would have been inevitably received by that impressionable creature, the ordinary practitioner, in attendance at the recent meeting of the American Climatological Association here in New York is that the value of mere climate as a therapeutic factor in the treatment of pulmonary tuberculosis has greatly deteriorated of late years in medical estimation. It seems to be more and more generally conceded that it is not the combination of favorable meteorological conditions we call a suitable climate which has effected the cures of consumption at health resorts so much as the attention to rest, diet, hygiene, fresh air, and sunlight, which has always characterized the medical direction of patients in such places.

This impression as to the comparative efficacy of the regulated out door life rather than of mere climate is confirmed by a number of considerations apart from the proceedings of the Climatological Association. It has been clearly demonstrated by the valuable results obtained at such places as Davos, that even cold temperatures do not militate against the value of a place as a health resort for consumptives. Recent extensive European experiences with sanatoria for consumptives, especially in Germany, show that almost any climatic conditions and any altitude may favor the progress of a consumptive's cure if other therapeutic factors are properly provided.

In the vicinity of a number of the larger German and Swiss cities sanatoria for consumptives are giving excellent results. It seems only necessary that they should be situated at a reasonable distance from the dust and dirt and, above all, the contamination of the air incident to large bodies of population to prove suitable places for successful treatment of tuberculosis. Air, sunlight, rest, and nutrition are the essential elements in the successful treatment of phthisis. As these important indications have asserted themselves more and more, cures have been more common, and even the compromising hospital treatment of consumption in large cities has taken on a highly encouraging aspect.

It is an almost universal experience that consumptives improve even in the public wards of a general hospital when first admitted. Rest and suitable nourishment for these poor patients whose nutrition has often been neglected at once sets up a conservative reaction in the organism which causes general improvement. That this amelioration is not continued indefinitely is due to the fact that the disease is usually too far advanced in such patients to yield permanently to the improved environment. The monotomy of hospital life palls on them, vital interest is lessened, appetite diminishes from lack of proper exercise and general nutrition again suffers in consequence.

The lesson of these recent developments is a very interesting one for the general practitioner. It is difficult to induce patients with only incipient phthisis and very little discomfort, perhaps, to leave their homes and friends and go to a distant though favorable climate. It is not difficult, however, to persuade them to go a short distance from home, and that too at an early stage of the disease. The incipient stage is that in which rapid and permanent cure of the disease is effected by sanatorium treatment. Rest, careful attention to nutrition, sunlight, and pure air can be secured without traveling thousands of miles. And clinical experience has shown that cures are effected and lasting results obtained near home.

It is interesting to note how long it has taken for this idea to percolate into the present stratum of accepted medical truth. Years ago, as was stated at the Climatological meeting, Chicago, when a frontier town, was considered by Eastern physicians as a health resort for tuberculosis, and numbers of tuberculous patients were sent there. Good and lasting results were secured too in the early days, but finally the influx of population drove the health center farther West. The wonderfully clear air of Colorado and its possibilities in permitting patients to live out of doors has retained for it the reputation of a health resort despite growth in population. This has been fortunate, for the study there of the best conditions for the cure of tuberculous patients by a set of interested and eminent specialists has taught the world much of the therapy of the dread disease. Their wonderful country remains for the present the ideal place for consumptives who have the financial means and are willing to break up existing home ties and make a new home in a new country.

MEDICAL EDUCATION IN JAPAN.

The February number of the *Sei-i-kwai Medical Journal*, which has been published at Tokio for the last eighteen years by the Sei-i-kwai, or Society for the Advancement of Medical Science in Japan, contains an interesting account of the condition of medical education and practice in the Island Empire. Modern education in Japan dates back only some twenty years, and for that length of time in Tokio University only. Ten years will cover most of the modern education furnished in the other schools, so that one can gain some idea of the rapid changes for the better that have been going on in the last decade, and which are still in progress. Thus in 1897 it was ordered that the University of Tokio be duplicated at Kioto. This has been done as far as the departments of physics and engineering are concerned, but the medical department will not be opened until fall.

The Tokio Imperial University has 23 professors, besides a number of assistants, and a student attendance this year of 256. Like all other medical schools in Japan, it has a four-years' course, each year lasting from September to June. There are two hospitals connected with it, having 328 free beds and 186 beds for pay patients. The courses of study, including laboratory and clinical instruction, compare favorably with those of many American colleges. The fees are $2.50 a month, and are remitted to those of each class who the previous year received the highest marks for scholarship and good conduct. In the provinces there are five medical schools under the control of the Imperial Government, and three under the provincial governments of the particular provinces in which they are situated. There are also two private medical schools in Tokio. The graduates of the last two are required to pass a State examination before beginning practice.

There are at present about 40,000 licensed practitioners in the whole country, 6000 of whom received the license by virtue of their graduation from government schools; 8500 by passing the State examinations, while 24,000 (including 10,000 followers of the Chinese system, bone-setters, shampooers, administrators of acupuncture, priests, etc.) were in practice at the time the present law went into effect, and were accordingly licensed without examination. The remaining 500 persons are sellers of nostrums, charmers, and midwives, licensed for limited districts only, in which no physician is accessible. Thus it appears that more than one-half of those who practice the healing art have some knowledge of modern medicine, a very good showing indeed for the youngest member of the family of modern nations.

ECHOES AND NEWS.

The School of Medicine of Georgetown University.—The commencement exercises of this medical school were held May 15, 1899. The usual interesting program was presented, the address to graduates being delivered by Dr. John Madison Taylor of Philadelphia.

Commencement Exercises of Bellevue Medical School.—On Tuesday evening, May 16, 1899, the commencement exercises of the University and Bellevue Hospital Medical College were held at the Metropolitan Opera House, New York. There were 162 men in the graduating class. The president of the University, Dr. McCracken, presided, and the Rev. Dr. Burrell, pastor of the Collegiate Church, delivered the address.

Internes at the Cook County Hospital.—Dr. Hektoen of Chicago announces that the official statement regarding the successful candidates for the interneship in the Cook County Hospital at the recent examinations reads as follows: From Rush Medical College, 6; College of Physicians and Surgeons, 4; Northwestern University Medical School, 2. Of the four alternates two were from Rush and two from the College of Physicians and Surgeons.

To Disinfect Havana.—Mr. Woolf, the inventor of a system for making sea-water a germicide by means of electricity, is superintending the construction of a new disinfecting-plant which was expected to be in operation in Havana about May 15th. By this means 50,000 gallons of water will be sprinkled upon the streets of Havana every day. The water will also be used by the sanitary authorities for disinfecting the houses of fever victims.

The Prevalence of Smallpox.—The United States Marine Hospital Service reports that during the week ending May 6, 1899, there were reported in the United States 93 cases of smallpox with 5 deaths; in foreign countries 160 cases with 65 deaths. The high mortality from this disease in foreign countries is undoubtedly due to lack of vaccination. It is a well-known fact that previous vaccination renders an attack of smallpox mild and insignificant.

Officers of the New York State Board of Health.—The New York State Board of Health, at its annual meeting at Albany on May 11th, reelected Dr. Daniel Lewis of New York City as its president. Dr. F. W. Smith of Syracuse and Dr. S. Case Jones of Rochester were reelected tuberculosis commissioners. At the request of

Governor Roosevelt, Dr. Lewis and Commissioner Owen Cassidy were appointed a committee to investigate an alleged nuisance in Catskill caused by the State brick works in that city.

Officers of the Climatological Association.—At the recent meeting of this Association, held in New York, the following officers were elected for the ensuing year: President, Dr. Abraham Jacobi of New York City; vice-presidents, Drs. R. H. Babcock of Chicago and J. W. Brannan of New York City; secretary and treasurer, Dr. Guy Hinsdale of Philadelphia; representatives to the Executive Committee of the Congress of American Physicians and Surgeons, Dr. Frederick I. Knight of Boston and Dr. Roland G. Curtin of Philadelphia. The next meeting of the Association will be held at Washington, D. C., during May, 1900.

Pure Food Investigation.—The Senatorial Pure-Food Investigating Committee met in Chicago, May 11th. The first witness was Dr. Henry G. Piffard of New York City. He believed that Congress should order an investigation of every branch of food in the market and that pure-food laws should be fixed by Congress and accepted and supplemented by the State Legislatures. Professor A. B. Prescott, of Ann Arbor, Mich., discussed the effect of using preservatives on meat, which he considered deleterious. Professor Victor C. Vaughan, also of Ann Arbor, corroborated Dr. Prescott's testimony and declared that the adulteration of any kind of foods or drinks, if allowed, should be governed by law as to the extent of the adulteration and the kinds of adulterants used.

The Fifth District Branch of the New York State Medical Association.—The fifteenth annual meeting of this association will be held in Wurzler's Building, Brooklyn, Tuesday, May 23, 1899, at 11 A.M. The president's address, by Dr. Joseph D. Bryant, will open the discussion of malignant disease. This will be followed by Dr. Edward K. Dunham on "The Nature of Malignancy in Neoplasms," Dr. L. Grant Baldwin on "Malignancy in the Female Genito-Urinary System," Dr. Jonathan Wright on "Malignant Disease of the Nose and Throat," Dr. Max Einhorn on "The Early Recognition and Management of Malignant Disease in the Digestive System," Dr. J. S. Gouley on "Malignant Disease in the Male Genito-Urinary System," and Dr. Wm. B. Coley on "The Treatment of Inoperable Malignant Tumors."

Obituary.—Dr. William Arthur Gorton, for eleven years Superintendent of the Butler Hospital for the Insane at Providence, R. I., and widely known as an expert on insanity, died on May 1st in Boston, Mass.—Dr. Frederick Karl Christian Ludwig Büchner died in Darmstadt, Germany, on May 1st. He was seventy-five years old. Dr. Büchner was the author of the famous book on "Force and Matter," published in 1855, in which was set forth an atomistic and materialistic view of the universe. This book had great influence in its day as a popular exposition of the ideas of modern materialism. Dr. Büchner wrote many other works of the same character.—Dr. William Whitney Godding, Superintendent of the Government Hospital for the Insane in Washington died in that institution on May 6th.—Dr. William Russell, Harvard's oldest graduate, died on May 6th at Barre, Mass. He was ninety-nine years old.

Death of a Practical Philanthropist.—The death of Richard Cadbury, one of the firm of Cadbury Brothers, who, since 1872, have carried on a wholesale grocery-house and manufactory near Birmingham, has brought out many facts in reference to his personal and business life. His donations to various objects mount up into the hundreds of thousands of dollars; but even more interesting is the fact that from the day of the starting of the factory until the present time, when nearly 1500 people are employed in it, there has never been a strike, nor any difficulty about wages. The interest of the members of the firm in the social well-being of their employees has been untiring. There are cooking-, dining-, and reading-rooms connected with the factory buildings, and gardens and arbors outside of it for rest and conversation, and each morning before beginning work every one connected with the business, from the head of the firm down, gathered in the women's dining-room and listened to a chapter of the Bible and a few words of Christian counsel. Nearly all the work done was paid for by the piece and the service rendered was of the highest character. It is gratifying to record that such attention to the moral and physical health of their employees resulted in very handsome business returns to the owners of the establishment.

Christian Scientists Prosecuted.—Two cases in New York treated by faith "healers" are now engaging the public attention. The first is that of Mrs. Charlotte M. Barguet of Mount Vernon, who died on May 3d. Mrs. Barguet had been ill for a long time, but no physician was permitted to see her. Instead, one Mrs. Maggie Fowler, a Christian-Science "healer," by arrangement with a son and a daughter of the deceased, made many visits, during which she sat by Mrs. Barguet's bedside and meditated. This was all the "treatment" Mrs. Barguet received. Coroner Banning of Mount Vernon held an inquest on May 8th. An autopsy had been made by Drs. Nathan Nutting and George C. Meiss, who reported that death was due to dropsy and acute pleurisy. The Coroner's Jury rendered a verdict to the effect that proper treatment was "precluded by the deceased holding to the so-called Christian Science faith, aided, abetted, and encouraged by other followers of that faith, to wit: Mrs. Maggie Fowler, Liston W. Barguet, Jr., and Miss Ethel L. Barguet." Mrs. Fowler and Mr. Barguet are held in $1000 bail each to await the action of the Grand Jury; Miss Barguet is held as an accessory without bail. Two months ago Lizzie Krauz, twelve years old, of Brooklyn, became ill. Physicians were called in who advised her removal to a hospital, a toe on the left foot having become gangrenous. Instead, her mother dismissed her physicians and called in one Mrs. Müller of 312 East Twelfth street, Manhattan, having heard of remarkable healing powers that were attributed to the latter. Mrs.

Müller applied German tea and a paste to the affected limb and prayed that it might be cured. The limb grew worse and the mother, when the gangrene had finally spread to the knee, had the child removed to the hospital. The limb was amputated above the knee on May 6th and hopes are entertained of the child's recovery. Mrs. Müller received fees amounting to $51. She is not a registered physician and has no apparent authority from any source to practise medicine. She was arrested on a warrant issued by Justice Brenner and will be prosecuted. President Murphy of the Health Board has expressed a determination to prosecute all persons who pretend to cure disease by methods not sanctioned by enlightened medical practice. The assistant sanitary superintendent in each borough will hunt up fake "healers." Various medical societies are assisting the Health Board.

American Gynecological Society, Program of the Next Meeting.—The twenty-fourth annual meeting will be held at Philadelphia, May 23d, 24th, and 25th. The sessions will be held in the Hall of the College of Physicians, corner of Thirteenth and Locust streets. The profession is cordially invited to attend. First day.—Tuesday, May 23d, morning session at 9 o'clock. Roll-call, reception of guests, etc. Address of welcome by Dr. Edward L. Duer of Philadelphia. (1) "Early Abdominal Section for Fibroid Tumors, with a Tabular List of All Operations Prior to 1865," by Charles P. Noble of Philadelphia. (2) "Etiology of Non-malignant Rectal Stricture in Women," by Reuben Peterson of Chicago. (3) "Sixty-five Consecutive Abdominal Sections without Death; with Clinical and Pathological Reports," by Hunter Robb of Cleveland. (4) "A Case of Spondylolisthesis, with Demonstration of the Pelvis," by J. Whitridge Williams of Baltimore. Afternoon session at 2.30 o'clock. (5) "Report of the Committee on Antistreptococcic serum in Puerperal Sepsis," by William R. Pryor of New York. (6) "Report of a Case of Kraurosis Vulvæ," by J. Montgomery Baldy of Philadelphia. (7) "Inversion of the Uterus," by B. Bernard Browne of Baltimore. (8) "Thrombosis Following Celiotomy in Aseptic Cases," by Henry C. Coe of New York. (9) "Clinical Data Bearing upon Tubercular Peritonitis," by Egbert H. Grandin of New York. (10) "The Avoidance of Infection Following the Operation for Complete Tear of the Recto-vaginal Septum" and "The Localization of Obscure Pain in the Side," by Howard A. Kelly of Baltimore. Second day.—Wednesday, May 24th, morning session at 9 o'clock. (11) "Is a Sloughing Process at the Child's Navel Consistent with Asepsis in Childbed?" by Robert L. Dickinson of Brooklyn. (12) "Surgical Treatment of Acute Puerperal Sepsis, with Special Reference to Hysterectomy," by H. N. Vineberg of New York. (13) "The Abuse of the Curette in Puerperal Fever," by Robert A. Murray of New York. (14) "Experience in the Use of Tuffier's Angiotribe in Intrapelvic Surgery," by Clement Cleveland of New York. (15) "The Use of Compression Forceps in Salpingo-oophoorectomy and Hysterectomy, with Remarks upon the Angiotribe," by I. S. Stone of Washington. (16) President's address at 11 o'clock. Afternoon session at 2.30 o'clock. (17) "Vaginal Celiotomy," by A. Lapthorn Smith of Montreal. (18) "The Treatment of Broad Ligament Cysts by Vaginal Incision and Drainage," by T. J. Watkins of Chicago. (19) "Surgery of the Ovaries and Tubes per Vaginal Incision," by William H. Wathen of Louisville. (20) "Surgery of the Ovaries," by Fernand Henrotin of Chicago. (21) "Remote Results of Shortening the Round Ligaments by Vaginal Section," by Henry T. Byford of Chicago. (22) "The Scope of Vaginal Work," by J. Riddle Goffe of New York. Executive session at 5 o'clock. Third day.—Thursday, May 25th, morning session at 9 o'clock. (23) "Tuberculosis of the Kidney as an Indication for Nephrectomy," by Edward Reynolds of Boston. (24) Abdominal Operations for Conditions Complicating Typhoid Fever," by J. Wesley Bovée of Washington. (25) "Management of Surgical Injuries to the Ureters," by Beverly McMonagle of San Francisco. (26) "Use of Iodoform Gauze in Pelvic Disease of Women," by William R. Pryor of New York. (27) "Conservative Gynecology," by Seth C. Gordon of Portland, Me. (28) "Report of the Committee on the Use of Mammary and Thyroid Extracts in Solid Tumors of the Uterus," by William E. Moseley of Baltimore. In memoriam: (1) "Theophilus Parvin, M.D.," by William H. Parrish of Philadelphia. (2) "James H. Etheridge, M.D.," by Fernand Henrotin of Chicago.

VISIT OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION TO THE LOOMIS SANITARIUM.

ON Thursday, May 11th, the members of the American Climatological Association, who had been holding their sessions for the two preceding days at the New York Academy of Medicine, devoted the third day of their meeting to a visit to the Loomis Sanitarium for Consumptives at Liberty, Sullivan County, N. Y. Through the courtesy of the Ontario and Western Railroad a special train was provided for them. Though not in the early part an ideal day for sight-seeing, the weather cleared in the afternoon, and gave an excellent opportunity to judge of the beautiful scenery and the invigorating mountain air. The opportunity to see the sanitarium and its surroundings under the unfavorable circumstances of a rainy day was not without its advantages, since it afforded an excellent idea of how light and free from depressing influences the atmosphere of the place is compared to that of the city and sea coast during rainy weather.

After a generous luncheon a visit in parties of eight or ten was made under the guidance of nurses and physicians to the dozen or more houses that make up the sanitarium. The institution is able to accommodate about seventy patients, and has at present very nearly that number of inmates. The charges per week are from $12 to $25, and at present there is difficulty in providing accommodations for all those who desire to come. There is a resident medical staff and eighteen nurses at the institution, though the infirmary is not large and is intended

rather for intercurrent illness among the patients than for those who are confined to their rooms and require constant medical care because of their advanced tuberculous condition. The latter class of cases is not deemed desirable, and there exists a city branch of the sanitarium for patients deemed incurable. The city branch is not self-supporting, but the sanitarium at Liberty is expected to be, and is proving itself to be.

That the directors of the Loomis Sanitarium were not mistaken in their opinion that there was need for an institution where a class of patients would get sanitarium treatment for tuberculosis for which they were able and willing to pay reasonable charges, if certain comforts and a certain amount of exclusiveness and association with others of their class were provided for them, is evident from the financial success of the institution. That the methods employed and the situation are eminently favorable factors for the treatment of tuberculosis is clear from the published results, which are excellent, and which bear comparison with the results of sanitarium treatment anywhere in the world.

A feature of the nurses' training at the sanitarium seems to deserve special notice. After the regular training of two years is finished nurses may stay for post-graduate work, which consists of practice in details designed to fit them for rendering assistance to doctors in their offices. They are taught the microscopy of sputum, the chemical and microscopical examination of urine, the keeping of doctors' accounts, and the making of abstracts from medical journals, including as far as possible abstracts from German and French; in a word, everything that will enable them to relieve the physician of certain routine work for which he often finds it difficult to get the time.

The members of the Climatological Association returned to New York City by their special train late in the evening well pleased with their visit and with many expressions of confidence in the future of the sanitarium treatment of tuberculosis as it is conducted at no great distance from the patients' homes.

CORRESPONDENCE.

THE YELLOW TINGE OF PALMS AND SOLES IN TYPHOID.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Referring to your statement on page 467 that little attention had been given in this country to the yellow tinge of palms and soles in many cases of typhoid fever (I should say approximately 75 per cent. in my own observation—this guess being subject to correction from records) I beg to say that if you will consult the files of the MEDCIAL NEWS I am sure you will find an editorial reference to it from my own pen, crediting the observation, then recently reported from Germany, to the late Dr. Ellwood Wilson of Philadelphia. I have demonstrated it to my classes at the Philadelphia Hospital since 1890 as "Wilson's sign," and have known it since Dr. A. J. Biddle, who derived it from Dr. Wilson, showed it to me in 1883. How much older the observation is, I do not know. "It bobs up serenely" as something new every little while. Yours truly,

SOLOMON SOLIS-COHEN.

PHILADELPHIA, April 18, 1899.

PARTIAL RETENTION OF CONSCIOUSNESS DURING ANESTHESIA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Dr. Goldan's report of "An Extraordinary Case of Retained Consciousness During Anesthesia," in the MEDICAL NEWS of April 15th, seems to have created considerable interest among the medical profession. Will you kindly permit me to offer a solution of the phenomenon?

As is now well known, the nervous system is made up of a multiplicity of neurons, each consisting of a cell and two functionally different sets of processes, viz.: the dendrites and the axon or axis cylinder.

The psychic neurons, those located within the cerebral cortex, have exactly the same anatomical structure as a central sensory or motor neuron, that is, each one consists of a cell with its processes, its dendrites and axon. The axis cylinders must of necessity be extremely short, as they nowhere pass beyond the limits of the gray matter. When the processes of these neurons are agitated by stimuli it is felt by the ego as a sensation, from which, and upon which, is built the entire fabric of mentality. If there is a difference in the general mobility of the psychic neurons in different individuals why may there not be a difference in the mobility of the special neurons of any one individual?

I believe all will agree that anesthetics act by paralyzing the processes of the neurons. That under its influence they fall so far asunder that stimuli are powerless to bridge over the hiatus between them, consequently stimuli fail to reach the psychic elements of the brain, and as a natural corollary, no sensation can be felt. The processes of the common sensory neurons become paralyzed and, of course, sensation of pain cannot be evoked. In this manner, one by one, the areas involved in the special senses lose their sensibility until finally no form of stimuli finds its way into the mental precincts. The patient is then said to be fully anesthetized.

In the case of Dr. Goldan's patient I infer that she was fully anesthetized with but one exception, and that exception was the neurons concerned in the process of audition. I can readily understand how it is possible that the auditory neurons and those of the auditory centers might be the last to succumb to the influence of the anesthetic. It was only necessary for them to be a little more stubborn than those of the other senses. It required a more than ordinary degree of anesthesia to paralyze them. As long as their processes were not disconnected it was perfectly natural that they should perform their function as usual, and I see nothing extraordinary in the fact that the patient was conscious of a conversation going on; that she heard an instrument drop, or a knock at the door, or a voice through the speaking-

tube. If stimuli instigated by the waves of sound succeeded in passing the barriers between the auditory neurons and the psychic neurons of the auditory centers, the result could possibly be none other than the causation of the consciousness of sound. Yours truly,

H. H. STONER, M.D.

ROCK RAPIDS, IOWA, May 1, 1899.

[This application by our correspondent of the neuron theory to the phenomenon under discussion constitutes an interesting but extremely fanciful hypothesis and has the value of hypothesis only without even demonstrated or accepted analogy to support it. The neuron theory, even at the hands of its most enthusiastic advocates, has never extended to the psychic field. It is in its entirety an assumed premise and, therefore, may or may not be correct in its conclusions. It is, however, quite worthy of careful consideration.—ED.]

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

LIQUID AIR AS A GERMICIDE—TUMOR OF THE CAUDA EQUINA—TREATMENT OF RODENT ULCER BY CATAPHORESIS—PHENOMENA AND MECHANISM OF INHERITANCE—ANNUAL COMMENCEMENT OF JEFFERSON MEDICAL COLLEGE—HEALTH STATISTICS.

PHILADELPHIA, May 16, 1899.

"THE Resistance of Bacteria to Cold" is the title of a paper presented by Dr. M. P. Ravenel to the Pathological Society, May 11th, in which the results of some experiments with liquid air, made in March, 1898, were reported. The claim frequently expressed that liquid air is a germicide has led Dr. Ravenel to make this premature report, for while this agent has a temperature of 312° F. below zero, it is far from being proved that it is a germicide. Experiments were carried out by placing silk threads in sterile water to which had been added cultures of anthrax spore, diphtheria and typhoid bacilli, and the bacillus prodigiosus; these threads were then immersed in the liquid air for periods from one to sixty minutes, and then transferred to a culture-medium of bouillon. In no case was any effect noted upon the vigor or life of the organism. In the many experiments made in this line it has been found that sporeless organisms are retarded in their growth by freezing for one hour, and frequently destroyed when the time is extended beyond this period. Typhoid bacilli, however, have been found experimentally to be able to survive freezing in ice for more than three months, and practically we know this to be true, as is evidenced by the epidemic which occurred in this State in 1885, when feces after being frozen all winter caused an epidemic coincident with the spring thaw. In regard to the use of cold as a germicide, however, Dr. Ravenel concludes that it cannot be relied upon so far as any degree of temperature thus far obtained, with our present means of application, is concerned.

In the discussion Dr. Riesman asked whether 50° or 100° F. additional would make any difference after zero was once reached, to which Dr. Ravenel replied that he believed not. Dr. Stengel expressed himself as surprised that as long as liquid air is destructive to more highly organized tissue, it does not affect the organisms, for while a globule of liquid air may be held in the hand, owing probably to the formation of a layer of air under tension (vapor), which protects the tissue, the length of time to which the organisms were exposed excluded this phenomenon. It also seemed likely that cold would be injurious to the organisms inasmuch as ice to the chest in pneumonia is believed by some, though ridiculed by others, to do good and possibly does so by retarding the pneumococcus which is sensible to cold. Dr. Coplin called attention to the difference in the volatility of the gases forming liquid air, and suggested that changes might be induced in "stale" liquid air which would have some bearing upon the subject, to which Dr. Ravenel relied that these changes were present, "stale liquid air becoming blue in color as the oxygen volatilizes while normally it is of the color of glycerin."

At the same meeting, under the title of "Tumor of the Cauda Equina," Dr. Joseph Sailer reported a case of *primary sarcoma of the cord*, which is an extremely rare condition, only two cases (both doubtful) being recorded in the literature as primary, and only four authors having reported cases of secondary sarcoma, which were melanotic, as was Dr. Sailer's. The tumor, which was fusiform in shape (1½ by 2½ by ⅓ inches), granular, and contained numerous hemorrhagic foci, sprang from the left side of the cauda, and was enclosed in a firm capsule. There was no evidence of any infiltration of the cord, nor were the vertebræ diseased. The tumor was composed of pigment, spindle-shaped connective-tissue cells, with oval nuclei, and was in an unusual position, between the anterior and posterior roots of the left side. A most careful search failed to reveal the slightest sign of a tumor elsewhere in the body, and it was therefore regarded as primary.

At the Philadelphia County Medical Society, May 10th, Dr. G. Betton Massey exhibited a patient suffering from "rodent ulcer," or slow-growing epithelioma. When the patient, who was a physician, first presented himself, the ulcer was the size of two silver dollars, and had already eroded the eye, exposing the fatty tissue of the orbit and part of the skull. The treatment consisted in cataphoresis, produced by means of strips of zinc and mercury after small punctures had been made in the ulcer. Although cocain cataphoresis was done simultaneously, the patient was unable to stand a current of more than 2½ to 10 milliamperes. An immediate effect in the production of an area of necrosis, surrounded by new inflammatory tissue, was noted, according to Dr. Massey, and he regarded this, his first attempt to treat carcinoma of the short hair-follicles by cataphoresis, as a marked success.

Professor E. G. Conklin of the University of Pennsylvania. at the same meeting read a paper, entitled "Phenomena and Mechanism of Inheritance" in which he defined inheritance as the sum total of all the qualities which are passed from parent to offspring. As phenomena he mentioned the inheritance of like qualities, of qualities from the father or from the mother, and the blending of qualities from both as exemplified in the off-

spring of negro and white which usually takes a color between, or the blending of qualities which produce in the child entirely new attributes. He called attention to inheritance in anatomical characteristics, of which stature, color, etc., are examples; to physiological, of which longevity, the tendency to beget twins, etc., are examples; to pathological, of which monstrosities and deaf-mutism are examples.

As to the manner of mechanism, as all hereditary transmissions take place through two cells (the egg and the sperm), it is a question of studying the cells. This was discussed very fully by Dr. Conklin, the substance of his remarks being that as the chromozones of the cells are probably the bearers of hereditary traits, and these are equal in quantity in every cell in the body, it is evident why heredity is of the male as well as the female although the sperm is so small compared to the egg, for each contains chromozone which is constant in quantity.

Dr. Conklin's definition of acquired and inherited characteristics is that the former are those developed in response to extraordinary environmental and the latter to ordinary environmental conditions. Yet he believes they must both be truly inherited and as an example stated that to speak Chinese, English, and other languages is an acquired characteristic, yet *to speak* is inherent. Then arises the interesting question as to whether these *acquired* or unusual conditions will bring about like results in the second generation. There is little evidence to prove this true.

As an example it is supposed that changes due to use and disuse of faculties are the easiest to prove transmitted yet there is no evidence to support this view, for if it is adduced, as an example, that animals needing to climb and run have developed long limbs, so it can be deduced that animals who do not need to run should shorten their limbs which is not true. Dr. Conklin believes that *inherited habit* goes hand in hand with *inherited structure* and that evidence for hereditary mutilation is therefore unreliable, of which the "docking" of sheeps' tails which has been going on for years without resulting in any change in the natural tail, is an example. So, too, the experiment of a German botanist who transplanted plants from all parts of the Continent to his garden where, in the thirteen years he kept them, their descendants gradually acquired the characteristics of native plants; yet when transplanted back to their original habitat they immediately reverted to their original type. For these and other reasons, therefore, Dr. Conklin does not believe in the transmission of acquired characteristics. In the lengthy discussion which followed, Dr. Mills stated that he was inclined to believe in the transmission of acquired characteristics of which he believes there are many instances in disease. Dr. Riesman quoted Zieler as believing in this transmission and said that acquired immunity to disease, if transmitted, would prove this. The transmission of immunity, however, has not been proved, for rabbits made immune to tetanus give birth to young which are also immune *if they nurse from an immune animal*, but not otherwise. This would preclude the chromozone of the cell as being the seat of transmisssion. Dr. Lautenbach quoted Bell as having concluded that acquired deafness is not transmissible, though congenital deafness is.

Class-day exercises of the graduating class of Jefferson Medical College were held Saturday evening and the annual commencement on Monday. Hon. William Potter presided at the latter, an oration was delivered by Judge Mayer Sulzberger and the valedictory by Dr. de Schweinitz. In the evening the annual banquet of the Alumni Association was held at the Art Club.

The total number of new cases of contagious diseases occurring in Philadelphia during the week ending May 13th, was 271, reported as follows: diphtheria, 73 cases, with 14 deaths; scarlet fever, 45 cases, with 2 deaths; typhoid fever, 153 cases, with 22 deaths.

OUR LONDON LETTER.

[From Our Special Correspondent.]

PRACTICAL WORKING OF THE CONSCIENCE CLAUSE—PENSIONS OF ASYLUM PHYSICIANS—ADULTERATED SAUSAGES—HONOR TO DR. LEONARD WOOD—MELTING-POINT OF FATS—TUBERCULOSIS IN THE ROYAL DAIRY—SKULL OF SIR THOMAS BROWNE.

LONDON, May 6, 1899.

EVEN cowardice may give excellent counsel. The late Government surrender to popular clamor and anti-scientific prejudice, the renowned "conscience clause," is working unexpectedly well. Some time ago we called attention to its surprising results at Oldham and Burnley, the hot-beds of the "anti" movement, and now at the close of its first quarter's operation, the President of the Local Government Board is able to congratulate himself and party that the number of vaccinations under it has far exceeded that of the corresponding period for many years past.

The Liverpool School of Tropical Medicine has shown a distinct faculty for "arriving" already. Its opening exercises were held on April 22d, as announced, under the presidency of Lord Lister, before the distinguished audience of invited guests mentioned last week, almost every one of whom was present. The ward built for the school in the Royal Southern Hospital was dedicated in the afternoon, and a banquet held in the evening, with the public-spirited merchant prince, Mr. Alfred Jones, to whose generosity the scheme is indebted for the major portion of its sinews of war, in the chair.

The proposed amendments to the Lunacy Bill are exciting some uneasiness in the minds of medical officers of asylums, in respect to their pensions. The present provision is a fairly equitable one, a physician being entitled on retirement to a yearly pension of at least one-sixtieth of his pay and emoluments for each year of his service. That is, after twenty-years' service, a pension of one-third of his regular salary; after thirty years, one-half of his regular pay. The new proposal calmly ignores all this and provides that if the retiring officer shall have displayed "diligence satisfactory to the committee" this magnificent body may "grant such allowance as they think proper," thus making not merely the amount, but the very pension itself dependent upon the whim or favor of an autocratic board, an arrangement which few, who

have had any experience with the frequent ignorance, unreasonableness, and tender mercies of official bodies, will have any confidence in.

The *Lancet* still continues to expose the skeletons of our gastronomic family cupboards. It has just reached sausages, and we are, of course, prepared here for revelations which will cause our *arrectores pilarum* to contract, but the results are agreeably disappointing. No mention whatever is made of the classic claw or the traditional trousers-button, and the only adulterants referred to are the tame and comparatively unobjectionable horse-flesh, and bread tinted with ferric oxid. The interesting statement is made that horse-flesh is so rich in glycogen that its presence can be detected by the iodin test, even in as small proportions as five per cent. of the mass. The analysts find colored bread by far the most common adulterant, and as popular taste in England prefers a certain proportion of this substance in sausages, they recommend that a maximum bread-percentage should be established by law. And this is certainly needed, for some brands of sausages which one stumbles upon in the market here, are little more than well-flavored poultices.

A most sensible warning has just been issued by the Government of Natal, against the prevalent practice among English physicians of sending tuberculous patients in all stages of the disease out to South Africa, indiscriminately, often in almost destitute circumstances, apparently in the vague hope that the climate is a sort of specific, and will restore the strength so rapidly as to enable them to earn a living by out-door work. The report very properly points out that, as we have found out by bitter experience with this delusion in California and Colorado, consumptives in the third stage are really better off at home, that public hospitals are few and hard to get into, and that all the expenses of sickness are higher than in England, and the food and accommodations often most inadequate. Many a poor young fellow has been sent out to die in some rough, little frontier town, where it was impossible to secure proper accommodations, or even the ordinary comforts of civilized life.

A most ingenious method has just been devised for determining the different melting-points of fats, a test much used in detecting the presence of suets in butter. Two platinum wires coated with the fat to be tested are connected with the two poles of a battery. They are then plunged into a cup of mercury, the temperature of which is gradually raised by a Bunsen-burner. As soon as the melting-point of the fat is reached, the coating is, of course, dissolved from the wires and a circuit made between them through the mercury, the passage of the current ringing an electric bell. All that is necessary is to listen for the bell, and when it rings read off the thermometer which stands in the mercury.

The *British Medical Journal* pays a most unusual and gratifying compliment to the American profession and nation by publishing in its last number an excellent portrait of the medical hero of Santiago, General Leonard Wood, with a sketch of his life taken from the April number of the *Buffalo Medical Journal.*

Another honor conferred upon us last week was the election of Dr. Frederick S. Dennis of New York as a Fellow of the Royal College of Surgeons. The Honorary Fellowship of the College is one of the highest honors which can be won by an English-speaking surgeon, and is only granted by the Council at rare intervals.

The College of Surgeons has appointed as its delegates to the International Congress on Venereal Diseases Jonathan Hutchinson and Alfred Cooper.

The death was recently announced of Mr. Jabez Hogg, the well-known eye consultant and author of that most successful book, "The Microscope," which passed through no less than fifteen editions.

The slaughtering of the Queen's dairy-cattle for tuberculosis, mentioned by the Prince of Wales in his Marlborough House speech, which attracted such wide attention, has now been reported upon by Professor Macfadyean, the well-known veterinarian, by whose advice it was carried out. The herd was first tested by tuberculin, and so many of them reacted that it was decided to slaughter all of them, when no less than *thirty-six out of the forty* were found to be tuberculous. And as if this were not enough, four of the cows had a "septic" disease of the udder, and five were riddled as to their livers with echinococcus cysts. Professor Macfadyean says that the stabling, food, and care of the herd were simply ideal, but ninety per cent. of tuberculosis is something frightful, and well may "uneasy lie the head that wears a crown" if this is the sort of milk and butter which it has to subsist upon.

The proposed erection of a statue to Sir Thomas Browne, author of the famous "Religio Medici," in his native town of Norwich, has called attention to the fact that his skull now occupies a place of honor in the Norwich Hospital Museum, where the writer had an opportunity of examining it a short time ago. It is of a beautiful, well-balanced dolichocephalic type, now recognized by ethnologists as that of the highest races, rather low in the frontal, but very broad and full in the parietal and occipital regions. His grave was opened by accident, while repairing the foundations of the church in 1840, and his skull and coffin-plate, with rather irreverent enterprise, were secured by the museum. So well preserved were his remains that the hair was nearly perfect and of a bright red-brown color, closely corresponding to the descriptions given in his biographies. The gentle Sir Thomas, in spite of his shrewd and scientific turn of mind, evidently shared one of the pleasing delusions of his age, for the quaint Latin inscription on his coffin-plate states that the casket is filled with a powder "corporis Spagyrici"—whatever that may be—which will turn its leaden shell into gold, though what satisfaction he expected to get from such a post-mortem triumph puzzles one to imagine, unless he expected to wear it as a sort of "golden slipper" on Resurrection Day.

"Bulletin of the Cleveland General Hospital."—The first number of this new medical quarterly does credit to its editor, Dr. Charles J. Aldrich, and to the staff of the hospital. The make up is attractive; its original articles are all clinical memoranda from the hospital wards and are of a thoroughly practical character.

TREATMENT OF PHTHISICAL PATIENTS WITH ANTITUBERCULOUS SERUM — PREVESICAL HERNIA — BILIARY CALCULI IN INFANTS—CURE OF CANCER BY OOPHORECTOMY AND THYROID EXTRACT—SKIN AFFECTIONS IN RENAL DISEASES—DEATH AFTER GAS AND OXYGEN FOLLOWED BY CHLOROFORM.

AT the Royal Medical and Chirurgical Society, March 28th, WILLIAMS and HORROCKS reported the failures which had followed the treatment of several tuberculous patients with antituberculous serum, obtained from a horse. The general condition of the patients, and the examination of their chests and sputa, showed that the disease progressed steadily, and in some instances rapidly. A second series of experiments was undertaken, with serum taken from the horse at a much longer period after inoculation (seventy-two days), and the doses employed were much smaller (from 1 c.cm. up), while all of the patients chosen had limited lesions. The results under these conditions were gratifying. All of the patients gained in weight and strength; the tubercle bacilli in their sputum decreased in all instances save one; while physical examination showed that the areas of consolidation and the cavities had ceased expanding, or had actually diminished in size. Various cocci which were present had disappeared. The experimentors were encouraged to proceed with this method of treatment.

At the session of April 11th, MAKINS read a paper on prevesical hernia, based on a personal experience. A man, aged forty, after exposure to a storm was seized with violent pain and vomiting. He was found to have a reducible right inguinal hernia. The symptoms persisted after the reduction, but subsided under rest in bed, light diet, and poultices. In three weeks the patient suffered a similar attack, which was relieved in the same way. Eight weeks after the first attack the abdomen was opened over a hard mass in the suprapubic region, which proved to be a peritoneal pouch containing adherent omentum, and one adherent loop of small intestine. The sac was removed, and the wound sutured. It had no connection apparently with the right inguinal hernia. The author mentioned four cases of preperitoneal hernia in which the internal sac projected into the vesical region, but these did not seem to him to be true prevesical cases.

HUTCHINSON related the case of an otherwise healthy man who had had for a long time a reducible inguinal hernia which gave him no trouble. He was seized with pain in the lower abdomen and vomiting. Examination showed a fulness to the inner side of the ring, and abdominal section was performed. Immediately to the right of the bladder there was a pouch in which was a strangulated loop of intestine. It is noteworthy that in all such recorded cases, an ordinary hernia pre-existed. The origin of such a hernia is obscure, but it is plain that if symptoms persist after the reduction of a hernia, one ought to open the abdomen and seek the cause of obstruction, just as he would if there was no visible hernia.

At the Pathological Society, April 4th, STILL reported three cases of biliary calculi in infants, aged nine, eight, and five months. There were no symptoms during life pointing to this condition, except that one child screamed frequently, and drew up its legs as if in abdominal pain. There was no jaundice. The calculi were very small, the largest measuring only one-eighth inch in diameter. They seemed to consist of pure pile pigment. No less than fourteen of twenty-three collected cases of calculi occurring in children were in infants less than ten months old. Biliary calculi must, therefore, be reckoned as one of the causes of persistent jaundice in the new-born, as well as one of the causes of colic in young infants.

At the Medical Society, April 10th, HERMAN showed a woman, aged forty-nine, whose right breast together with the pectoral fascia and axillary glands had been removed four years before for cancer. Recurrent nodules were excised the same year. Three years ago the cancer recurred and ulcerated, and continued in that condition. Nine months ago both ovaries were removed, and the patient was put on thyroid extract, 5 grains, three times a day. In eight months the ulcer had entirely healed, and a scirrhus nodule in the left breast, three inches across, and the enlarged left axillary glands had entirely disappeared. There remained some keloid-like nodules in the cicatrix of the ulcer. This is the second apparent cure of cancer by oophorectomy and thyroid extract which Herman has reported. He considered the combined treatment better than either part of it if carried out alone.

BOYD mentioned a case in which thyroid extract was given for twelve months, the tumor remaining stationary. The patient then disappeared from observation. Six months later she presented herself, the tumor in the meantime having wholly disappeared. Gould published a case in which nodules in the femur and elsewhere, recurrent after removal of cancer of the breast, had entirely disappeared without any treatment. It is to be noted that all of these cases were in patients at about the menopause.

At the Clinical Society, April 14th, WEST read a paper on skin affections in renal disease. Rashes associated with edema are for the most part erythematous in character, transitory in duration, produce few symptoms, and unless general, have but little clinical importance. Rashes without edema occur almost exclusively in the course of "granular kidney." They are generally widespead, and often universal, of great obstinacy, and of grave significance, taking the form of erythema, pityriasis rubra, dermatitis exfoliativa, general eczema, and lichen. They are rarely hemorrhagic. West remarked that the rashes occur only late in the disease, and when the signs of granular kidney are well-marked, though not infrequently overlooked. The association of a generalized skin eruption, with albuminuria, is of great importance, and if the cause of the albuminuria is granular kidney, it is of the gravest significance, for the patient will soon die —not of the skin affection but of the granular kidney.

At the Society of Anesthetists, March 17th, GRANVILLE spoke of the death of a boy, aged seventeen years, to whom gas and oxygen were administered for twenty minutes. The supply being exhausted chloroform was given with great care. After four or five minutes the

pulse became weakened, and the chloroform was at once withdrawn. The pulse quickly failed, but the breathing continued deep and regular for five minutes, and then the patient died in spite of every restorative effort. He thought that chloroform should not be given after gas and oxygen, the effect of which is undoubtedly to dilate the the heart.

SILK'S experience went to show that the after effects of gas and oxygen are more frequent and varied than those which follow gas alone. They may persist after the individual has regained consciousness. The mixture was not one to advise for indiscriminate use.

CROUCH said that he had experimentally proved that gas and air, or gas and oxygen, dilate the heart.

BUXTON said that the mixture had been praised as a panacea by some who were unaware of its limitations.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, Held at the New York Academy of Medicine, May 9, 10, and 11, 1899.

FIRST DAY—MAY 9TH.

MORNING SESSION.

THE opening address by the President, DR. BEVERLY ROBINSON of New York, had for its subject

THE IDEAL PHYSICIAN—HIS CHARACTER AND ATTAINMENTS.

He said in part: Nowhere could this subject be more suitably spoken of than here in the New York Academy of Medicine, the walls of which are adorned with portraits of ideal physicians whose lofty character and superior attainments made them the leaders of men and of medicine in their day and generation. Unfortunately, as time goes on and the spirit of commercialism spreads, there is noticeable a degeneration from the high ideals of other days and money-getting becomes the great desideratum of certain professional men instead of that honorable position in public esteem with a modest competence and thorough feeling of self-respecting consciousness of duty fulfilled that was the aim of other days. The invasion of specialism has had much to do with this for the general practitioner was and is ever cast in a different mold and has other purposes. Only the few, very few, have been affected by this sordid spirit as yet, but it must be decried and if possible gotten rid of.

Physicians must cultivate a high personal ideal that shall affect their every action in life. While assuming none of the priestly character they must ever be found in the forefront of the battle for high public ethical standards. They must be leaders in reform, not alone in sanitary and hygienic matters, but in everything that concerns the public good, in politics, in public morals, in education. With the highest reverence for Nature's laws they must countenance no indecency and no crime perversive of natural order. Their education must include the heart as well as the mind.

As to their scientific attainments they must, of course, be of the highest possible order. Yet it must never be forgotten that the practice of medicine is an art, not a science, and due weight must be given to the results of their own experience. While keeping thoroughly abreast of modern advances in science the physician must not allow his practical judgment to be overruled by supposed scientific discoveries. In our own time, in the midst of the germ theory of disease, for instance, he must remember that great conservative medical authorities still hold out for the special liability of the organism to disease as the true cause of disease rather than specific germs.

The general practitioner, especially while not permitting the great special advances in medical science to escape him must be able to direct the specialists' work, not merely referring patients to the specialist because their treatment is not of his own range, but carefully providing that at no time a narrow view is taken of the patient's ailments. There will always remain for the family practitioner in the midst of the invasion of specialism an important rôle in this guidance of the work of the specialist, a rôle that will be of the greatest benefit to the patient himself and to the progress of practical medicine. While the high character and wide attainments this rôle demands may seem ideal, it is striving after this ideal that will keep the profession on the lofty plane it should occupy if it will be true to itself and its own great inherent purposes.

The first paper of the meeting, entitled

TREATMENT OF CONSUMPTION BY AIR AND LIGHT IN COLORADO,

was read by DR. CHARLES FOX GARDINER of Colorado Springs. He considers that air is the first requisite in the treatment of pulmonary tuberculosis. There are those who put nutrition in the first place, but herds of cattle well housed and well fed are often known to develop tuberculosis while the disease is rare among the ill-fed, neglected cattle wandering on the plains. The conditions requisite are mainly a dry thin air that encourages increased expansion of the lungs, for which altitude is an efficient factor, and that it shall be pure and free from dust. An important element in the cure of tuberculosis is light. For that the climate of Colorado is especially favorable since there is fifty per cent. more sunlight than at any city in the East. This has been experimentally demonstrated by photographic exposures. The collection of the experience of patients, even during the unfavorable weather of this last winter shows that there are very few days on which they cannot be out of doors between 10 A.M. and 4 P.M.

Ranch life in Colorado would seem to be ideal for tuberculous patients, but there are opportunities for exposure and overexertion, and the diet is often hard of digestion, so that ranching is only suitable for strong patients. Tent-life for young adults gives excellent results. The tent should have an opening at the top and should be raised a few inches above the tent-floor (there should always be a floor) so that a constant circulation of air is secured. Tents without such precautions can be, as any one who has lived in them knows, extremely stuffy

and unbearable. Such a tent may be habitable even in severe weather, and Dr. Gardiner has lived in one in a blizzard. Light and air are the important factors in all treatment of tuberculosis.

DR. PHILLIPS of Washington, D. C., said that he was glad that Dr. Gardiner called attention to the importance of light in the treatment of tuberculosis. To his mind this plays even a greater rôle than altitude in the success of Colorado for the disease. The rarefied air of altitudes requires more exertion of the lungs while a damaged organ usually gets better by rest. The subject of the influence of light deserves careful investigation.

In answer to a question Dr. Gardiner said that patients could get at least five and one-half hours of piazza life every day between 10 A.M. and 4 P.M., but it was not always easy to secure control over them to make them take this much out-door life.

DR. W. D. ROBINSON of Philadelphia said that any climate brought improvement for tuberculosis if the air was reasonably good and patients took proper care of themselves. In the early days when Chicago was a frontier town consumptives were sent there as to a health resort and were benefited.

DR. N. S. DAVIS, JR., of Chicago said that while he would not wish to underestimate the value of climate, still in the treatment of tuberculosis, nutrition was the other important element in treatment, and the two things must go hand in hand to bring success.

DR. SHERMAN G. BONNEY of Denver, Col., read a paper, entitled

SUGGESTIONS CONCERNING EARLY DIAGNOSIS IN PULMONARY TUBERCULOSIS.

Dr. Bonney said that it was clear that thousands of lives were sacrificed every year because of late diagnosis of tuberculous invasion. The earlier the diagnosis the better chance for cure, and it was in early cases that cures were lasting. In Colorado the doctor sees advanced rather than incipient cases. It would seem well to review the means of early diagnosis. The bacillus will sometimes not be found in the sputum until there is destruction of tissue, and at times even secondary infection. After physical signs are marked sometimes the bacillus cannot be demonstrated. The Röntgen-rays would form a valuable aid to early diagnosis, but they are of course out of the question for the general practitioner to whom most cases of tuberculosis come for treatment. The hope that a pretubercular stage could be recognized from the blood has proved illusory so that the old physical signs retain practically all their significance. The lesson they teach is not, however, realized soon enough or not acted on.

Solly has shown that two years pass after infection before patients go to Colorado. In my own experience it has been almost as long. There was in my cases an average loss of nineteen pounds, and a good proportion of cases with distinct phthisical heredity, or who developed their symptoms subsequent to influenza. These circumstances were of enough significance to have suggested very careful examination at least. A number of patients had had hemorrhages so that delay in diagnosis seems inexcusable. No one physical sign is pathognomonic, but certain groupings of signs are very significant, and a history of such incidents in the patient's life as idiopathic pleurisy, even slight pulmonary hemorrhage, slow recovery from pneumonia, persistent cough, even though without expectoration, should arouse grave suspicion. The absence of febrile movements is not convincing as to the non-existence of phthisis; their presence is almost pathognomonic.

As a rule, full examination seem not to be made until a provisional diagnosis of tuberculosis has been reached. Even then the bases of the lungs and the interscapular spaces are not given the attention they deserve. Even variations of the respiratory murmur, when connected with other suspicious signs in the absence of adventitious sounds are significant. The doctor should realize that on early diagnosis probably depends the life of the patient, certainly his physical welfare for years.

DR. E. O. OTIS of Boston read a paper, entitled

NOTES ON THE TUBERCULIN TEST.

He considers that there is an unreasonable prejudice against the use of tuberculin for diagnostic purposes because of the bad results that followed its use in the early days. In small doses—5 to 10 milligrams, never over 20—he thinks it without danger. It is an excellent diagnostic measure, and much more generally applicable than the Röntgen-rays. It is simple, and gives definite results. He has used it now in 111 cervical adenitis cases. Practically all of them were in dispensary service, ambulatory cases, and he is convinced that even under these conditions it is a useful agent, and to be relied on.

He has used both Koch's and the Adirondack tuberculin, but prefers to use one for the sake of uniformity. Usually 5 to 10 milligrams have been sufficient, and he never goes above 20. Different tuberculins are of different strengths, and this has led to some difference of opinion as to the dosage. As a rule the results obtained have been absolutely reliable. Certain syphilitic cases gave a reaction in the absence of tuberculosis, and advanced cases gave a local rather than a general reaction, and in general the constitutional reaction from these small injections is in inverse ration to the extent of the tuberculous process present. Bearing these guiding principles in mind, the significance of the reaction can be depended on. The fact that a reaction occurs in syphilis is not a great source of error in this country as syphilis is not very common, and the history of it can be elicited.

DR. VINCENT BOWDITCH of Boston read a paper, entitled

SUBSEQUENT HISTORIES OF ARRESTED CASES OF PHTHISIS TREATED AT THE SHARON SANATORIUM (NEAR BOSTON, MASS.).

The sanatorium has none of the climatic advantages usually considered so helpful in the treatment of tuberculosis. It is not on high ground. It is near a large city and near the sea, and in a climate not much different from that of Boston itself. It is on good, dry, gravelly soil. The success of treatment at it shows that an in-

stitution near home on dry soil, protected from inclement weather by woods and hills, may give excellent results. Of 36 patients discharged as arrested cases, 6 have since died, usually from other causes than tuberculosis, 24 are pursuing their ordinary avocations; of the remainder some have not been heard from; some have had relapses. All of the patients had lost weight or had other signs, but in only 12 were bacilli discovered. Altogether the results speak highly for sanatorium treatment of tuberculosis, so that it is interesting to note that Massachusetts has established a State sanatorium, the first State to do so, and New York is about to follow suit.

As a rule, an effort was made when the patient was discharged not to have him or her go back to the conditions under which the phthisis originally developed. Dr. Bowditch does not believe much in drugs, but in careful nutrition, judicious exercise, and air.

DR. STUBBERT said that bacilli could at certain times not be found in the sputum of tuberculous patients, so that with other physical signs Dr. Bowditch was perfectly justified in treating the cases as consumptives. Dr. Stubbert thinks that the treatment of complications and the relief of symptoms constitutes an important auxiliary element in the treatment of consumption.

DR. F. H. WILLIAMS has seen tuberculous patients improve a great deal even after admission to the wards of a general hospital because of the regular quiet life and the better nutrition.

DR. BOWDITCH considers this improvement only temporary, and that it occurs especially in cases in which the nutrition was poor before.

DR. FRANCIS H. WILLIAMS of Boston read a paper, entitled

ROENTGEN-RAY EXAMINATIONS IN INCIPIENT PULMONARY TUBERCULOSIS.

After 165 examinations made with the X-rays and the thoracic screen Dr. Williams saw their value for diagnostic purposes. The shading of the apices and the lessened excursion of the diaphragm are only rivalled by the discovery of the bacilli in the sputum or the tuberculin test. The patients examined can be divided into two groups, first, those who had physical signs but no râles, and second, those who had no physical signs. In the first group Dr. Williams has reported three cases before; he now has seven more. In the second group examinations of the thorax were made usually for heart trouble and the shading at the apices being found the tuberculin test was used to confirm the diagnosis.

In two rheumatic cases absolutely without physical signs the apical shading was distinct and the tuberculin test proved positive. Dr. Williams has often been struck by the frequent association of tuberculosis and rheumatism. Experiment, post-mortem, has shown that consolidated lung is ten times more resistant to the passage of the X-rays than normal lung. Hence nodules of consolidation in the midst of healthy tissue may be discovered and even an increased congestion of the organ produces its effect upon the thoracic screen.

The X-rays alone will not make the diagnosis, but taken with the physical signs they assure. On the other hand, where suspicious physical signs without râles are present they may clear up the case and make the prognosis better.

In emphysema they are especially useful, for while the pathologically inflated lung tissue offers an almost insuperable objection to getting the physical signs of a tuberculous process in such lungs it makes no difference to the X-rays how much air or air-containing tissue there may be. The diagnosis once made may be confirmed by finding the bacilli or by the tuberculin test.

The thoracic screen is very much superior to the X-ray photographs for these cases. Dr. Williams exhibited X-ray photographs showing how certain shady areas had been missed in some cases, and showing how different appearances were according to the printing of the photographs.

DR. STUBBERT said he had watched the development of the use of the X-rays for diagnosis in tuberculosis with a great deal of interest. It had now become a valuable diagnostic aid. In his experience the thoracic screen was far ahead of the X-ray photographs in the amount and definiteness of the information they conveyed.

AFTERNOON SESSION.

The first paper was read by DR. B. P. ANDERSON of Colorado Springs, and was entitled

INTERMEDIATE ALTITUDE FOR THE CONSUMPTIVE.

The fact that high altitudes are of benefit to consumptives has turned the Colorado desert into a crowded paradise. But not all consumptives do equally well at high altitudes and some are not able to stand at all the rarefied air of Colorado. There is a feeling of discomfort that develops almost at once and that does not wear off with time. It disturbs rest and nutrition and finally makes it clear that this elevation is unsuitable for the patients. For such cases an intermediate altitude often does good. They feel better at once at an elevation of 3500 to 3800 feet, and improvement continues.

During the winter months they may be sent to places of about this altitude in New Mexico. New Mexico is, however, too hot in the summer-time. Often after a few months' sojourn in an intermediate altitude these patients may return to Colorado without experiencing the former discomfort and continue their residence there with continued improvemen'.

In discussion DR. LEONARD WEBER of New York City said that in hemorrhagic cases especially there is danger in sending patients to a high altitude. In advanced disease with the normal respiratory power already decreased by the extensively diseased lungs, the call for over-exertion on the part of already crippled organs was liable to cause serious harm. As a matter of fact, it was not the altitude that was the important therapeutic element, but the pure, dry air and that may be obtained without the ascent.

DR. SOLLY of Colorado Springs said that all cases with continuously high pulse or continuous fever, many hemorrhagic and advanced cases, and all those that can not take regular exercise do not stand high altitudes well; some cannot bear them at all. All the physicians in Col-

orado recognize that such cases do better in certain parts of Arizona and New Mexico. The Las Cruces Valley and certain places near Tucson, Arizona, seem especially favorable as far as regards meteorological conditions. The accommodations for patients are very poor, however, long stage rides have to be taken, the food is often coarse and unsuitable, the life indoors not agreeable. The Climatological Association would accomplish a great, good, work, if, by calling attention to the needs in this direction they could get the proper people to provide the accommodations.

DR. NEWTON of Trenton, N. J., said that this question of food is important, for nutrition is the key-note of the struggle with tuberculosis. So long as people digest well there is hope, but people with poor digestion do not get well.

DR. CHARLES F. MCGAHAN of Aiken, S. C., read a paper, entitled

WHY FUMIGATION OF APARTMENTS OCCUPIED BY TUBERCULOUS PATIENTS AT HEALTH RESORTS SHOULD BE UNDER MUNICIPAL CONTROL.

There is real danger for patients at health resorts unless the most careful disinfection is enforced. It may be that a patient with incipient tuberculosis will succeed to the room of an advanced case of tuberculosis, the walls, floor, and furniture of which are perhaps reeking with tubercle bacilli. It is important in such a case that the medical attendant shall be assured that the room and everything in it has been thoroughly disinfected. Owners often do not believe in the contagiousness of tuberculosis, and so are careless in cleansing or they do not know how to disinfect properly and make it scarcely more than a perfunctory cleaning. Every room in houses devoted to the receiving of tuberculous patients should be examined by some local Board of Health, and certificates granted only for those known to be in good condition. Besides this, the ordinances as to spitting in cars and on sidewalks, etc., should be rigidly enforced in these towns, and the washing regulated so that handkerchiefs and other clothing shall not be washed together. Patients should be required to use pieces of cheese-cloth to expectorate into, which should be burned afterward, not sent to the laundry.

DR. E. O. OTIS of Boston considered Dr. McGahan's suggestions as very practical and important. The method of certification so as to secure the object intended, effective disinfection and not perfunctory work, will require careful consideration. At Cannes where there seems to be a good system in operation when a patient who has been under the care of a physician either dies or leaves a room the physician sends a card to the proprietor of the house who must send it to the Bureau of Hygiene. The bureau, after having disinfected the room or apartment, returns the card stamped to that effect to the physician. All hotels and houses that wish to keep lodgers are registered with the mayor, and as the records of disinfection are kept a physician may easily learn the condition of any of them.

DR. GARDINER of Colorado Springs thought that the danger of infection is less at an altitude. Though in years gone by disinfection was imperfect in some of the older hotels no bad results seemed to follow either for patients or their attendants. He collected last year dust from one of the oldest of the Colorado Springs Hotels, since burned down. Yet when injected into susceptible animals it did not produce tuberculosis. Infection in human beings does not seem to follow so much from dust inhalation as from recrudescence of old tuberculous processes. Fifty per cent. of people have tuberculous foci somewhere in them which light up when they run down in health, or when placed in unfavorable hygienic circumstances that lower their resistive vitality.

DR. HINSDALE said that the American Climatological Association should draw up a set of regulations setting forth how rooms that have been occupied by tuberculous patients at health resorts should be disinfected. This would supply a standard by which those interested in keeping lodgers should direct their efforts at disinfection. When left entirely to themselves their work is necessarily more or less perfunctory.

DR. MCGAHAN, in closing the discussion, said that the methods at present employed are often worse than perfunctory. Very little that is really effectively disinfecting is done, yet from the fact that something has been done a false sense of security is developed. Perhaps after a careless sealing or no sealing at all of doors and windows a sulphur candle is burned in a room, the doors and windows are left open till the sulphur fumes escape, then the furniture, the woodwork of which has been brushed off with an antiseptic solution, while the upholstered parts have been perhaps left severely alone, is returned to the room and it is considered to have been disinfected. Some reliable system of disinfection, the employment of which should be enforced by rigorous inspection on the part of some constituted authority should be adopted. Only this will keep ignorant landlords, or those to whom money is the all important consideration, from neglecting their duty toward their guests in this matter.

DR. J. B. WALKER of Philadelphia read a paper, entitled

SOME REMARKS ON CLIMATE IN RELATION TO RENAL DISEASE.

which will appear in a subsequent issue of the MEDICAL NEWS.

DR. THOMAS D. COLEMAN of Augusta, Ga., agreed with Dr. Walker as to the influence of climatic conditions, and especially temperature and humidity, upon renal disease, for kidney trouble is rare at the South and occurs certainly much more infrequently than at the North.

DR. JUDSON DALAND of Philadelphia thought that the influence of climate may be exaggerated and that the difference in diet, in temperatute, and warm countries, just as between winter and summer, must have a great deal of influence. Especially does the greater quantity of water consumed in hot weather and in warm climates serve to flush out the kidneys and relieve them of the irritation of excreting concentrated toxic materials.

DR. W. F. R. PHILLIPS of the Weather Bureau at Washington, D. C., said that in steadily warm or cold climates the diurnal range of temperature is not great and

patients can clothe themselves more suitably and so are not subject to the effects of sudden changes of temperature. It is these sudden changes of temperature, often interfering with the function of the skin, that especially act unfavorably on the kidneys and are the etiological factors of more frequent renal disease in temperate climates.

DR. SAMUEL A. FISK of Denver, Col., said that at the stockyards in Chicago Western steers could be recognized by the perfect kidneys they usually possessed. The climatic conditions in the West were good, not alone for the lungs, a fact that was well known, but for the kidneys too, and account should be taken of this in recommending a climate to patients. Very seldom did the physician see acute Bright's disease in the West.

DR. L. D. BULKLEY of New York City said that his personal experience with renal trouble was of interest. When young he had found albuminuria and resolved to live in a mild equable climate. He had begun to pack his trunk for Brazil, when circumstances had detained him, and he has been enabled by judicious care of himself to remain here in comparative health. He had succeeded especially in limiting the amount of albuminoid material he would have to take in other forms by drinking milk on an empty stomach in large quantities, when he believes it is directly absorbed and does not lead to the production of irritative excrementitious substances. He has had several acute exacerbations of his kidney trouble, the severest some years ago, while in the Yellowstone Park, and certainly not from exposure to dampness there.

DR. N. S. DAVIS, JR., of Chicago said that he had recently seen the statistics of deaths in various parts of the country from renal disease in some insurance statistics that he was looking up for another purpose. As they threw light on the question of the geographical distribution of renal disease he would quote from them. According to those statistics the fewest deaths from renal disease among the insured occurred in the Northern States of the Mississippi Valley, the most on the Pacific Coast, and after them in the Eastern States. The South was not especially favored in the absence of kidney troubles according to this.

The next paper, by DR. L. B. BULKLEY of New York, was entitled

CLIMATE AS IT AFFECTS THE SKIN AND ITS DISEASES.

By climate is to be understood not alone meteorological conditions, but in general the manner of life under these conditions. A good deal of the influence upon the organism usually attributed to climate is effected through the skin, though this fact has not been paid sufficient attention to hitherto, and the present paper is probably the first, for there seem to be no others on the subject in the literature in which the effect of climate upon the skin has been carefully studied.

Climatic influence on the skin may be judged first from the production of disease of the skin. Leprosy seems to require certain climatic conditions for its existence that are not fully understood. It is not especially favored by cold or heat nor by dampness or dryness. It does spread in Hawaii and in Iceland. It failed to spread in the United States, though introduced into Minnesota. Not a single case of acquired leprosy has occurred in New York, though lepers have been almost constantly in the city.

In syphilis temperature has an influence on the lesions that occur. In hot countries especially, the skin is affected and deep ulcerations occur. In cold countries lesions of the bones and internal organs especially are noted.

Eczema is much more common in our changeable climate than in warm or cold but more equable countries. It is aggravated in cold, damp weather. It is often better at high altitudes or when patients go South. It is usually aggravated by the damp air near the Great Lakes.

Psoriasis is not near so common in the tropics. Acne is usually worse at the seashore, and boils occur more frequently. Parasite diseases of the skin are worse near the sea coast than in the interior. It is evident that this question of the influence of climate on skin diseases is an important one that deserves careful study.

DR. L. D. JUDD of Philadelphia read a paper, entitled

THE HYGIENICS OF THE SKIN.

Dr. Judd considers the skin the most abused organ in the human economy except perhaps the stomach. It is subject to abuse from unseasonable bathing, the use of improper, irritating soap, rubbing with rough, harsh brushes or towels, and by the constant irritation of improper underclothing. Besides, the same people consider it necessary to subject it to a sort of periodical purging by the frequent use of Russian or Turkish baths. He would plead for a warm bath in the morning followed by a cold douche and gentle rubbing with a soft towel.

As to the kind of underclothing the question is most important. The use and prejudice in favor of woolens has become almost a fetish worship. Dr. Judd himself, after several years of personal experience, and noting the results in his own family and practice considers linen-mesh underclothing the only proper kind. It should not be fine but closely woven and should be worn all the year around. Woolen underclothing, despite the prejudice in its favor predisposes to colds. Linen protects from colds, and Dr. Judd himself and his family and patients have been less troubled with recurring colds since they took to wearing linen-mesh next the skin.

DR. BULKLEY said that his personal experience had been exactly the opposite to that of Dr. Judd. After trying the linen-mesh he had given it up and he now used the same weight of woolens summer and winter. They seemed to keep the heat out in summer as well as they kept it in in winter and he does not feel more uncomfortable than people around him in the warm weather. He believes that many people bathe too much. Years ago Hebra at Vienna called attention to the fact that certain skin diseases were aggravated by bathing and that in places around Vienna where bathing was more common, skin diseases were more frequent. In general the profession had laughed at Hebra, considering his opinion the expression of a man with whom his bath was

not a favorite, but gradually we have come around to think there is more in it than we used to think. Dr. Bulkley is not so much of an advocate of bathing as he used to be and is accustomed to tell patients jokingly that animals in water have scales and that those who are much in water may develop scales. Certainly injudicious, too frequent bathing causes congestion of the liver and other internal organs and causes other alterations of circulation not compensated for by its stimulant or sedative effects.

DR. IRWIN H. HANCE of Lakewood, N. J., read a paper, entitled

HYDROTHERAPHY IN THE TREATMENT OF INSOMNIA.

He has had excellent results in the treatment of very obstinate cases of insomnia with a combination of warm bathing and static electrization. The improved cutaneous circulation after the baths led to better general circulation and toned up the nervous system. Of course where local causes exist they will have to be combated by drugs, and the diet and exercise will have to be carefully regulated. There should be gentle exercise every day but never to over-exertion. Static electricity, the patient being positively electrized and the other pole grounded seems to add in Dr. Hance's experience to the alterative effect of the hydrotherapeutic measures and aids in establishing that nervous balance on which refreshing sleep in normal amount depends.

SECOND DAY—MAY 10TH.

DR. W. D. ROBINSON of Philadelphia read a paper, entitled

THE CLIMATOLOGY OF NUDITY.

After discussing the modern theories of light, and especially the ethereal wave theory, and the fact that light, heat, and electricity are only differing modifications of waves in the ether, Dr. Robinson suggested the possibilities there are for chemical action and reaction when light is permitted to impinge unhindered upon the skin. Probably many effects now attributed to other causes are really due to the action of light in this way. For instance, it is worth while recalling that the lesions of the ordinary contagious diseases are on the skin, and this may represent the result of Nature's effort to get the virus of the disease to the surface where it would be acted upon by light. We know very little of the therapeutics of light, but it is not impossible that such qualities as the well-known fluorescent power of quinin in solution may be found to be closely connected with its therapeutic power.

DR. S. E. SOLLY of Colorado Springs read a paper, entitled

RECENT INQUIRIES CONCERNING THE BLOOD CHANGES INDUCED BY ALTITUDE.

All who discuss the subject admit that there is a real or apparent increase in the number of red blood-cells within a day after ascension to an altitude. This is followed by a gradual increase in hemoglobin and specific gravity of the blood. There is a corresponding decrease on coming down to ordinary altitudes but this is followed by another increase that persists. The most recent work on the subject has been a series of experimental observations upon animals in bell-jars. The blood was counted with a Thoma-Zeiss instrument, hemoglobin estimated with Fleischl's apparatus, and in certain cases the blood for examinations was taken from the aorta and liver. As the relative humidity was high and the temperature in the bell jars was normal there could be no question of inspissation of the blood.

These observers found from twenty to fifty per cent. increase in the number of red cells as the pressure increased. They continued their observations of the animals used in the experiments for ten months after. They found a decrease in the number shortly after the animals were removed from under pressure, but reaction set in, the number again increased and persisted as long as the animals were kept under observation. This is confirmed by certain clinical experiences with anemic school children who were sent to the mountains and had a persistent increase of their red cells even after their return.

The Finnish observers also noted an increase in the average size of the red cells because of decrease of microcytes, and this decreased after a return of the animals to normal conditions. The nucleated red corpuscles were slightly increased in number, showing that there was an effort at blood making. A number of mitotic figures were seen also indicating the same thing. The number of red cells was the same in blood taken from the periphery, and from the aorta and liver, in two animals, so that it would not seem to be any special distribution of blood with more red cells at the periphery than usual. When the number of corpuscles returned to the normal many shadow corpuscles were seen, which would seem to indicate an increased destruction of red cells.

There would seem to be good grounds for believing then that the increase of red cells on ascending to an altitude is really not apparent. Our clinical observations in Colorado seem to confirm this, but as yet they are too few in number to materially contribute to the elucidation of the question. There are so many possible sources of error that the work must be done with extreme care. Great help would be afforded if physicians would carefully examine the blood of patients before they go to the higher altitude of Colorado. The subject is so important that the Climatological Association would be doing a good work if it appointed a special committee for the investigation of the question.

A paper on

ALTITUDE AND HEART DISEASE, WITH REPORT OF CASES

was read by DR. R. H. BABCOCK of Chicago. A synopsis of it is as follows: Report of nine cases of heart disease; a brief statement of the effect of altitude on blood-pressure; mountain sickness, according to Regnard, due to anoxyhæmia; as regards heart disease, the effect of altitude explicable through acceleration of blood-flow; application of this simple theory to the nine cases reported; conclusions.

It will appear in a subsequent issue of the MEDICAL NEWS.

DR. ABRAHAM JACOBI of New York City read a paper, entitled

FUNCTIONAL CARDIAC MURMURS.

He said in brief that after watching the subject carefully in children in whom the problem has less disturbing elements than at adult age he is convinced that real functional heart murmurs, that is, murmurs due to faulty action of the valvular or muscular mechanism of the heart but without pathological change in the organ are much rarer than used to be thought. Changes in the myocardium of the heart are only now being given their proper value and with that is coming the realization that they may sometimes be the cause of murmurs.

In children we often do not know a cause for a heart lesion. A preceding rheumatic attack makes it very clear in an adult. Rheumatism is often missed in children, however, and we do not care to pronounce on the existence of a heart lesion. At the time when the child's heart is developing, however, the cavities are growing larger yet the muscle does not grow thicker. During this period murmurs are not rare and they would seem to be due to myocardial insufficiency at times which shows that this may give a murmur really due to an organic, not functional, defect.

DR. N. S. DAVIS, JR., of Chicago read a paper, entitled

PROGNOSIS IN CHRONIC VALVULAR AFFECTIONS OF THE HEART,

which will appear in a subsequent issue of the MEDICAL NEWS.

DR. H. L. ELSNER of Syracuse read a paper on the

TREATMENT OF THE CARDIAC ASTHENIA OF PNEUMONIA.

As the toxins of pneumonia depress the heart from the beginning no cardiac depressants should ever be used. Needless to say, none of the coal-tar antipyretics should be employed. Nitroglycerin is contraindicated because this paralyzes the peripheral vasomotors and the toxemia of the disease is already accomplishing this purpose. In selected cases when the heart is laboring over-much, venesection should rather be done. Nothing could well be more ill-advised than the so-called bleeding of a patient into his own veins. The young men who are taught in pretty figurative language to use the concealed lancet of veratrum viride do great harm. Dr. Elsner has never seen a patient recover when this system of medication has been employed.

The next paper, read by DR. ROLAND G. CURTIN of Philadelphia, was entitled

ESOPHAGEAL GUSH AND CLICK AS A CAUSE OF A SIMULATED HEART MURMUR.

DR. JOHN C. MUNRO of Boston followed with a paper, entitled

EMPYEMA FROM A SURGICAL STANDPOINT.

Both of these papers will appear in subsequent issues of the MEDICAL NEWS.

DR. RICHARD C. NEWTON of Philadelphia read a paper on

TRAUMATIC RUPTURE OF THE HEART WALL WITHOUT PENETRATION OF THE CHEST WALL. WITH A CASE.

The case was one of rupture of the walls of the right ventricle in a young and vigorous young man, brought about by a bicycle accident. The handle-bar seems to have been driven forcibly against the chest, causing fracture of the sixth left costal cartilage. This produced the heart rupture which started from without, but there was no rupture of the pericardium. Post-mortem the heart was found perfectly healthy. In practically all the cases reported some pathological condition of the substance of the heart was found. Up to 1870 Gamgee collected reports of twenty-eight of such cases, and to these Newton now adds sixteen new ones. The patient reacted well to stimulants, and there is no doubt that could a diagnosis of the real condition have been made surgical intervention might have saved life, but collapse supervened and he died.

The next paper on the program was by DR. A. C. GRETCHELL of Worcester, Mass., and was entitled

BICYCLING IN RELATION TO HEART DISEASE.

It will appear in a subsequent issue of the MEDICAL NEWS.

DR. HOWARD S. ANDERS of Philadelphia read a paper on

THE RELATION OF LOCAL METEOROLOGICAL CONDITIONS TO THE INFLUENZA EPIDEMIC IN PHILADELPHIA IN THE WINTER OF 1898–99.

On *a priori* grounds there is no encouragement to take up the study since there is an almost universal impression now that weather influences have no effect on the spread of grip, or of other contagious diseases. It is interesting to note, however, that during the recent months, when influenza was spreading so rapidly in Philadelphia, the temperature was higher than during preceding years, and the barometer higher also. The mean daily range from which the mean daily variability can be deduced was also high. The month of January, 1899, in which grip was so prevalent, was especially notable for its inequableness.

DR. GUY HINSDALE of Philadelphia read a paper on

THE COLD WAVE OF FEBRUARY, 1899,

in which he described the meteorological conditions which preceded and accompanied this, one of the most striking weather disturbances ever known.

DR. HAROLD WILLIAMS of Boston read a paper, entitled

THE EFFECT OF PROLONGED AND VIOLENT MUSCULAR EXERTION UPON THE HEART.

Dr. Williams had the opportunity to examine a number of athletes shortly after they had completed a Marathon or cross-country race, up hill and down dale, for twenty-five miles. Most of them were extremely exhausted, some were very cyanotic, some ashen-colored, and some of them had to be carried to the examining-room. All of them had notably lost weight, one of them as much as six pounds.

On inspections in nine of the cases there was found

bulging left costal cartilages on percussion very carefully done by a number of physicians, and controlled by tracings and copies which each succeeding examiner did not see; there was found to be dilatation of the left ventricle. Contrary to the general impression there was lowered arterial tension. After a run of five miles the trained athlete is exhilarated and then arterial tension is high, but after twenty-five miles there is exhaustion and a fall in tension.

The temperature was found lowered in every case, in all a degree, in three cases two degrees, in one four degrees. This is contrary to what is usually stated in text-books on physiology, which state that the temperature is higher after exercise on the theoretic principle that muscular work means increased heat production and consequently higher temperature. In all of the runners albuminuria occurred, in some associated with casts so that either casts have not the significance attributed to them of a lesion of the kidney, or such lesions occur as the result of severe physical exertion.

In eleven out of thirteen of the athletes there was a murmur to be heard in the second intercostal space the same in quality and pitch in all the cases though varying in intensity. In six of the cases this was transmitted to the apex and beyond it, and could be heard in the axillary region. In a word, it had all the qualities of a mitral regurgitant murmur. In the other five cases the murmur was not transmitted. It was concluded that this was a real mitral regurgitant murmur due to the fact that the papillary muscles and the myocardium were exhausted as well as the systemic muscles and so did not act coordinately. In answer to a question as to the duration of these murmurs, Dr. Williams said that some of them had disappeared after twenty-four hours, others after forty-eight hours. As to the effect on the athletes, many of them he knew engaged in other such races within a few weeks. One of them, despite a severe fall had made an excellent record in a race only a week later.

Dr. Thomas Darlington, Jr., of New York City read a paper on

A CASE OF ANEURISM WITH EROSION OF THE STERNUM, RUPTURE TWICE AND DEATH.

The patient gave a syphilitic history and had been wounded by a shoemakers' knife when young through the sternum. The etiology of the aneurism may thus have been syphilitic or it may have been traumatic.

The aneurism grew to be of enormous size, eroding the sternum in its whole width and making the tissues in front of it thinner and thinner. At two points especially the skin became adherent, reddened and eroded to dangerous thinness. Finally during a fit of coughing it ruptured. About a pint of blood was squirted out of it almost to the ceiling. Then the hemorrhage was stopped by the engagement in the opening of a clot that had been contained in the aneurism. A photograph exhibiting the condition was shown. A dressing with plenty of cotton was put over the opening. Three days later it ruptured a second time, this time at the other thinned spot and with an immediately fatal result. No autopsy was permitted.

REVIEWS.

Transactions of the American Orthopedic Association. Vol. XI., 1898.

This official volume of the association is more voluminous than any heretofore published, and by virtue of its numerous excellent articles bears testimony to the fact that the same spirit which was so largely responsible in securing for American orthopedists the foremost position is still very active.

Keenly aware of the trend of the times the president in his address sounds the key-note of warning that the pathological and bacteriological laboratory with its staff of workers are now as much a *sine qua non* for maintaining the supremacy as the machine-shop and its mechanics had long been conceded to be. The subject most frequently presented is the forcible correction of the deformities following Pott's disease. To give just consideration to the vast fund of information conveyed by the forty-five articles contributed, the space alloted to the reviewer does not permit. In lieu of this we can best say that this volume is little short of an excellent text-book on orthopedics.

Railway Surgery. By Clinton B. Herrick, M.D., Lecturer on Clinical Surgery, Albany Medical College; Surgeon to the Delaware and Hudson and the Fitchburg Railways, etc. New York: William Wood & Co., 1899.

To satisfy the call for a work pertaining to railway injuries the author has submitted the conclusions of his extensive experience in this brochure. We believe it to be the pioneer work of its kind, though collected writings of the Association of Railway Surgeons are extant.

The *raison d'être* for this treatise the author sees in the extraordinary forces which produce this class of injuries, but which, for our part, differ in degree only from those encountered by any surgeon in civil practice, yet the author is in the position to speak ex cathedra on this subject. The chapter on amputations, as might be anticipated, is most elaborately dealt with. Referring to amputation at the hip-joint we venture to say that the author's estimate of the high mortality would be greatly lowered by resorting to Wyeth's excellent method of hemostasis. The narrative of the other injuries is barely short of a summary, so terse is the account; yet throughout the work the author evinces a thorough appreciation and understanding of asepsis and antisepsis.

To us the term railway surgery also calls to mind the organization effected to meet the demands of treatment of a large number of injured, in which respect it is akin to military surgery, and on which score the author leaves us poorly informed; again the medico-legal aspects are very important and these receive a fair exposition in the later pages. Finally, one cannot help believing that this work might arouse greater interest if many more of the author's actual experiences had been incorporated in its pages.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIV. NEW YORK, SATURDAY, MAY 27, 1899. NO. 21.

ORIGINAL ARTICLES.

NON-TUBERCULAR INFLAMMATION OF THE SPINE.[1]

BY T. HALSTED MYERS, M.D.,
OF NEW YORK;
ATTENDING ORTHOPEDIC SURGEON TO ST. LUKE'S HOSPITAL; CONSULTING SURGEON TO THE NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL; CONSULTING ORTHOPEDIC SURGEON TO ST. JOHN'S RIVERSIDE HOSPITAL, ETC.

SINCE the discovery of the bacillus of tuberculosis the tendency has been to ascribe to this source an increasing number of the inflammatory lesions of the spine until, at the present time, I think the pendulum has swung over too far in that direction and that now a considerable number of kyphoses are considered tubercular which are really the result of syphilitic or malignant diseases or due to some of the infectious diseases, or to traumatism. I wish to make this paper as practical as possible, so have aimed to contrast the non-tubercular lesions with those tubercular. The field to be covered is a very broad one, and while in almost every work on orthopedic surgery one hundred or more pages are usually devoted to Pott's disease alone, the non-tubercular lesions are barely mentioned. I shall consider very briefly each division and endeavor to give the histories of one or two typical cases in each.

The syphilitic lesions of the vertebræ present a special difficulty in diagnosis, more particularly those due to congenital syphilis, as in these a reliable history is often lacking. The relation of congenital syphilis to tuberculosis is not understood, though many believe there is some relationship, expressed, perhaps, by making the syphilitic offspring a more than usually favorable soil for tubercular infection. Moreover, there may, of course, be a mixed infection; a tuberculous subject may acquire syphilis, or *vice versa*.

Syphilitic lesions of the vertebræ are comparatively rare, but Dr. Matthias Nicoll has kindly looked over the literature of this subject for me and has found a good many cases reported by such men as Fournier,[1] Virchow, Michel,[2] Gross, Lancereaux, Neleton,[3] Astley Cooper, Verneuil, Westphal,[4] Koenig,[5] Leyden,[6] Jansinski,[7] and others. In these cases lesions were found in every region of the column—cervical, dorsal, lumbar, and sacral, and in every part of the vertebræ—in the bodies, intervertebral disks, transverse and articular processes, laminæ and spines; in the ligaments and in the muscles adjacent; and also every variety of this inflammation—periostitis, rarefying and condensing osteitis, gummata, etc. The cervical region, however, seemed the most often attacked, and one writer thought this might be due to its proximity to the pharynx, which is so often the site of syphilitic lesions. I will relate very briefly the history of two patients I have treated.

Polish boy, twelve years of age; no tuberculosis in family. During the previous year he had been suffering from pain and stiffness of the neck. Motion in any direction was resisted, and he held his head in his hands continually. The head was inclined to the right shoulder and the chin rotated to the left. This deformity was so marked that the sternocleidomastoid muscle had been divided. When I first saw him, however, there was well-marked reflex muscular spasm and some induration about the upper cervical vertebræ, which were a little prominent and somewhat tender on pressure. In November, 1891, a spinal assistant brace, with chin piece, was applied to support and immobilize the head, and the relief from pain was marked. Pott's disease was the first diagnosis; later on (August, 1892) the boy developed lesions in both elbows, the left hip (January, 1894), and a typical syphilitic dactylitis. These symptoms were held in abeyance by specific treatment, but the boy was very irregular in attendance and the treatment, in consequence, was intermittent. When he omitted his iodid and mercury there was an increase of pain and swelling, or new lesions developed. He finally died with cerebral symptoms, about three years after his first examination. I make the diagnosis in this case from the absence of tubercular history, from the multiple lesions in a strong, healthy boy, several of them being periosteal; from the dactylitis, and the effect on all the lesions of antisyphilitic drugs.

A fat, rosy boy, four years old, whose general health was always excellent, without any history of injury, gradually developed a kyphosis at the eleventh dorsal vertebra. About the same time a dactylitis appeared of the first phalanx of the index-finger, which was typical: a fusiform swelling of the whole shaft, only slightly tender, with moderate induration of the skin, and some ulceration. Rapid improvement followed specific treatment, although no change had been effected in the ulcer under antiseptic treatment alone

In this case there was no induration about the spine and very little pain. Weakness was a promi-

[1] Read at a general meeting of the New York Academy of Medicine, February 17, 1899.

nent symptom. The application of a spinal assistant brace relieved all symptoms referable to the spine. The development of the kyphosis was like that of tubercular disease. There was nothing in the local condition from which to make a diagnosis, but the dactylitis and the result of specific treatment established it. His family history also indicated more than a possibility of syphilis.

The following case was reported by Fournier (*Arch. der Dermat. et Syph.*, II., 1, p. 19, 1881).

Man, aged fifty-six, always well until three months ago, when he began to lose flesh and strength and is now hardly able to walk. Pain over kidneys and occasionally in lower extremities. Examination showed a sarcocele, evidently of syphilitic origin; ten subcutaneous gummata in different parts of the body, an ulcer of the thigh and toe, and marked atrophy of gluteal muscles. Antisyphilitic treatment affected only the local lesions, and he died cachectic in three months. The autopsy showed, also, cirrhosis of the liver, perihepatitis, cicatrices on the surface of the kidneys, and gummatous involvement of the left fourth lumbar nerve at its exit. The bodies of the third and fourth lumbar vertebræ were infiltrated with a caseous material; the intervertebral cartilage was also destroyed and the cavity filled with greenish-yellow pus. The posterior ligament was detached, reddened, and thickened over the vertebræ. In the center of the second lumbar vertebra was an empty cavity. The intervertebral disk between the fourth and fifth lumbar vertebræ was also infiltrated with pus and contained a caseous focus. Under the microscope the bodies of the third, fourth, and fifth lumbar vertebræ showed condensing osteitis, with purulent and caseous infiltration exactly as in gummatous osteitis.

Fournier considered the case syphilitic on account of the man's age, fifty-six, his fine physique, because the spinal lesions developed at the same time as the other undoubtedly syphilitic lesions, and because of the nature of the microscopical findings and the gummatous degeneration of the nerves in the region of the affected vertebræ.

Rheumatic inflammations are an interesting group in making a differential diagnosis. As the cause or causes of these conditions are still unknown we must divide the cases according to their clinical history and their gross pathology. By far the most common condition is rheumatoid arthritis, which is described as affecting the bones themselves as well as the other joint-structures, atrophy and absorption taking place under pressure and osteosclerosis occuring elsewhere. It is never accompanied by suppuration. It is a chronic progressive disease attended by aching pains, especially at night and in damp weather, which do not yield to treatment. The ribs are often involved. The cervical region of the spine seems to be the last affected.

Goldthwaite divides these cases into two classes clinically. These he calls rheumatoid arthritis and osteoarthritis, which demand radically different treatment. The first is more acute and occurs early in life, as well as later. During the acute stage the joints, those which can be examined, show a spindle-shaped swelling which finally subsides, leaving the joint much atrophied and usually ankylosed. In these cases the joints should be manipulated after all acute symptoms have disappeared. The second class, called osteoarthritis, seems identical with what is usually called osteitis deformans. This is much more chronic, occurring only in middle life or old age, and is characterized by a proliferation of the articular cartilage, with the formation of nodes about the joints. Manipulation should not be practised in these cases as an injury or undue violence results in a more rapid development of the cartilage. It is this tendency which explains the impairment of function which so often results after comparatively simple injuries to a joint. Protection and immobilization are important in such cases. In them there is crepitation on motion from the eroded cartilages, and neuralgias, and paralysis caused by pressure on the nerves by the new bone formation.

I have seen a number of cases of what may be considered a third form of rheumatic joint-disease, which attacks chiefly the ligamentous structures, transforming them into bone, but leaving the bones and the intervertebral cartilages in a comparatively normal condition. The history of a previous attack of gonorrhea is not infrequently obtained in these cases.

At the December meeting of the Orthopedic Section of the Academy of Medicine Dr. A. M. Phelps presented a sagittal section of a spine which seems to belong to this category. The spine was perfectly rigid from the cervical vertebræ to the coccyx. The bones themselves appeared normal, not condensed, perhaps a little rarefied. The intervertebral disks also were normal, but all the ligaments were transformed into hard, shining bone. A dorsolumbar kyphosis replaced the normal curves, and the femur was ankylosed in a flexed position. This, of course, was a most extreme case, but the picture is not a unique one. The same lesion of a less-severe grade would present clinical symptoms closely resembling the caries sicca of adults—a slowly increasing, poorly defined deformity more disabling than painful, without suppuration, and without very acute symptoms, but obstinately progressive.

Through the kindness of Dr. Reeves of London I saw, last fall, a very good example of this condition, which he called fascial rheumatism, occurring in a man about thirty-six years of age, who had had syphilis at twenty-two years, gonorrhea at twenty-eight, was married at twenty-nine, and had three

children. When first brought to the Royal Orthopedic Hospital he was bent over so much that his head was on a level with his umbilicus. The treatment adopted included antirheumatic drugs, massage, and suspension. Under this method, when I saw him, the curvature had been reduced fully one-half, and he was improving daily. I cite this case as it seems to me that we should make every effort to se cure ankylosis in the best possible position, if ankylosis is inevitable. Thus massage, suspension, and

Deformity in so-called fascial rheumatism.

bracing are distinctly indicated in addition to the constitutional remedies. Certainly in Mr. Reeves' case the result was most gratifying (see figure). As the amount of pain varies a great deal in these cases, it may be found that there is least pain where there is least motion; that the pain ceases when ankylosis is established.

I have had no experience with the so-called Paget's[8] disease. This is principally seen in England and is a peculiar form of enlargement of the bones. There is no chemical change in them and the disease seems to have no relation to syphilis, rheumatism, or tuberculosis. The tibia is generally first attacked, but later the bones of the skull and spine are also affected. It occurs late in life and is a rarefying osteitis, progressing more and more rapidly. The joints are not attacked and suppuration does not occur. Vague but not severe pains accompany it. Great bowing of the limbs and marked exaggeration of the normal spinal curves follow. The bones seem unable to withstand the superimposed weight. No treatment is of any avail. Dr. H. L. Taylor reported two cases a few years ago and appended an excellent bibliography.[9]

Malignant disease of the vertebræ is rare and often the diagnosis is made only at *post-mortem* examination. Carcinoma and sarcoma are present in about equal frequency. Both may be primary, but both usually are metastatic. I will briefly outline two cases I have seen. The history of the first, kindly furnished me by Drs. Briddon and Thacher, I have abstracted as follows:

F. G., twenty-eight years of age. Family history tubercular. Personal history negative. The patient was perfectly well until six months ago. He then noticed enlarged cervical glands. Two months later pain appeared in left hip, running down thigh to knee. This limb gradually lost power and he had to remain in bed. Of late the glands have enlarged and he has lost flesh and strength. Yesterday, while being moved in bed his right thigh was fractured. He is anemic and emaciated. Urine, sp. gr. 1028; alkaline, turbid, and contains casts, pus, and blood. All the cervical, axillary, brachial, inguinal, popliteal, and post-peritoneal glands are enlarged. Spleen large. Left limb in position of third stage of hip disease, with abnormal mobility of head of bone, and crepitus. Edema of both legs; blood showed hemoglobin seventy per cent. Red cells nearly normal; white cells not markedly increased. His temperature ten days later was 104.5° F. and large sloughing area developed over sacrum. He died three days later. The autopsy showed sarcomata of lymph-glands, liver, spleen, pancreas, and bones; chronic cystitis, adherent pleura, perisplenic abscess, and pyelitis. The lower lumbar vertebræ and upper part of sacrum and crest of right ilium were necrotic and bathed in greenish pus. Superficial necrotic spot in front of body of tenth dorsal vertebra. Sarcoma of left femur; fracture of right femur due to sarcoma.

In this case there was no mention of the lesion of the vertebræ nor of the spinal cord symptoms save the bed sores.

The history of the second case was kindly given me by Dr. Norton.

Woman of forty-five years. Malignant tumor was removed from breast in May, 1896. Three months later a second, and in May, 1897, a third operation was necessary. In August, 1897, she began to have

what were considered rheumatic pains in the back, not sharply localized, but chiefly in the lower dorsal region. After three months weakness and numbness of the lower extremities were noted. Absolute motor paralysis followed in two weeks. There was no deformity of the spine, but some deep edema in the lower dorsal region and slight tenderness. A fairly marked girdle sensation was noted also. Below this muscular and tactile sense were diminished, as were the sensations of heat and cold. Pain sense absent. Increase of knee-jerk; occasional lightning pains down legs; sphincter paralysis, bed sores followed by rise of temperature. Death of the patient about five months after the vertebræ became involved.

When a primary malignant growth has been recognized, the occurrence of spinal symptoms would, of course, be traced to their proper source, as in this case, but when the inflammation of the spine is primary, or is overshadowed by more active symptoms, the diagnosis is not so readily made. The first of these cases was thought to be leukemia for some time, and the later symptoms were masked by the fracture.

Kyphosis was seen in only nine out of Dr. Amidon's twenty-four cases. The disease may occur at any age, but the average age is forty-five years. It may infiltrate the bodies, transverse processes, laminæ and spines, or may occur externally on the sides of the vertebræ or ribs. The average length of life after the onset of vertebral symptoms, Amidon found to be eight months. Pain has been a prominent symptom in all these cases, motor paralysis less constant. The cachexia at times did not appear till late. The spinal nerves are often involved in the new growth. Sometimes there are small metastases in the neighborhood which assist in making the diagnosis. These cases are sometimes mistaken for sciatica, lumbago, or Pott's disease.

Hodenpyl,[10] speaking of the association of malignant disease with tuberculosis, says that carcinoma may be grafted on an old tuberculosis, and a tubercular lesion may act as a predisposing cause in locating this deposit just as a traumatism might. Still more rarely a carcinomatous subject may become tubercular. The lesions are not antagonistic, but occur at different periods of life usually.

Hydatids have been found attacking the spine. Dr. Lloyd has given me notes on such a case. A diagnosis of multiple sarcomata had been previously made. Sharp pain existed in the lower lumbar region for two years before any tumor was seen. The tumors were removed nearly nine years after the onset of symptoms, which finally included girdle pain, partial sensory and quite complete motor paralysis below the eleventh dorsal segment, vasomotor disturbances, sphincter paralyses, cystitis, etc. Cysts were found extending between the spines and transverse processes of the eighth and ninth dorsal vertebræ. The adjacent bone was eroded. Crevillier's first case of "paraplegia dolorosa" was caused by an intraspinal hydatid cyst.

Syringomyelia is another rare condition which must be mentioned. Howard Marsh[11] says that scoliosis of the spine, possibly due to an arthropathy of vertebral joints, has been observed in nearly half of the cases of syringomyelia, but he adds, this does not occur in locomotor ataxia.

Very recently[12] the diplococcus intracellularis has been isolated from the pus of an arthritis occurring in a case of cerebrospinal meningitis. This condition used to be considered an arthropathy and suggests the importance of bacteriologic examinations in such cases.

Gonorrheal affections of the spine are exceedingly rare. In one series of 119 cases of gonorrheal rheumatism reported the spine was not involved at all. In another series of 116 cases, reported by Nolan,[13] only two cases of arthritis of the vertebræ occurred, and in these other joints were also affected. One patient was cured, but the other passed from observation before a cure could be obtained. I have seen but one such case, as follows:

B. D., twenty-seven years of age. Good family history. Three years ago had gonorrhea. Six weeks after its onset he had pain in the spine, both knees, and nearly all the joints. He made a good recovery from this attack. Ten weeks ago he had a second attack of gonorrhea, and for eight weeks he has had pain in the lumbar region of the spine and in the right hip, especially on motion and at night. His general health is not now very good. His spine is very rigid and painful on pressure in the lower dorsal and lumbar regions. No pain anteriorly; slight general kyphosis of the affected region. Unfortunately this patient was lost sight of after the first examination.

The histories of these cases are, therefore, very imperfect, as well as few in number. They seem to show, however, that the affection runs a similar course in the spinal articulation as that observed in other joints. The recurrent attacks are more apt than the original inflammation to leave the affected joints ankylosed. As has been mentioned, the cases of "fascial rheumatism" often give a history of an antecedent gonorrhea.

The "typhoid spine" is now pretty well recognized. Dr. Gibney has especially contributed to our knowledge of this condition. It is supposed to be an inflammation of the periosteum or fibrous structures of the spine. There is acute pain on the slightest movement at first; also tenderness. There is little rise of temperature as a rule, and none of

the cases affecting the spine have gone on to abscess formation. Some slight injury may be the localizing cause. The patient is usually attacked shortly after the subsidence of the fever and recovery may be rapid or delayed for eight or ten months.

Many cases of periostitis and caries after typhoid fever are reported and the typhoid bacillus has been found living in one of these foci as long as seven years after the onset of the disease. The paper on the bone lesions following typhoid fever by Parsons [14] of the Johns Hopkins Hospital is the most complete bacteriological study we have thus far. He found the typhoid bacilli only in some of the typhoid nodes, while in others this bacillus was associated with the staphylococcus pyogenes aureus, and once with the staphylococcus pyogenes citreus. He concluded that the typhoid bacillus alone was capable of producing suppuration. As this bacillus is very generally present in the bone-marrow the question is why there are not more cases of bone lesion. Professor Welch remarks that months and years after typhoid there occur cases of periostitis and osteomyelitis due to the typhoid bacillus.

A typhoid node on the tibia or ribs may become swollen, tender, red, and hot, and apparently be on the point of rupture, and then subside again for months, only to repeat the cycle perhaps several times. Parsons suggests that the typhoid spine is either due to such nodes or it may be a simple neurosis. I have never heard of abscesses connected with the vertebræ in a case of typhoid spine, which seems to me rather singular in view of the fact that there is so little tendency for these nodes to subside permanently in other situations. After one or two exacerbations they usually are opened and the typhoid bacilli have been found in them years after the fever has subsided. Partial operations do not cure these nodes; they should be radically excised.

Under the somewhat indefinite term of infectious inflammations might properly be included some of the rheumatic inflammations, the typhoid and gonorrheal, which I have already spoken of, but I now wish to refer only to those of probably pyemic origin which follow scarlet fever, tonsillitis, etc. The lesion is, I think, a periostitis, or an arthritis of some of the vertebral articulations. The germs in these cases become active in the depraved condition of health during, or immediately following these diseases, and generally attack the cervical spine, probably by direct transmission from the throat lesions. Moullin thinks these pyemic conditions have little tendency to become diffuse and that the necrotic sequestra are small if they are formed at all.

I will give the history of the two cases which I think belong to this class.

E. H., three and a half years old; good family history; no traumatism. One and one-half years ago she was "croupy" for two nights. Her neck became stiff and the head took a wry-neck position. Some swelling and tenderness under left ear. Family physician said there was no throat trouble. The deformity disappeared in one week, and all motions of the head were free. Six months later another similar "croupy" attack for one night. Some deformity occurred, persisting for one week. She was then well until September, 1897, when, after a third "croupy" attack, her head became inclined toward the right shoulder with chin rotated toward the left. There was no tension of the sternocleidomastoid muscle on the right side, nor any swelling. No kyphosis; nothing seen in throat. The head was held quite rigidly in this position by reflex muscular spasm. A spinal assistant brace with chin piece was applied and within ten days the head was straight and the range of motion greatly increased. The child is fat and rosy and does not look at all tubercular. (Since writing the above I have learned that this child developed bronchitis and died in four days with symptoms of meningitis.)

R. C., aged seven years; no phthisis in family. Patient was a fat rosy girl. In June, 1897, suddenly developed high fever and sore throat. Next day head was inclined to the right. At night she had pain in the back and right side of her head. After two months she held her head better, but continued to have a little fever for two months longer. A month later, September, 1897, right otorrhea for two days. She had now a marked wry-neck, the contraction being chiefly in the scaleni and deeper muscles. Rotation of head to right impossible; to left, free. Held her head in her hands to prevent jarring. Spinal assistant and chin piece applied with marked and immediate relief of pain and some improvement in position. The head, one month later, February, 1898, was nearly straight. Motions somewhat restricted, but much less so. No swelling; no kyphosis. Continuing this treatment head is now, January, 1899, still slightly rotated to the left and inclined to the right shoulder, but there is no pain, no reflex spasm, and the disease is apparently cured. General condition excellent.

These two cases represent a rather large class. The absence of tubercular history and very healthy appearance of the children, but especially the mode of onset and the rapid improvement are points in the diagnosis. The deformity depends upon the location of the lesion of course and would be the same if the cases were tubercular.

I have seen several cases of traumatic osteitis in which I had some difficulty in excluding Pott's disease. If there are such cases, especially if there are any considerable number of them, it is time they should receive more attention than has been given them thus far. Of course there are many cases of traumatisms of the spine in which the diagnosis is clear. Evidently there has been a dislocation or a

fracture of the vertebra. The cord, perhaps, has been more or less severely injured also, and the ensuing paralysis may obscure the symptoms due to the lesion of the bone itself. The clinical picture, however, bears no resemblance to a case of Pott's disease. Then there is a very large class of cases in which the traumatism is followed within a few days or weeks by symptoms of Pott's disease, and which the subsequent history proves to be this disease, where, in other words, the tubercle bacilli have infected the site of the injury. I shall not refer to either of these classes.

The cases which I wish to call to your attention are those in which the traumatism is followed by such symptoms or by such deformity as is commonly found in Pott's disease, and yet which are proven by the subsequent history not to be tubercular. Injuries of the vertebræ are usually the result of indirect violence. Of course there are numerous instances of kicks, blows upon the back, falls against projecting objects, etc., but the great majority are the result of falls which bend the head or trunk forcibly in some direction. The cervical and lumbar vertebræ are most vulnerable, as the upper ten dorsal vertebræ are ably protected and solidified by the ribs. Where a rigid part of the spine joins a less rigid part there seems to be special liability to injury from these bendings, that is, the cervical region and the eleventh and twelfth dorsal at the lower end of the thorax, and the fifth lumbar adjoining the sacrum. These remarks do not apply so well to very young children as to adults, as I have tried twice to produce a fracture or dislocation in the bodies of children a year old by forcible anterior flexions and failed. None of the cases which I have observed has been in a very young child and most of them have been in adults. I will give the histories of a few cases to illustrate the point I wish to make.

D. S., eight years old. February 7, 1890. Good family history. Perfectly well until injury. Fell down seven steps striking head on floor. After four hours in bed he went about again complaining of headache, stiff neck, and pain in right shoulder. Examination on sixth day showed slight prominence of fifth and sixth cervical spine, and a dorsal curve to left. Drooping of right shoulder; swelling above right scapula. Slight limitation of flexion and a rotation of head to left. No spinal-cord symptoms. Dr. Shaffer also saw the patient and thought as I did, that the boy was in need of mechanical support. Three weeks later the pain had disappeared with most of the limitation of motion and some of the deformity. He wore the spinal assistant and chin piece less than three months. Spine then straight, motion of head free; no pain, and kyphosis less evident. No further symptoms.

M. B., fourteen years old. Diving in surf injured neck, and a wry-neck position was soon noticed. Whether it occurred at the time of the accident or not was not known. He had, however, no mechanical treatment until I saw him nearly a year later. Then the head was rotated to the left and inclined toward the left shoulder. Motions of the head were limited and painful. General health good. Spinal assistant and chin piece were worn for a year, with fifty per cent. improvement in position, and cessation of all pain.

The question at first in both these cases, when I saw them some time after the injury, was whether the limitation in motion was due to reflex spasm or to a purely mechanical cause. There was mechanical resistance surely, but was the additional pain on motion and resistance, voluntary or involuntary? The proper treatment was evidently protection, whether there was a simple inflammation of the periosteum or bone, or a tubercular process, but it was not so easy to give a reliable prognosis to the anxious parents. As a matter of fact the first patient recovered perfectly in a few months, while the second required a year to secure a cure and then the deformity was but partially corrected.

While the dorsal region of the spine is the most frequent seat of Pott's disease, yet, theoretically, if a fracture occurs here the parts are so splinted anatomically that recovery without increase of deformity is to be expected unless a subsequent infection occurs with its attendant caries or necrosis. Besides the spine is so strongly protected here that any injury severe enough to fracture a transverse process or the body of the vertebra will injure the cord also, in all probability, and I do not recall a case and did not find one in the case-book of the New York Orthopedic Dispensary, which I examined, through the kindness of Dr. Shaffer, from 1890 to 1896, inclusive, in which a traumatism without spinal-cord lesion or subsequent tubercular infection was followed by kyphosis with the symptoms and history of a simple osteitis only.

By far the larger number of cases are found in the dorso-lumbar region. The following occurred in my private practice and caused me considerable uneasiness from time to time.

J. E., forty-two years of age. Good family and personal history. Fell from roof twenty-five feet, striking on feet, then bending forward. On admission to a hospital he was repeatedly examined and assured that his spine was not injured. He complained of a good deal of pain in the left gluteal region, and this continued from three to four weeks. His spine was examined repeatedly during the next three weeks but nothing was discovered to account for the weakness he felt in his back, which was so pronounced that he could not hold himself erect, either sitting or standing, without support. There was

slight tenderness over the dorsal and lumbar spine. A month after the accident I found a very slight kyphosis at the twelfth dorsal and first and second lumbar vertebræ. A spinal assistant was applied. The cure was perfected in four months though the patient was an adult. There could not have been any tubercular infection in this case.

G. D., a man twenty years old, more than six feet tall and weighing more than 200 pounds, slipped while carrying a weight and was thrown backward. He felt something give way in the lumbar region. He experienced a sensation of "pins and needles" in his feet for a short time but soon went to work on his farm as usual. Two months later he injured the same place, and again seven months later; this time he was in bed ten days. A fourth and fifth similar injury soon made his back so painful that he had to stay in bed.

I first saw him in September, 1889, and found a very slight kyphosis at the ninth and tenth dorsal vertebræ with some tenderness and a slight lordosis of the twelfth dorsal and first lumbar. The knee-jerks were exaggerated. Pain on motion, and some paresthesia and muscular twitchings of legs. Could walk only one or two steps. January, 1890, four months later, I saw him again at St. Luke's Hospital and put him to bed wearing a plaster-of-Paris jacket. July, 1893, three and one-half years later, he could walk half a mile; reflexes normal; no deformity found; no pain; tired readily; final brace applied. February, 1895, one and one-half years later, walks three miles; does farm work with crowbar, and the like. Splendid general health; fat and rosy; cured.

Notwithstanding the long duration of the local symptoms I do not believe this man had Pott's disease because (1) of his good family and personal history; (2) his splendid physique; (3) the absolute carelessness of his conduct which prevented his ever giving long-continued rest to the injured spine; (4) local condition. At the present time there is no deformity except a slight depression at the first lumbar vertebra. Motions of the spine are almost perfect. He has no pain and no disability.

Mr. C.; good family and personal history. When fourteen years old had a severe fall on back in a gymnasium. He was laid up for two or three days, and his back was very sore for a long time. During the following years, though he rowed, drove, etc., three or four times each year he would have severe pains in the dorsal and lumbar regions for a week or so, then they would gradually die away. When he was eighteen years old he noted a swelling in the right lumbar region which became large and tender, and he had chills. The abscess contained pus and blood. Three months after this was opened a spicule of bone was discharged. There was no spinal deformity at this time. After two months he was taken to St. Luke's Hospital, where a small kyphosis was noted and I applied a spinal assistant brace. The abscesses continued to discharge for three years, when a large sequestrum was discharged and the abscesses promptly closed. The pain was always in the back, not anteriorly, but was at once relieved by the brace which he wore six years, though he was believed to have been cured two years before he discarded it. Examination February 16, 1898, six years after the brace was removed, shows the eleventh dorsal vertebra to be slightly prominent only because the twelfth dorsal and first lumbar are a little depressed. Anterior, posterior, and lateral motion about normal. Fat and well, weighs 175 pounds, and has a chest expansion of 5 inches. I do not consider this case tubercular, nor does Dr. Shaffer, who also saw the patient several times with me. The patient, however, was refused insurance by a life insurance company within the past four years because there is a rule against taking risks on persons with Pott's disease. This was done although the medical inspector highly recommended the risk. He was also refused by another life insurance company for the same reason within the last eighteen months. A third company, however, was willing to take the risk to any amount.

I have the histories of about a dozen other cases, but I will not weary you with them, but will say that a number of the subjects were in the large general hospitals for days and weeks even without a correct diagnosis having been made. This may be accounted for often from the fact that the deformity will frequently not appear until the patient assumes the upright position.

The lumbosacral juncture is another part of the spine which is especially liable to injury. I have notes on two cases of spondylolisthesis which had at some time been mistaken for Pott's disease, which I will very briefly cite on this account as well as to show the good effect of treatment.

Mrs. de C.; seen with Dr. P. H. Fitzhugh; thirty years of age, fell heavily when two years old, injuring the fifth lumbar vertebra. At eight years another severe fall; seven months in bed. Never well since. Wore imperfect supports for a time. A third fall a year ago, and was in bed two weeks at that time. Has been married twelve years and had two still births, with great increase of spinal pain, and increase of curvature after the last one, eighteen months ago. Examination shows well-marked deformities of spondylolisthesis. Can walk but a few steps. Cannot sit up, and has pain even when supine. Has a great deal of pain in abdomen, legs, and back. A spinal brace with abdominal belt was advised in order to give rest to the spine, and to relieve the lordosis. The result was immediate relief, and within a few months she could walk miles, sit out an entire performance at the theater, etc., which she had never before been able to do.

M. T., twenty-six years old, fell on some stones when six years old, striking back; never perfectly well again. At sixteen years could hardly walk at all on account of weariness in legs and tired feeling in back. Then was in hospital two years, gradually improving with quiet life. Now, after two

years of heavier work than she had been accustomed to, she presents herself for treatment on account of a marked tired feeling in her back. She can walk two miles, and can stand jars, but cannot stoop forward. Marked lordosis. Pubes prominent, and pelvis tilted upward. Spondylolisthesis. Spinal uprights applied February 11, 1891, with marked relief of the tired feeling.

The explanation I would offer for these cases of traumatism of the spine simulating Pott's disease is as follows: a fracture in a long bone will require from six to eight weeks to become consolidated. Where the vertebræ are fractured and little or no injury is done to the cord there is local weakness and some tenderness, but often only a moderate amount of pain (that is, comparing it with that accompanying fractures of the long bones) and often no crepitus, so that the injury to the bone may escape notice. As a rule, therefore, a sufficiently long period of rest and protection is not enforced. Moreover, it is very difficult to keep these parts quiet on account of the small size of the bones themselves and the length of the body above and below the injured part. Probably non-union results. There may be no deformity at first on account of the many powerful ligaments and muscles holding the parts in place, but when the erect position is assumed the weight of the body will *gradually* produce a kyphosis or lordosis, as the case may be. Aside from the history of the accident the picture now presented is one of ordinary chronic osteitis and might easily be mistaken for Pott's disease. We have the characteristic deformity, the reflex spasm, and continuing pain and disability.

I cannot believe that tuberculosis occurs in the osseous system primarily. At the New York Foundling Hospital I made many autopsies when I was an interne there, in cases in which this looked possible, but always found enlarged bronchial or mesenteric glands also, showing the path by which the bacilli gained entrance to the system.

I do not think, either, that the presence of abscess and extrusion of bone prove an inflammation to be tubercular. I have seen several cases in which a severe traumatism of the spine was followed within a short time by abscess formation which did not appear tuberculous, both in the cervical and dorsolumbar region.

Tubercular lesions of the bone run a pretty definite, well-known course, and while no sharp lines can be drawn, I should be inclined to doubt the diagnosis of tubercular spondylitis if the cure were effected within one year.

Several practical points are suggested by this consideration of the non-tubercular lesions of the spine:

1. Syphilitic treatment should be pushed when there is a possibility of this disease being present. The pain will be relieved and the progress and extension of the disease stopped generally; moreover, many very brilliant cures are recorded when the symptoms seem to be due to pressure on the cord or nerves from gummata, and periostitis.

2. Fractures should be more carefully protected and for a longer period to prevent occurrence of deformity and paralysis and to relieve pain and disability.

3. Rheumatoid arthritis can be rendered less deforming and less dangerous to life, therefore, by securing ankylosis in a good position, if ankylosis cannot be avoided.

4. From a medico-legal standpoint it is important to remember that not all chronic increasing kyphoses are tubercular, and, therefore, exorbitant damages should not be awarded in all such cases. We should also consider the beneficial effect on the mental complexion of the patient and his family of the recognition of this fact.

5. Life insurance should not be refused such subjects. Some of the companies have hard and fixed rules, such as the one referred to, that no risks should be taken on a person with Pott's disease. When a mistake in diagnosis can so readily be made, which would work to the applicant's disadvantage, it would seem most just to consider each case separately.

AFRICAN BLACK-WATER FEVER.[1]

BY FRANKLIN PIERCE LYNCH, M.D.,

RESIDENT PHYSICIAN OF THE SANITARIUM OF THE AMERICAN BAPTIST MISSIONARY UNION, MUKIMVIKA, CONGO ANGOLA, SOUTH-WEST AFRICA.

GEOGRAPHICALLY considered, the African black-water fever appears most frequently and in its most severe forms in the African tropics, following the foreigner as he enters the country from its western or eastern coasts. Although many places on the western coast have been occupied by foreign residents for more than a century, it is only in comparatively recent years that this peculiar form of fever

[1] Read before the New York Academy of Medicine, April 6, 1899.

has appeared. The writer of this paper was stationed on the Congo from 1893 to 1898; and on arrival found the black-water fever held in great dread and reported of frequent and fatal occurrence. Information of its symptoms and history was obtained from various residents, especially from one who had lived in the Congo region for twenty five years, but had never contracted the disease. He stated that during the first ten years of his residence in the lower Congo he had never seen a case or heard of that form of fever.

The purpose of this paper is to present briefly some points of clinical observation rather than a consideration of the various present theories of its cause and origin. The range of observation and experience was confined to the lower Congo and its immediate coast-line, in which the number of foreign residents, comprising traders, officials and missionaries, is limited to less than three hundred scattered over an area of one hundred miles. The disease is confined exclusively to the white population; and so is not known among the natives, neither has a case come under observation among the half-castes of the country. It prevails in the rainy or hot season, and not a single instance is recalled of an occurrence during the cold or dry season. The most marked and characteristic symptom is that from which it derives its English designation, African black-water fever, as the urine of the patient varies in color from that of a light claret to a deep porter appearance. So far as the histories of the patients under personal observation would indicate, the disease comes suddenly and without marked premonitory symptoms. The first indication of its presence is the changed condition of the urine. A test of temperature will give a record varying from 101° to 106° F., which as a rule responds readily to treatment. The fearful dread in which the disease is held renders the patient nervous and keenly apprehensive, as he has doubtless heard of or seen some one, seemingly as strong or of better constitution than himself, who has suddenly been stricken and died within two or three days. The expression is therefore anxious, the eyes often yellow and the skin dry and sallow. Vomiting is present and is sometimes depressingly severe, with bile in surprising quantities. Constipation has always been present; and with purgation and following rectal injections the evacuations are profuse and tar-like in color and consistency. The duration of the disease may extend from one to three days, and if there is no improvement by the third day the prognosis is fatal. Should suppression of the urine occur and continue unresponsive to treatment, the patient will sink into unconsciousness and pass away. The disease is comparatively painless, although passing reference may be made to a headache or a sense of heaviness with a sensation of soreness in the back and over the abdomen. The mind of the patient seems to be so absorbed in the condition of the urine that other matters are of but little interest. He may be much depressed, but delirium is rarely present. Apparent physical conditions do not seem a factor as a determining cause or predisposition toward an attack of the fever. A vigorous man will fall as readily a victim as one of delicate constitution, and each stands an equal chance of recovery.

In the lower Congo region the disease is found exclusively in those who have been two or more years in the country. A return to the Congo after a vacation in Europe will sometimes be followed by an attack. In a few instances, persons who have never had the fever on the Congo have had an attack on the homeward voyage or some time after arrival. A matter of note and interest is its rare occurrence among the women who have bravely entered the country, remaining in some instances from three to five years of continued residence. In most of the cases treated the patients had been of careless habits in the matter of exposure to the sun or rain, would rarely take needed medicine, and often with pronounced prejudice regarding quinin.

In the event of recovery, convalescence is remarkably rapid, and in a few days the patient may return to normal conditions and will experience a sense of general well-being and satisfaction with his surroundings. There is an occasional recurrence in one or two weeks, and in that event, the second attack may be more severe than the first. In each case of relapse under observation there was neglect of suggested precaution and of the continued use of quinin. Quinin would almost seem to be a specific for the disease, and its marked benefit as a prophylactic cannot be questioned. An instance is personally known to the writer, of a resident who after neglecting the use of quinin was taken with a severe form of black-water fever. Upon recovery he determined to use quinin with careful regularity, and has taken five grains of the bisulphate daily for at least ten years. He has been in England on furlough and back to his station and has never had a return of the fever. His last term of service extended over six years of continued residence (the usual term for the Congo is three years) and he has maintained good health during that exceptionally long period.

The treatment, which has been most satisfactory in results, must be prompt and persistent, though seemingly drastic. The conditions of the stomach are often difficult to control. In the early cases which came under my charge subnitrate of bismuth and bicarbonate of soda were used, but marked

benefit was obtained in the later cases by the prompt administration of mustard and water. This simple emetic cleared the stomach and the counter-irritation of the mustard seemed to have a decided sedative effect and left the stomach free for the first administration of medicine. The bismuth and soda were more satisfactory after the emetic. Prompt and free catharsis is indicated, which was obtained by compound cathartic tablets, crushed for ready assimilation, or the administration of calomel and jalap. The calomel is to be preferred in severe irritation of the stomach, as it will be retained even with severe retching. The dose of calomel was never more than 5 grains, but European physicians are reported as using 15 grains as a dose. A rectal injection of from one pint to one quart of warm water should immediately follow the administration of the cathartic and should be repeated twice a day until recovery. The patient should be stripped of all clothing and rolled in blankets and hot-water bottles applied to his back and feet. Rubber sheeting spread over the bed will be of great convenience and advantage when it is desired to change the patient from the blankets to the dry sheets, as the bed will then be perfectly dry. Diaphoretics should immediately follow the application of the hot-water bottles, and a dram of sweet spirits of niter in 8 ounces of hot water, sipped slowly, after which 20 grains of antipyrin should be given. In some cases the odor of the sweet spirits of niter suggests nausea, but firmness with the patient will generally insure its safe administration. A ready response will usually follow the treatment and within fifteen minutes or half an hour the patient will be in a profuse perspiration. He will find the confinement in the blankets irksome, but it is of the highest importance that he be kept in them until the temperature drops to normal or to 100° F. The time may vary from three to nine hours, but if the temperature can be reduced in that manner a returning rise of temperature is rare.

Digitalis is also indicated in the changed condition of the pulse and for its stimulating effect upon the kidneys. Hemostatics were used in the early cases, but without appreciable effect, so they were discontinued to save needless strain upon the sensitive stomach. As soon as the temperature begins to lower 15 grains of the bisulphate of quinin should be administered, and it is of the utmost importance that the patient be kept under the constant influence of that invaluable remedy until recovery. It is also advisable to continue the use of quinin in doses of from 3 to 5 grains every two or three days, and in some cases it should be given daily for a long time after convalescence. The form of administration must be determined by the condition of the stomach, by the mouth, rectum or hypodermic injections, as the case may require. Diet is highly important and the individual needs of each patient will be evident. Alcoholic stimulants are rarely indicated, and should be employed, if ever, with extreme caution. Free purgation with rectal injections of warm water twice a day; diaphoresis, if possible, until the reduction of temperature, and the daily administration of quinin are the cardinal points in successful treatment. Prompt action and constant care with a firm but gentle command of the patient which will inspire confidence are also essential to successful results. In eighteen cases in which the treatment outlined was followed but one patient failed to recover.

Criticism has been offered on the evident lack of scientific investigation in reports of this disease. The conditions of life and the limited resources of a physician in the pioneer places in which the disease is found can scarcely be appreciated except by actual experience. The means of travel and the surroundings of the foreign resident are often most primitive, and the physician must rely completely upon his own resources without opportunity for professional assistance or consultation. He may have traveled all night in a canoe, and wearied with the trip, arrives at last to find the patient in a desperate condition. A trader rarely makes provision for sickness. An empty quinin bottle, an unwise investment of some former occupant of the station, and a bottle of fruit salts, a "cure in all climates and conditions," completes the usual list. The writer never found a suitable woolen blanket in a trading station. The physician must often be nurse and attendant, and with a disease so swift in its onset and severe in its progress and of such fatal possibilities, every energy must be bent to the paramount purpose of saving the life of the patient. Under such circumstances he has no opportunity for complacent and deliberate scientific investigation. No one can regret more than the physician upon whom rests the responsibilities of treatment of the disease the present lack of thorough knowledge of the etiology and pathology of African black-water fever. The present investigations are full of promise, and every fresh suggestion is of keen interest to the physician battling alone with the dread disease at the far outposts of progress.

A $25,000 Fellowship.—Alvan R. Johnson, Esq., of Brooklyn has presented to the Trustees of the Long Island College Hospital securities worth $25,000 for the endowment of a fellowship in the department of pathology, to be known as the Van Cott Fellowship, in honor of Dr. Joshua Van Cott, who will during his lifetime select the incumbent annually. The income will be about $1250.

THE RELATIVE DEATH-RATES FROM CANCER AND CONSUMPTION.[1]

BY JOHN H. PRYOR, M.D.,
OF BUFFALO, N. Y.

It is a part of probability that many improbable things will happen.—*Aristotle.*

THE term consumption, when employed in this paper, refers to pulmonary tuberculosis only.

Recently considerable literature has appeared in medical journals, lay periodicals, and the daily newspapers concerning the death-rate from cancer in this State. It has been compared with consumption to show a relative gain which has surprised the profession and the public. Wild statements have been accepted without examination, and they have caused alarm, and given rise to opinions which are erroneous and misleading. One writer of eminence has repeatedly published statistical information, conclusions, and predictions with reference to the death-rate from cancer which are startling if true.

At this time special attention will be invited to two recent contributions: First, an article, entitled "A Further Study into the Frequency and Nature of Cancer," MEDICAL NEWS, April 1, 1899, and, second, "First Annual Report of the Director of the New York State Pathological Laboratory of the University of Buffalo," transmitted to the Legislature, January 26, 1899. This report to the Legislature is an official communication, and the following quotation explains the relations of the institution and the State: "Last year the Legislature appropriated $10,000 to the Medical Department of the University of Buffalo for the purpose of equipping and maintaining a laboratory to be devoted to the study of the causes, mortality-rate, and treatment of cancer." In each articles figures derived from the reports of the State Board of Health are given, and the increase of cancer during the last eleven years is offered in support of this remarkable conclusion: "A careful study of these tables permits one to make the following startling prophecy: If during the next ten years the relative death-rates are maintained we shall find that ten years from now, *viz.*, in 1909, there will be more deaths in New York State from cancer than from consumption, smallpox, and typhoid fever combined." The extraordinary nature of this prediction is appreciated, and italics are employed to emphasize its portentious meaning. Incredulity has led to a scrutiny of the data presented in proof of this assertion.

In the MEDICAL NEWS the following figures are published to show the mortality from cancer and consumption during the last eleven years, or twelve years inclusive: Deaths from cancer in New York State, 1887, 2363; from consumption, 1887, 11,609. "In 1898 there were 4456 deaths from cancer, and only 12,552 from consumption." The figures for 1898 are incorrect; they should be deaths from cancer, 4385; deaths from consumption, 12,979; a decrease of 71 for cancer, and an increase of 427 for consumption. Now to estimate the increase from 1887 to 1898, without any reference to yearly increase or averages, is manifestly inaccurate, but allowing that privilege, the gain in the death-rate from cancer is 85 per cent., and consumption 11.8 per cent. If fractions of percentage be dropped the gain of cancer over consumption is 77 per cent. for eleven years, or for twelve years, inclusive.

The sources of error due to the peculiarities displayed by disease and the influencing conditions are so numerous and glaringly apparent that one can place slight credence upon any estimate for future years. But if any one has sufficient interest to compute the probable increase in deaths from cancer according to the percentage given he will find that cancer must increase more than three times faster in the next ten years than it has in the last eleven years to destroy as many lives as consumption. "If the relative death-rates are maintained" cancer will destroy as many as consumption and typhoid fever in from forty to fifty years. I repeat, all such generalizations and predictions are unjustifiable scientifically, and only excite morbid interest and promote novel theories which mislead.

If any consideration of typhoid fever and smallpox be eliminated some confusion and misapprehension may be avoided. The dread disease smallpox caused one death in this State last year, and the very small percentage of deaths from typhoid fever in proportion to the number who suffer from that disease may lead to false views of its prevalence as compared with cancer. Perhaps the danger of any prognostication regarding the future conduct of a disease may be illustrated in passing by citing the death-rate from typhoid fever last year when it jumped up 469 over 1897, due largely to epidemics in military camps. Consumption increased its death-rate 338, and cancer 254, a gain of 503, which cancer must overcome at its average increase of 160 per year. In the report to the Legislature mentioned, tabulated figures prepared from the reports of the State Board of Health are furnished, and the principal part of the report devoted to mortality is employed to show the relative increase of cancer and decrease of consumption. Statistical Table VI., page 15, contains the estimated population for each death from these two diseases from 1887 to 1898. The deductions are based upon the whole increase again, not upon the average. To quote: "Thus,

[1] Read at a meeting of the Alumni Association of the University of Buffalo, April 25, 1899.

in 1887 1 person in every 2402 died of cancer, and 1 of every 499 of consumption. . . . The table also shows an increase (of deaths from cancer) of 40 per cent. during the eleven years tabulated." "In other words, in 1887 1 out of every 2400 died from cancer, in 1898 1 out of every 1500. The same table shows that the mortality-rate from consumption has shown a marked decrease." The figures given for 1898 are 1568 for cancer, and 544 for consumption. They are incorrect, and should be 1596 and 540, respectively, a decrease of 28 for cancer, and an increase of 4 for consumption. A consideration of these figures given in the statistical table leads the author to the alarming prediction in italics intended to show that the deaths from cancer will exceed those from the three diseases already mentioned. It will be found that an increase of 40 per cent. for the next ten years, even provided the death-rate from consumption remains the same, will yield the following result: Deaths from cancer, 6139; deaths from consumption, 13,000.

An estimate of the average death-rate to the population to equalize variations shows for eleven years: cancer, 1 death per 2210, and consumption, 1 death per 476. Thus consumption exhibits an average death-rate per year much higher than the figures given in the summary above. Consumption causes about 11 per cent. of all deaths. The percentage for each of the eleven years runs from 10.6 to 11 per cent. The deaths from cancer show an average gain of 1 per cent., an increase of 1.5 per cent. in 1898 over 1887. The number of deaths from cancer in 1898 is given as 3.7 per cent. of the total deaths for that year. The average increase of deaths from cancer during eleven years is 160 each year, and at the rate of increase for ten years the total number of deaths from that disease in 1909 would be 5985. Consumption increased its number of deaths on an average of 136 per year, and if the same ratio is maintained 14,839 will die from that disease in 1909.

This computation is introduced simply to illustrate a discrepancy in estimating results based upon vital statistics, and to show that the expected increase of cancer is exaggerated. Nor can it be fairly claimed that the death-rate from cancer increases progressively. By dividing a series of twelve years into two periods of six years, and estimating the increase it will be found to be very slight, and certain districts of the State show a tendency to preserve an unchanging death-rate, or a gradual decrease in rapidity of increase. The reports from New York City for thirty-one years, divided into three decades reveal an increase represented by 55, 73, and 39 per cent., and for the last five years, 23 per cent. Cancer is not the only disease characterized by a steadily increasing death-rate. Diseases of the urinary system, and particularly Bright's disease and pneumonia, have increased almost if not quite as fast, especially if considered in relation to mortality and the number affected. The fact that cancer is increasing is best illustrated by the advance in percentage of the death-rate in comparison with the general death-rate. However grave the outlook may be, there is no justification for the expected increase of more than 300 per cent. in ten years, when by the most liberal and questionable methods the past gain has been 85 per cent. in eleven years.

For some reason not explained by an examination of the mortuary returns the statement has repeatedly been made that a certain locality in New York State, of which Buffalo has been said to be the center, belongs to a distinct "cancer-belt," where cancer is prevalent to a remarkable degree. The belief in this myth has became quite widespread, and recently inquiries from a distance have been reaching physicians here. There seems to be no good reason why the rumor should go longer without a denial It is doing the City of Buffalo no particular good, especially in view of its boasted low death-rate. The returns of deaths from cancer in the Lake Ontario and Western District, in which Buffalo is included, gives a death-rate of 61 per 100,000 for 1896 and 1898. This shows not only no increase per population, but a rate below the average for the State. The death-rate for Buffalo is 58 per 100,000, or below that of the district. It is also below that of other cities in different parts of the State. Compared with the State of Massachusetts, certainly far removed from any supposed "cancer-belt," and noted for the reliability of its vital statistics, it is found that the rate for that State in 1895 was 64 per 100,000, or 6 per 100,000 more than Buffalo. In Massachusetts the death-rate from cancer has almost trebled in forty years, and in Michigan is about three times as great as it was thirty-one years ago. In both States the increase is somewhat greater than in New York State in spite of the larger population.

There are possible sources of error which must be considered as bearing upon the death-rate and prevalence of cancer and consumption. The increase in reports of death from cancer may be accounted for to an indefinite extent by more complete and accurate returns, improvements in diagnosis, and added knowledge due to operative interference, particularly in the abdominal cavity. We must also bear in mind that an unknown number of patients come to large medical centers in this State and, dying, add to the mortuary records. Practically every

case of cancer is reported, because almost invariably fatal. On the other hand, many consumptives leave the State for other climates, and the deaths are unrecorded here. A certain unknown percentage recover, and at least 25 per cent. of autopsies reveal evidences of tuberculosis not fatal or healed. The difficulties in securing Sick, Industrial, and Life Insurance, and efforts to protect the family at times, is giving rise to evasion and false returns.

Surgical treatment of tuberculosis, which has improved remarkably in recent years, has lessened the number of consumptives by the eradication of foci of infection. Finally, the fact cannot be emphasized too strongly that consumption indicates an affection of one organ and tuberculosis of all other organs is not included in recent comparative death-rates. This is partial and misleading. If all the deaths from tuberculosis in the unclassified list, and the deaths in childhood, due to the same cause, were added, the disparity between the deaths from cancer and consumption already shown would be still further magnified.

Of late the assertion that consumption has materially decreased and steadily declined in New York State has been reiterated without any explanatory data of a broad or comprehensive character. It is now sixteen years since Koch's discovery of the cause of tuberculosis, and since new methods of prevention were suggested. The death-rate continued to advance numerically until 1887, then fluctuated until 1892, since which time it has remained stationary or has slightly declined. Since 1887 the average increase has been 136 for twelve years. In 1897 there was a marked decrease, and the enthusiasts made promising conjectures and attributed great results to so-called prevention. In 1898 there was an increase of 338, and 12,979 deaths, very near the 13,000 average again. Whenever a decrease has occurred it has not been general, and the slight diminution in recent years is largely due to a lower death-rate from the disease in New York City, particularly among females.

In the districts of the State, all save the maritime, which includes New York City, the number of deaths per 100,000 population has increased. The percentage of all deaths, and the number per 1000 deaths, has remained practically the same save in 1897, and it increased again in 1898. In 1893 the number of deaths per 1000 from all causes was 105.94; average for six years 108.13; and in 1898, 108.13. Consumption causes as many deaths, but not as many in proportion to the population. The explanation is to be found in the recent great diminution in the general death-rate, and consumption simply shares with other zymotic diseases in the prolongation of life and greater freedom from disease. It claims its proportion of the small death-rate as it has of the high, but its death-rate does not decrease so rapidly as the general death-rate.

The death-rate in New York has decreased twenty-two per cent. since 1888, and much more rapidly in some cities, *viz.:* Buffalo, whose death-rate last year was 12.25 per 1000, and that of the State, 18.10. Compared with a preventable disease, *i.e.*, scarlet fever, the difference is very plain, and with a disease where prevention and saving of life is combined, *i.e.*, diphtheria, the remarkable decrease of the latter and the curious constancy of consumption are most striking. To repeat, the number of deaths from all causes in proportion to the population has undergone a most remarkable decrease in the last ten years. The population has steadily increased from 5,800,000 in 1888 to 7,000,000 in 1898, while the death-rate has declined. There are fewer deaths from all causes, but consumption continues to claim its proportion. Numerically, the death-rate may vary or diminish during certain periods, but tuberculosis in all forms is still responsible for one-seventh of the deaths in this State.

When considered in relation to all the facts, the claim that consumption has markedly decreased is exaggerated, and the statement that the disease has been checked in its spread is more accurate and trustworthy. Furthermore, this limiting of its ravages cannot be ascribed except in small part to any special efforts in the way of prevention. The wave of sanitary improvement has probably accomplished the result by removing the cause, increasing vital resistance, and eradicating vicious and, therefore, encouraging environments and conditions. Modern ideas of prevention have never been put in practice in this State except to a slight extent. What changes their adoption might produce are unknown. Unless new methods of dealing with the disease are introduced there is no sufficient justification for the pleasing prophecy so often heard that the scourge will pause in its awful work. That its death-rate will diminish in the next ten years enough to allow cancer to overtake it, obviously calls for no comment. The fatal disease, cancer, appears to be increasing with such rapidity that the mere mention of the fact is enough to cause apprehension and alarm and to stimulate a desire to learn more of the cause and nature of the malady. Any comparison is unnecessary, and is apt to prove harmful by confusing the public mind and distracting attention from problems of the day pressing for solution.

The State has made a commendable move in establishing a State Laboratory in which investigations relating to the cause and nature of cancer may

be pursued. If appropriations are liberal enough to allow of a proper prosecution of the work, something may be accomplished. As yet no proof has been established of its infectious nature or parasitic origin, but many signs point in that direction, and the fact that those qualified to undertake the investigation are pursuing the matter with scientific zeal makes the future outlook somewhat more hopeful. How near or how far we are from the time when more may be known of cancer cannot at present be conjectured. We know the cause of consumption and the conditions which promote the disease. We know that it is infectious and largely preventable. We know that a percentage, varying from 60 to 75 per cent. of early cases can be cured, and the remainder improved by proper treatment. Therefore, an immense and unnecessary loss of life, and an appalling and unnecessary amount of suffering prevails in this State because of stupid, antiquated, inhuman, and wasteful methods of dealing with the consumptive. How long the death-rate from consumption will remain a disgrace to the medical profession and the State we cannot know, but the time will not be shortened by the recent tendency to exaggerate the importance of one disease and belittle the dangers from another. The possibility of the death-rate of cancer exceeding that of consumption in 1909 on the present ratio of increase can only be realized by some unlooked for and very unusual occurrence. Undoubtedly the number of deaths from consumption can be greatly decreased by prevention and proper care, and if rational methods of relief are ever adopted the time may come when the wide difference between the mortality-rate from cancer and consumption may be greatly diminished or obliterated.

COD-LIVER OIL.[1]

By THOMAS E. McARDLE, M.D.,
of Washington, D. C.;
Professor of Minor Surgery, Medical Department, Columbian University;
and
W. H. WILEY, M.D., Ph.D.,
of Washington, D.C.;
Chief of the Chemical Division, U. S. Agricultural Department.

THREE years ago I read a paper before this Society on the therapeutic value of cod-liver oil. It was my purpose to impress upon the members the true value of this agent in certain diseases, fearing they might have forgotten this old remedy in the continued search for novelties. During the time which has elapsed since the reading of that paper I have given much thought to the study of this subject, and I have become more convinced than ever that it is one of the most valuable remedies of the Materia Medica for the treatment of a large number of the so-called wasting diseases of children, and also for those peculiar conditions of adults embraced under the common term anemia. In other words, whenever the blood is deficient in the red blood-corpuscles, when the body weight is below normal, and when every function seems deranged, we have in cod-liver oil a remedy of great value.

The potency of the remedy, however, lies in its proper use. One of the principal efforts of my first paper was directed toward proving the necessity of using the whole oil. In order to prove of value, it might as well be understood first as last that the whole oil must be used. Indeed, we prescribe cod-liver oil mainly because of the fat it contains. Whilst the so-called active principles of alkaloids may have some therapeutic power, I am fully convinced, after having given this subject most careful study for a long time, that the fat in cod-liver oil is its chief factor in furthering the processes of nutrition. We must not lose sight of the fact, however, that the combination which Nature has formed so perfectly between this particular fat and its accompanying alkaloids gives a peculiar and ideal value to this oil which no other fat possesses. To separate the so-called active principles from the oil is, in my opinion, to destroy the efficacy of both. It is the whole oil we need. It is the whole oil we must have.

When I had the honor of addressing this Society before on this subject, I contended that we oftentimes make a mistake in our method of prescribing cod-liver oil. I said that usually too large a dose was given. Consequently it was not assimilated, and served only to add nausea and indigestion to the other ills already present. I hold that 10 or 20 drops three times a day are the largest doses we dare prescribe in many cases. These doses may be gradually increased as the patients continue to improve. Frequently it is impossible to get an individual to take the plain oil. For this reason and also because of its easier digestion, this remedy is usually given in the form of an emulsion.

We all know that the making of an emulsion prepares the oil for digestion; indeed, some say that it is already digested when it is in the form of an emulsion. When placed in the position of deciding as to whether we will write a prescription in detail for a certain amount of cod-liver oil to be made into an emulsion or of merely ordering one of the prepared emulsions to be found in the drug-stores, I prefer the latter, because of the difficulty in finding pharmacists of sufficient skill to prepare a suitable and satisfactory emulsion. When persons have made emulsions exclusively for years they acquire a certain skill which only comes from such experience.

But it is absolutely essential that we know what we are prescribing. That is the principal objection to prescribing the preparations offered for sale. We know so little of what their constituents are. It is for the purpose of finding out what these preparations really contain that Professor Wiley and I entered upon the study of this subject. Professor Wiley has found that for the most part the claims set forth by the proprietors have been justified

[1]Read before the Medical Society of the District of Columbia, May 17, 1899.

by his examinations. The profession as well as the laity are indebted to Dr. Wiley for entering upon this work so heartily, and we owe him much for the skill, industry, and perserverance with which he has undertaken a thorough study of five or six of the preparations which are best known to us, either through representatives or through personal experience. He places before us, for reference, analyses of some of the more important preparations of cod-liver oil, and from these we can select the one to our liking.

Preparations of this kind are mostly proprietary, and their exact composition is not given on the label. There are two typical groups of these compounds. The first group consists of the true emulsion containing an approximately fifty-per-cent. content by volume of the pure oil, together with the emulsifying reagent, some glycerole, a flavoring extract usually dissolved in alcohol, and other less important ingredients. Scott's Emulsion, Ozomulsion, and Parke, Davis & Co.'s Egg Emulsion are typical members of this group. It was not the object of the analysis to determine all these bodies, but only the total non-volatile constituents, the proportion of oil, and of alcohol. The non-volatile constituents, that is, those bodies left after heating to constant weight in a vacuum at the temperature of boiling water varied from fifty-eight per cent. to sixty-four per cent. in the samples analyzed.

The purified oil in every case responded to the color tests for cod-liver oil. The proportion of oil in these samples, as has already been said, is approximately half their volume. In the samples analyzed the oil by volume varied from a little over forty per cent. to a little over forty-six per cent. The quantity of alcohol was very small in Scott's Emulsion, and ranged from this to a little over nine per cent. by volume in other samples of the first type. It is evident that this small quantity of alcohol is derived from its use as a solvent in some of the other ingredients of the emulsion. No quantitative determinations were made of the glycerole, hypophosphites, essential or flavoring oils, or other minor ingredients of the compounds.

The second type of preparations includes those in which the oily part of the cod-liver oil is removed, and the greater part of the nitrogenous and other constituents thereof is held in solution as a tincture. The principle on which the preparation of these compounds rests is that the nitrogenous bases, lecithenes, and other non-oily constituents of cod-liver oil constitute its really active principles. It is evident from the above considerations that these compounds contain considerable quantities of alcohol and only small quantities of non-volatile solids and oil. The analytical data fully corroborate this statement. Typical preparations of this class are found in Vinol, Wampole's Extract, and Stearn's Wine of Cod-Liver Oil. In these the analytical data reveal the fact that the non-volatile matter ranges from five per cent. to ten per cent.; the oil from 1.01 per cent. to 0.86 per cent.; and the alcohol from nineteen per cent. to twenty-four per cent.

The above analytical data are offered in the hope that the physician prescribing these remedies and tonics may know their general character, and thus be guided in choosing wisely those forms which are best suited to the needs of his patients.

Having noticed in some of the pharmaceutical journals statements regarding the occurrence of morphin in Scott's Emulsion, I deemed it advisable to examine the samples for this ingredient, for the profession should certainly be informed on this subject. Accordingly, two samples of 50 grams each, from a bottle of Scott's Emulsion, bought in the open market, were secured and treated as follows: Into one sample 10 milligrams of morphin, as a fine powder, were added, and the whole mass thoroughly stirred until an intimate mixture was secured. The two samples were then subjected to exactly the same treatment for the separation of morphin from the organic matter. The method followed was strictly that recommended by Wormley on page 492 and following, in his work entitled "Micro-Chemistry of Poisons." It is not necessary here to give a résumé of that method, since any one desiring to practice it can find it described in full in the place mentioned. The residues, according to the method of Wormley, were tested with two of the characteristic reagents for morphin, namely, nitric acid and ferric chlorid. In each case a brilliant reaction characteristic for morphin was secured in the residue from the sample to which the morphin had been added. In the other sample not the faintest trace of the reaction for morphin could be detected. These parallel tests show convincingly that the commercial sample contains no morphin.

CLINICAL MEMORANDUM.

EIGHT CASES OF TOADSTOOL POISONING.[1]

By WILLIAM McD. STRUBLE, M.D.,
OF TRENTON, N. J.

CASE I.—H. G., an adult, on October 16, 1898, ate freely of supposed mushrooms at 8 A.M., again at noon, and at 4 P.M. At 5 P.M. he began to vomit. He supposed this to be due to acute indigestion from overeating as he had had several such attacks before. About 10 P.M. the vomiting became so severe that he sent for me as I had prescribed for him before for a similar trouble. I also concluded his trouble to be due to acute indigestion and prescribed accordingly. About an hour later I was again summoned as he was no better. I now found several other members or the family sick, and having made more careful inquiries, found that all who had eaten of the so-called mushrooms were sick and the one who had not eaten of them was the only well one, and concluded the sickness must be due to a poisonous form of the fungus as the symptoms were too severe for a simple indigestion.

H. G. was now vomiting a large amount of watery mucus. There was no food in the vomitus, his stomach having been emptied by his previous vomiting which began at 5 P.M., nine hours after the first ingestion of the poison. Every few minutes he would vomit a mass of stringy mucus, so tenacious that it had to be whipped from his lips. He did not complain of pain, but the

[1] Read before the Mercer County, New Jersey, Medical Society.

nausea was so pronounced that I gave him a hypodermic injection of morphin and atropin, applied a mustard plaster over the epigastrium and ordered him to bed. This seemed to quiet him, and with the exception of an attack of retching every fifteen or twenty minutes, he was comfortable for about two hours, when he began to complain of being cold. His temperature was normal, but the skin felt cold; there was no sweating. His heart was quite weak, 110 per minute, and I, therefore, gave him a hypodermic injection of strychnin, $\frac{1}{30}$ of a grain, followed n half an hour by $\frac{1}{100}$ of a grain of atropin. This made him feel more comfortable, his pulse became stronger, and he dozed, with occasional waking and retching spells, until morning.

The following morning he felt comfortable but was weak. His pulse was 110, but of better volume than during the night. He was given iced champagne and white of egg in water at short intervals, with a mixture containing bismuth subnitrate and spirits of chloroform. These he retained about half the time. He was also given occasional hypodermic injections of atropin or strychnin as the pulse became weak. Toward night he seemed decidedly better, retained nearly all he was allowed to take into the stomach but complained of great thirst, and a burning in the esophagus and pharynx, and wanted large amounts of fluid, but was perfectly conscious, and seemed satisfied when it was explained to him the reason he could only receive very small quantities. His pulse was of good volume, 100 to the minute, but he was very restless. He had had no morphin during the day so was ordered a 1-grain opium suppository at 10 P.M. He rested quietly the first part of the night, though he slept very little. He had occasional retching spells, but not severe enough to cause much exhaustion. Later in the night he became very restless. About 6 A.M., forty-four hours after the ingestion of the poison, he became pulseless. The heart sounds were very weak, 130, he felt cold, his temperature falling to 96.5° F., but he was perfectly conscious.

At this time serous diarrhea developed for the first time. At first the movements were voluntary but later became involuntary. The passages were quite frequent but of very small amount. This continued up to the time of his death. He passed very little urine, but this was probably due to the amount of fluid vomited, and the very small quantities taken into the system. Hypodermics of atropin, $\frac{1}{100}$ of a grain, followed in a few minutes by strychnin, $\frac{1}{30}$ of a grain, hot applications, rectal injections of hot normal salt solution, and hot water bottles to the surface of the body, did not seem to produce any effect. These were repeated at short intervals during the day but he died about 4 P.M., fifty-four hours after the first meal of mushrooms.

CASE II.—Mrs. H.G., wife of the foregoing, 5½ months pregnant, ate of the so-called mushrooms at 8, 12 and 4 P.M. of the same day. Fifteen hours after eating the first meal vomiting began, at first contents of stomach, later watery mucus, without pain or much depression for some hours.

On the morning of October 17th she was hardly able to rise, but did not complain of pain. A few hours later her stomach began to retain albumen-water and iced champagne, her pulse improved and her condition seemed much more favorable. She appeared to be resting better than her husband who was extremely restless, while she could be roused only by an effort. At 7 A.M. on the 18th she had a very loose bowel movement which was followed by a very sharp depression of the heart. She nearly died before the nurse could get her from the commode to her bed. Her pulse was rapid, heart sounds almost imperceptible. Only a slight thready pulse could be felt at the wrist. Temperature normal. She did not complain of the cold as her husband did. Her heart did not respond to hypodermics of atropin and strychnin, and she died about forty-eight hours after the first meal of mushrooms.

CASE III.—C. G., aged six years. Amount eaten not known. He was sleeping quietly until 1 A.M., seventeen hours after the first meal, when he roused up, had a painless vomiting spell, voiding only a watery mucus. He was given warm water to encourage the vomiting, which soon stopped, and he dropped asleep. He awoke again in about one hour with another attack. This was repeated every one or two hours all night. In the morning his pulse continued good, but he was weak, depressed, and pale, Surface of body was cool, pulse 100, and of good volume. Some tendency to roll eyes upward. Vomiting stopped, retained albumen-water and iced champagne. Continued about the same through the day and early part of the following night. Later became cold and pulseless, and died from heart failure, without pain or vomiting, forty-eight hours after taking the first meal of mushrooms.

CASE IV.—Annie, servant in the G. family, ate about four tablespoonfuls of the mushrooms at 8 A.M. Began to vomit sixteen hours later. Had numerous vomiting attacks during the night. During the day retained about half the albumen-water and iced champagne given her. During the following evening and night pulse was small but fairly strong. Early on the morning of the 18th her bowels became loose, this being accompanied by severe depression of the heart. Pulse was rapid and weak, but she rallied in a few hours, responding nicely to the medication. Stomach continued irritable, bowels loose. Urine very scanty. She gradually improved during the four following days when she was up and about, and taking a fair amount of food.

CASE V.—Female child, two years old. Was given a little of the broth, but she did not like the taste and spat it out. At 2 A.M., eighteen hours later, was taken with vomiting. After half an hour the vomiting stopped. The next morning she was running about playing, occasionally vomiting. The third day, she had a looseness of the bowels which lasted about twenty-four hours.

CASE VI.—B. G., adult, ate for breakfast about two tablespoonfuls of broth from the mushrooms. Fourteen and one-half hours later he began vomiting. A hypodermic injection of morphin and atropin seemed to control the emesis, and although wakeful he was quiet through the night, with occasional retching spells. On the morning

of the 17th he complained of feeling weak, but retained nearly all the iced champagne and albumen-water given him. He continued in this condition until night when his bowels became loose, and through the night he had very frequent evacuations of a greenish-watery fluid. Urine scanty. About this time he became very thirsty, complaining of a burning of the tongue, pharynx, esophagus, and stomach, and in spite of orders took large quantities of fluids, which he vomited almost at once, but without pain. Toward morning his pulse became weak, and it was necessary to administer hypodermics of strychnin. This continued during the day. He retained a fair amount of champagne and albumen-water. The next day he was stronger and retained milk. He slowly regained his strength and on the fifth day was up and about. His bowels continued loose until this time, when the movements were formed but still contained some mucus.

CASE VII.—D. L., aged forty-seven years. This patient ate about four tablespoonfuls of mushrooms at about 4 P.M. At 2 A.M., ten hours later, he began to vomit. Vomiting was encouraged by the use of warm salt water, but was never very free. There was a constant desire to have an action of the bowels, but without result. He had no pain. The following day he retained iced champagne and albumen-water, but had occasional vomiting spells. Bowels were still irritable. He was restless through the following night, and on the morning of the 18th complained of cold and weakness. Pulse 120, soft and weak. Hypodermics of strychnin continued through the day. Complained much of thirst and burning in pharynx. Began to take milk, which he retained in small quantities, but he was very indiscreet and would take a large amount in defiance of orders, and in a few minutes would vomit it. At this time he passed a small quantity of dark red urine which was pronounced by the nurse as "possibly bloody." There was much difficulty in promoting a free action of the bowels in the case of this patient. He took several doses of magnesium sulphate and castor oil, and had rectal injections before it was considered that the action was free enough. He gradually improved, the stomach slowly became more retentive, the heart stronger, and he was dismissed from treatment on the ninth day.

CASE VIII.—H. G., aged eighteen years. Ate about 4 tablespoonfuls of the mushrooms at 9 A.M. Began to vomit at 10.30 P.M., 13½ hours afterward. Her stomach was the most irritable of any of these patients, the vomiting of a frothy mucus continuing in spite of hypodermics of morphin and atropin to the limit of safety. She received during the night of the 16th 1¼ grains of morphin and $\frac{1}{20}$ of a grain of atropin. She passed a very restless night, not sleeping any or responding to the treatment. During October 17th her stomach retained almost none of the iced champagne and albumen-water, and rejected the bismuth mixture at once. No sleep during this day or the following night. Very restless; pulse 120, full; face flushed, and she began to have signs of the physiological effect of the atropin. This was the only patient to show this, although the others received fully as much, and in some instances more. The atropin was discontinued, and the strychnin only was given. The following morning the pulse became weaker, 120, and she complained of cold. A diarrhea of a serous character set in. Her stomach still rejected nearly all that was taken. Hypodermics of strychnin continued as required, according to the condition of the heart. Toward night the stomach was less irritable, and she retained a small amount of albumen-water and champagne. Temperature 100° F. She complained of considerable pain in the lower abdomen, which was probably due to her menstruation which was due, and began normally during the night. On the 19th she was still very restless but gradually improved. Bowels still too free and contained mucus, with occasional specks of blood. Urine scanty; no albumin. Heart stronger, less rapid, and of good volume. Her symptoms slowly improved, but her stomach continued irritable, and she was under treatment ten days. Her condition was the most serious of any of the patients that recovered, and she was apparently much worse than Mrs. G. until the severe attack of heart depression caused the death of that patient.

It will be seen from a comparison of these cases that the symptoms of poisoning were in all practically the same, *viz.*: A painless vomiting, coming on from nine to eighteen hours after the ingestion of the poison, which was very free and consisted of mucus and water. This was very evidently a centric vomiting, due to stimulation of the vomiting center in the medulla after absorption, as none of the symptoms seemed to be caused by the local effect of the fungus, there being no symptoms of irritation of the gastro-intestinal mucosa. The burning and dryness in the mouth, pharynx, and esophagus, were considered due to the atropin given. This vomiting continued for a number of hours, when heart weakness or depression began, with a resultant coldness of the surface. This heart depression was relieved in five cases by hypodermics of atropin and strychnin, but in three cases, while there was a response at first, later the patients died from heart failure, being cold and pulseless for some hours before death. With this cardiac depression there began a serous diarrhea. The movements, while frequent, were small in amount, and the condition did not seem to be severe enough to cause the intense, and in three of the cases, a fatal cardiac depression. It would seem that there was a simultaneous intestinal vasomotor paralysis, thus causing a serous leaking into the intestinal cavity. With this there was no sweating, showing no involvement of the cutaneous vasomotor system. In some instances the patients complained of the frequency of bowel movements, but nothing was given to stop this action, it being considered Nature's effort to rid the system of the poison, and was encouraged by salines, castor oil, and rectal injections. In no case was there any cerebral symptoms, or coma, as described as occurring in muscarine poisoning.

Mr. V. K. Chestnut of the United States Agricultural Department, Washington, D. C., and Mr. E. B. Sterling of this city, induced the man who sold the toadstools to this family to take them to the same spot and gather some more specimens of the same variety. These speci-

mens were also picked out from a number of other species by members of the family, thus doubly identifying the cause of the poisoning. This was the *Amanita phalloides*, or death-cup. Most cases of toadstool poisoning are due to the *amanita*. There are a number of varieties of this fungus, but only three or four are poisonous. There are two prominent poisonous varieties found here, the *Amanita muscaria*, or fly amanita, and the *Amanita phalloides*. The active principle of *Amanita muscaria* is muscarine, and the symptoms of its poisoning as given in Potter's "Materia Medica" are as follows:

"Muscarine is a powerful respiratory and cardiac depressant, paralyzing the respiratory center and arresting the heart in diastole by paralyzing its motor ganglia while stimulating its inhibitory apparatus. It lowers the arterial tension, produces profound salivation, lacrimation, and sweating, contracts the pulmonary vessels, causing intense dyspnea, and increases the intestinal, hepatic, and pancreatic secretions, and markedly diminishes the renal. It causes tetanic intestinal contractions, severe colic and purging, spasm of accommodation, and contraction of the pupil. It acts as an intoxicant on the cerebrum, producing vertigo, delirium, followed by sopor, with lowered reflexes, perhaps coma, and death."

It will be noticed that atropin is almost an exact physiological antagonist to muscarine in its effects on the heart, muscular spasms, sweating, salivation, pupil, and renal secretion, and may be considered a typical antidote.

The symptoms of poisoning by *Amanita muscaria*, as described by Dr. D. W. Prentis of Washington, D. C., are as follows: "Symptoms usually begin in fifteen minutes to two hours after injection of the fungus: Colic, more or less violent, vomiting, diarrhea, contracted pupil, salivation, profuse sweating. With these are cerebral symptoms; the patient feels as if drunk and becomes violently excited; dimness of vision which may be followed by blindness; epileptoid convulsions and trismus; drowsiness with loss of reflexes; pulse slow and thread-like; respiration short and stertorous; death from progressive loss of heart power."

It will be seen that these symptoms do not at all correspond to those in the cases described, which, as they were so uniform in all the eight cases, may be taken as typical of *Amanita phalloides* poisoning, unless the fungi eaten were contaminated by other varieties, which, from the statements of the family does not seem likely. The cerebral effects, the salivation, sweating, and colic were all absent in these cases, and this seems to show that the poison is different in the two varieties and not the same, as is claimed by some.

Mr. V. K. Chestnut affirms that the poison of *A. phalloides* is not muscarine but a toxalbumen called *phallin*. He considers the symptoms of poisoning "due to a decomposition of the blood, the serum escaping from the blood-vessels into the alimentary canal, the whole system being rapidly drained of its vitality," and he gives the symptoms of phallin poisoning as abdominal pain, cramps, convulsions, and other tetanic spasms; pulse weak; nausea, vomiting, extreme diarrhea, rice-water discharges simulating cholera, and death from general asthenia. These cramps of the legs and other convulsive symptoms may be due to the rapid drain of the fluids of the blood, and the symptoms present a typical picture of cholera, apparently due to an irritant or poison causing a vasomotor paralysis along the alimentary canal and a consequent pouring out of serum. My patients did not have this appearance; there was none of the sunken eyes, hollow temples, pinched nose, or the appearance as given by Tyson of "a wasted body, long immersed in the pickling-vat of a dissecting-room." In other words, my patients died from a failure of the heart and not from a draining away of the liquids of the body.

Again, as to the statement of decomposition of the corpuscles of the blood. As a typical disease in which this occurs may be mentioned yellow fever. Here the symptoms referable to this lesion—decomposition of the blood-corpuscles—are jaundice, black vomit, black and offensive stools, bleeding from the gums and mucous surfaces, and hematuria, these symptoms being due to the escape of the altered hemoglobin. None of my patients presented any of these symptoms, and it would seem as if a different poison had been described. The symptoms given by Mr. Chestnut so closely resemble those caused by muscarine that it would seem as if that action had been described and not the effects of *Amanita phalloides*.

In looking back over these cases the following points in regard to treatment suggest themselves to me: Having a history of *Amanita phalloides* poisoning (and the length of time before the beginning of the symptoms would almost diagnose the variety of the fungus) at once an attempt should be made toward free evacuation of the poison. Tannic acid as a chemical antidote is of no use. Vomiting should be encouraged until the stomach is empty, and the bowels should be cleaned out. This seemed impossible in my cases as the vomiting was so severe. Rectal injections do not reach high enough but should be urged. If I had another case I would put two or three drops of croton-oil on the tongue at the risk of increasing the irritation as the effects of the poison are so severe and so fatal; or hypodermic injections of magnesium sulphate may be tried in order to prevent any further absorption of the poison. Having accomplished this, morphin for the vomiting, strychnin and atrophin to stimulate the heart, with possibly galvanism of the cervical sympathetic, and large subcutaneous injections of normal salt solution should be given.

THERAPEUTIC NOTES.

Hydrotherapy in Adult Pneumonia.—BARUCH ("Hydrotherapy") advocates the use of the chest compress. Three folds of old linen are measured to fit exactly the entire chest, from the clavicles to the umbilicus. To embrace the shoulders slits are cut which should meet above. Two such jackets and two pieces of closely woven thin flannel of the same shape, but an inch larger in all directions, should be provided and fitted. One of the linen compresses is rolled up, soaked in a basin of water at 60° F., and wrung out so that it remains quite damp without

dripping. The flannel is now spread upon an even surface and the wet compress is put upon it. Both are then rolled together half way. The patient, who must not be allowed to exert himself, is turned upon the left side. The compress is so placed upon the bed that the rolled part lies in close proximity to the left side and the lower edge of the left slit is under the left axilla. The patient is then gently turned upon his back and the compress is unrolled. Both edges are brought forward and made to envelope the chest snugly. The flannel cover, which has been allowed thus far to lie upon the bed, is then brought forward, and the whole is then secured by two safety-pins in front and one over each shoulder. The compress should be changed every half hour, unless the temperature is below 102.5° F., every hour unless the temperature is 99.5° F., when it should be discontinued. The compresses are thus applied in rotation, day and night, unless the patient sleeps. A compress should be thoroughly rinsed before it is rolled up for soaking. The temperature of the water should be lower than 60° F. should stupor, or muttering delirium, or cyanosis or bronchi blocked by secretions be present. The chest of such a patient should receive one or more dashes of colder water before the removal of each compress. Water at a higher temperature than 60° may be used if there is much jactitation, insomnia or excitability. Here the compress, moistened more thoroughly before application, may remain two hours, thus converting it into a soothing fomentation that is not relaxing like a poultice.

Treatment of Pleurisy.—Pain requires the use of morphin hypodermatically or by the mouth *pro re nata*, for the first few days. Poultices give relief in mild cases. Blisters should not be used, if at all, until febrile symptoms have practically disappeared. Effusion is not likely to be dissipated by digitalis and iodid of potash; sodium salicylate in full doses (with from 2 to 3 grains of caffein citrate added to each dose if the heart action is weak) will be found more effectual. Do not aspirate during the acute stage unless the symptoms are urgent; inflamed surfaces would thus be brought together, with adhesion and increased irritation resulting. If possible, wait until the second or third week before aspirating. Irrigation by submersion in a bath at a uniform temperature of 100° F. is advocated in empyema. Any antiseptic may be put into the water, *e.g.*, saturated solution of boric acid, which is, however, expensive. Plain water, previously boiled, should answer. The entire body should be submerged for several minutes after expiration gives out clear water, from ten to twenty minutes. The pus will drop to the bottom of the tub. At first bathe daily, then every other day until recovery. At the stated temperature there will be no chilling.—"International Medical Annual," 1899.

Antitoxin in Diphtheria.—The syringe should invariably be sterilized immediately before being used. It is preferable to inject into the abdominal cellular tissue. (Jacobi, "Twentieth Century Practice of Medicine," vol. xvii.) According to the severity of the case 600, 1000, 1500 or 2000 units should be injected. The dose should be repeated unless the symptoms, both constitutional and local, be improved in from twelve to twenty-four hours. If necessary, patients two years old and over may be given at the earliest possible moment 2000 units, after from twelve to eighteen hours 2000 more units unless there is an improvement, and the same dose twenty-four hours after the second dose if there be still no improvement. Patients under two years may receive from 1000 to 1500 units. Early injection is necessary; the prognosis is impaired by procrastination. It is better in doubtful cases to inject even before the diagnosis is established. In addition to antitoxin, other treatment, both general and local, should be employed.

Treatment in Myxedema.—The condition of the kidneys, heart, skin, etc., must be carefully considered (Anderson, in "Contributions to Clinical Medicine"). The patient should be kept in an equable temperature. The food should be nourishing. Strychnin, arsenic, and iron may be used separately or in combination. The hair should be shampooed daily for half an hour. Every three days in rotation diaphoresis should be promoted as follows: On the first day a vapor bath. On the second ¼ grain of pilocarpin hypodermically. On the third day a hot, electric bath for half an hour followed by vigorous friction. From time to time this diaphoretic treatment is omitted for a week. Thyroid extract should be given by the mouth, *not* subcutaneously. If the latter method is employed abscesses, with resulting constitutional symptoms, tonic spasm, loss of consciousness, etc., are apt to result.

The gland itself, may be taken, or a glycerin extract may be administered. But the most convenient form is that of the desiccated thyroid either as a powder, tablet, or in capsule, such as a number of firms now prepare. Two grains of the desiccated powdered thyroid prepared by Parke, Davis & Co. are equal to 5 grains of the fresh gland, the ordinary sheep's thyroid weighing about 24 grains. The dose of this preparation is about 1 grain; and this dose is gradually increased until about 6 grains a day are reached. Then we stop and watch the effect of the dose for some days. If we have not overdosed on the one hand or if, on the other, the patient is not improved, we further gradually increase the dose up to 15 grains (no more) of the dried glands daily in divided doses. Overdoses of the thyroid produce violent headache, feeble heart action, and sometimes diarrhea and vomiting. Should these symptoms appear we stop the use of the drug for several days and return to its use gradually. The patient should be kept in bed for a few days after treatment is begun. After apparent cure the thyroid gland must be taken indefinitely, either in minute daily doses or in full doses for several days at the end of three weeks or a month. The latter plan is said to be preferable although more disagreeable. The diet should be largely vegetable.

Uses of Hypnotism.—Hypnotism is as yet of little service to the physician (Church, in "Nervous and Mental Diseases," by Church and Peterson). Now and again a minor operation may be done under its influence, saving the slight risk of surgical anesthesia, or by its aid a fixed

idea may be removed and a delusion expelled. Under ordinary circumstances the number of susceptibles is so small that its general use is impossible. In hysteria, as elsewhere, it is a two-edged weapon, and the patient may emerge from hypnosis instituted for a minor difficulty and go into severe hysterical convulsions. One delusion may be removed, but another and more serious one of mind reading or undue influence may be implanted. For obvious reasons, women should never be hypnotized without reliable witnesses, and the public use of hypnotism can only appeal to the morbid. In this connection its power for harm is proven. There is no doubt that its frequent repetition is harmful to the individual. It tends to destroy self-reliance and to make patients imaginative, weak-minded, and neurasthenic. It has also a tendency to bring discredit upon its employer, and in most instances would better be substituted by measures of equal efficiency and less disadvantage. Suggestion, however, is a mighty aid to the physician, and, without producing hypnosis, positive and intelligent assertion can accomplish all that is likely to be done by hypnotism short of the somnambulistic stage.

Treatment of Rheumatism in Children.—For pain ammonium salicylate should be used largely diluted. If this cannot be borne, antipyrin, phenacetin or lactophenin in small doses may be given. To produce alkaline effect use calcium or magnesium hydroxids, *e.g.*, milk of magnesia. Rest in bed will help to prevent endocarditis (Braithwaite's "Retrospect," vol. 118).

Treatment of Influenza in Children.—("Cyclopedia of Diseases of Children," vol. v.). Rest in bed until convalescent is essential. The course of the primary infection cannot be shortened by medication. Distressing symptoms must be relieved and the strength must be sustained. At the outset a mild cathartic of calomel and soda should be given. This should be followed by a diaphoretic of spirits of nitrous ether and liquid Dover's powder. For headache, nerve symptoms, and muscular pains give phenacetin in 1-grain doses to a child two years old, repeated every hour for two or three doses. Codein may be added. For high fever use tepid baths. Quinin may be given throughout the disease in moderately full doses, unless there be marked gastro-enteric disturbance. For the cough, codein may be used during the first days; later cod-liver oil and creasote may be employed. Local treatment of the nose is essential. Seiler's solution, diluted three or four times, or a normal salt solution should be used to irrigate the nose and throat two or three times a day. Prostration is best met by alcohol or strychnin. Convalescence demands a careful tonic treatment. Change of climate hastens the return to health.

Treatment of Chlorosis with Dyspepsia.—For the form of chlorosis exhibiting anorexia, flatulence, and vomiting, contraindicating the ingestion of much food, THIBAULT of Angers recommends a strict milk-diet for days or several weeks. Solid food is then to be given continuously for some time, using only eggs, then white meat, and boiled fish. Milk is continued, and coffee and wine are prescribed. No iron is administered until all gastric pain has disappeared. Small doses are then generally tolerated and induce rapid improvement. The protoxalate (gr. 2½) combined with the same amount of powdered rhubarb can be taken twice daily at mealtime in a cachet. If this disagrees, 3 grains of phosphate of soda should be taken at the same time, and hydrochloric acid prescribed after the meal. In case of intestinal sluggishness the following pill is useful:

℞	Ferri et potassii tartrat. . .	gr. xlv
	Pulv. nucis vom.	gr. x
	Pulv. fol. belladonnæ . . .	gr. iiiss
	Pulv. aloes	gr. xv
	Ext. gentian	q. s.

M. Ft. pil. No. XX. Sig. Two pills a day.

For Lead Colic.—

℞	Ext. belladonnæ alcohol. . . .	gr. v
	Ext. nucis vom.	gr. iiss
	Ext opii	gr. v
	Pulv. radicis et Ext. glycyrrhizæ	q. s.

M. Ft. pil. No. XXX. Sig. One pill two or three times a day.—*Leyden.*

For Diarrhea in Children.—When the food is passed in a state of partial digestion, SIMON advises that the meat, cooked vegetables, and eggs, included in the child's dietary, be reduced to a pulp before feeding. He prescribes as follows:

℞	Tinct. nucis vom. . . .		*m.* viii
	Tinct. rhei Tinct. calumbæ }	aa . . .	*m.* xxx
	Tinct. cinchonæ		*m.* lxxx.

M. Sig. Five to 10 drops in water or wine of cinchona before meals.

For Anorexia of Pregnancy.

℞	Pulv. rad. calumbæ Pulv. rad. zingiberis }	aa . . .	℥ ss
	Fol. sennæ		ʒ i
	Aq. bull.		Oi.

M. Ft. infus. Sig. A small glassful before each meal.

To Prevent Loss of Hair.—

℞	Acidi acetici		*m.* lxxv
	Tinct. pilocarpi Tinct. cinchonæ Tinct. rosmarini }	aa . . .	ʒ vi
	Rum		℥ iss
	Aquæ	q.s.ad.	℥ vi.

M. Sig. Rub into scalp.—*Brocq.*

It may be advisable to dilute further in case of a sensitive scalp.

For Nervous Headache and Hemicrania.—

℞	Methylene blue (Merck) Myristicæ }	aa . .	gr. x.

M. Div. in pulv. No. VI. To be put up in capsules. Sig. Two or three capsules a day.—*Lewy.*

The headache may yield to one dose, or the patient may be relieved from subsequent attacks by several days' treatment.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE ROENTGEN-RAYS IN THORACIC DIAGNOSIS.

The Röntgen-rays are steadily coming into more constant use by the great experts in physical diagnosis, in the recognition and differentiation of intrathoracic conditions. Last year at the meeting of the German Medical Congress Dr. Schott of Nauheim demonstrated by a series of most careful skiagrams that even our knowledge of so delicate a subject as heart dilatation could be greatly aided by this new diagnostic method. In the proceedings of this year's German Medical Congress, an abstract of which appeared recently in the Medical News, it will be seen that the distinguished heads of German clinics frequently turn to the X rays for help in conditions that were formerly supposed to be fully revealed by older methods of physical diagnosis.

In the diagnosis of aneurism practically all authorities are agreed that the Röntgen skiagrams are of the greatest service. In cases in which there are suspicious symptoms in the thorax, and especially if there is any, even the slightest, reason to suspect aneurism of the descending aorta the X-rays are a most reliable adjuvant.

There are heart conditions in which a series of skiagrams furnish information that is of the greatest value for prognostic as well as diagnostic purposes. This, to be sure, is the more exact and delicate side of the application of the Röntgen rays, and one that requires special training, but the time spent in acquiring the technic for thoracic diagnosis cannot fail to be profitably expended—a fact that will become more and more apparent in the near future.

ENGLAND'S INEBRIATE ACT OF 1898.

The passage of a new Vaccination Act by the British Parliament, and the heated discussions as to the preventive value of vaccination carried on by physicians and members of antivaccination leagues, have quite obscured another British law which may lead in time to far more important measures than compulsory vaccination or its neglect. The law in question enables a judge to commit to a suitable institution a man or woman who has been four times within a year arrested for drunkenness, or who has while intoxicated performed a crime of a certain degree. In the latter case his commitment for drunkenness does not relieve him of punishment for the crime done. Such detention in a reformatory shall be for an indefinite period, not exceeding three years.

This act went into effect January 1st, and it is still too soon to say what the effect of it will be. The recognition of drunkenness as a cause for the removal of a man from association with his fellows is a new and important departure in law. Theoretically a man who becomes intoxicated periodically is wanting in self control. A man who while drunk commits serious crimes is dangerous to society. But whether the greatest good to the greatest number will be brought about by the detention of such persons in special institutions will depend not a little on the ability of such detention to cure the tendency to drunkenness. At any rate, this classification of drunkenness with insanity will help to educate public opinion as to its real nature, a lesson which is needed still in both England and America, though perhaps more in the Old Country.

SPECIFIC TREATMENT FOR TUBERCULOSIS.

The New York County Medical Society, at its recent meeting, reported in our columns this week,

discussed the subject of adjuvants or auxiliaries to the climatic treatment of pulmonary consumption. It is evident that specialists in the treatment of this dread disease are still hopeful that some specific pharmacal or biologic remedy for the affection will certainly be discovered. The hope is shared very generally, by the younger specialists at least, in Europe. The present writer remembers distinctly with what assurance Professor Lesser of Berlin, about a year ago, in a clinic on lupus vulgaris, spoke of his confident expectation that a specific for tuberculosis quite as powerful against the lesions of that disease as is mercury against syphilitic processes exists and only awaits discovery.

The prospect is an alluring one and certain recent tendencies in microbiology rather confirm the hope of its fulfilment. Syphilis is now very generally considered a microbic disease and it is conceded that at least the major part of the action of mercury in the disease is due to its antiparasitic or bactericidal character. Against the syphilitic germ mercury has a selective action, and this specific growth-inhibiting or prohibiting action is not without analogies in modern microbiology. Nitrate of silver has a corresponding action upon cultures of aspergillus. This fungus will not grow if to the culture-medium is added scarcely more than the minutest trace of the silver-salt. A larger proportion than is necessary to produce this inhibition of even such strong drugs as the mercurial preparations are readily dissolved in the serum and tissue juices of the human organism without disturbing the economy, and are actually thus held in solution during the giving of a mercurial course of medication.

On the other hand there are those who claim that the action of mercury in syphilis is not specific because bactericidal but because it is a tissue stimulant of the first rank. From their standpoint it is questionable whether we should look with any confidence to the prospect of a specific medicament. Even during the last twenty-five years, while therapeutic observations have supposedly been gathered with more care and judgment than ever before in medical history, a series of new remedies for phthisis have been triumphantly introduced, quite generally used for a time, and then given up or allowed to sink into innocuous desuetude. Even the remedy at present so universally prescribed in America, creosote, has lost most of its popularity abroad. It is used very little in the foreign hospitals and clinics. Some time ago Eichhorst of Zürich, after a serious painstaking trial of it in his wards for more than two years, said that he could not persuade himself that he had ever seen any advantage accrue from its administration. In the last edition of his text-book, 1897, he recommends only ordinary tonic and stimulant treatment for tuberculosis.

The maxim, *primum non nocere*—be sure to do no harm—obtains very forcibly in the use of new drugs, and the slightest sign that a remedy is interfering with general nutrition by disturbing the appetite or the digestion, as is not infrequently the case with creosote, must be the signal for its withdrawal. Some of the newer remedies mentioned may prove, on further trial, to have specific virtues, meantime one thing is sure, that so long as they continue to bear the stamp of novelty the strong psychic element that enters into all novel therapy of tuberculosis will cause practically all cases primarily to improve under their administration. Due allowances must be made for the suggestive element. The local treatment of lesions whether tubercular or not of the nasopharynx and larynx, the endeavor to keep the digestive tract at its acme of healthfulness for nutritional purposes, respiratory exercises, and hydrotherapy, all these judiciously employed mollify the annoying symptoms, increase constitutional vigor, give tone to the general system, and encourage the hopefulness of the patient.

ECHOES AND NEWS.

Ambulances Sent to the Philippines.—Quartermaster-General Ludington has shipped to Manila fifty ambulances for use by the American troops.

A New Editor.—Dr. Emil Mayer of New York City has been appointed co-editor for America of the *International Centralblatt für Laryngologie und verwandte Wissenschaften*, of which Sir Felix Semon of London is editor-in-chief.

Laws as to "Faith Healers."—Commissioner William T. Jenkins of the New York City Health Board has conferred with counsel of the New York County Medical Society with a view to framing amendments to the law so that the faith-curists can be more promptly and successfully reached.

Tuberculosis Congress at Berlin.—The American delegate to the Tuberculosis Congress, Dr. Von Schweinitz

has arrived in Berlin. Baron Hoyl Zu Hoornhein, the National Liberal member of the Reichstag, donated on May 15th three million marks toward the tuberculosis asylum movement.

Professor Virchow on Disarmament.—Professor Virchow, who is not only an eminent physician, but who is also an intellectual leader of German liberalism, believes that disarmament will sooner or later be realized. He considers that the realization will come slowly, for the age we are now living in is little favorable to humane ideas, and public opinion is weak, almost decrepid.

The Penalty for Food Adulteration in France —Alphonse Karr's once famous epigram "I poison the grocer—guillotine; the grocer poisons me—ten francs" has been outgrown, according to *Food and Sanitation*, for, besides paying his ten francs, the grocer now has to post in two places in his shop large placards announcing the fact that he has been convicted of food adulteration. These interesting souvenirs are kept in place for many months.

The Utility of Gargling.—A German physician has made some experiments to determine the value of gargling. The velum, a portion of the tongue and the tonsils were dusted with wheat flour and a gargle in which iodin was mixed with glycerin was used by the patient. It was found after gargling that the velum and the tongue exhibited the blue color of the reaction on the starch, but the flour on the tonsils was neither colored nor washed away.

New Woman's Hospital.—The Woman's Hospital at Forty-ninth street and Lexington Avenue, New York City, is to be torn down and to be replaced by a six-story building of the French Renaissance style. It will be of granite and is designed to accommodate 200 patients. There will be five large wards. The operating-room will be the largest in New York. Six hundred thousand dollars will be expended on the building and more than a million upon its equipment.

The Spallanzani Centenary.—On May 15th in Reggio Emilia, Italy, the one hundredth anniversary of the death of Lazzaro Spallanzani was celebrated by a grand *festa*. Spallanzani was a strenuous opponent in his day of the theory of spontaneous generation, defending biogenesis against such men as Buffon. He was expert in the use of the microscope and was the first to demonstrate the phenomena of the circulation in warm-blooded animals. His researches on the egg of the chick called attention to the fact of how much there might be found of embryological importance in this simple, easily procurable material.

Sunshine and Rain in Europe.—According to a recent report issued by the French Bureau of Agriculture, at 78 Rue de Varennes, Paris, Spain and not Italy should have the adjective "sunny" placed before it. On the average, it is said, Spain enjoys about 3000 hours of sunshine a year, while Italy has 2300. France has almost as much sunshine as Italy, her figures being 2200. Germany has at her disposal no more than 1700 hours; while England, the land of fogs, has to get along with 1400, less than half of Spain's amount. The average fall of rain in England is, however, greater than that of any European country.

University of Michigan Medical Department.—The annual commencement of the University of Michigan will take place on June 22d. Besides the usual ante-commencement ceremonies, the medical department will have a special program for its friends and the alumni, an unusual number of whom have signified their intention of being on hand. All the laboratories will be open on the 19th, 20th, and 21st, demonstrations will be made on special subjects in anatomy, histology, pathological anatomy, pharmacology, bacteriology, and medical electricity, and clinics will be given in each clinical branch. These exercises will not interfere with those of the general program or with each other.

The American Electrotherapeutic Association.—The ninth annual meeting of this Association will be held in Washington, D.C., on September 19, 20, and 21, 1899, under the presidency of Dr. F. B. Bishop of Washington. Quite a number of papers of great scientific value have been promised and the Committee of Arrangements insures the members a very entertaining and pleasurable meeting. Aside from the sessions of the Association the Committee has completed arrangements for a trip to Mt. Vernon, one to Arlington, and several other social features. The headquarters of the Association will be at Willard's Hotel, where special rates will be given to members and their families during the meeting.

Increasing Duration of Life in Chicago.—The April Bulletin of the Chicago Board of Health makes the following startling announcement: "Measured by the average age at death of all who died in the City of Chicago thirty years ago and of those who died last year, the average duration of life in this city has more than doubled during a single generation. That is to say: In 1869 there were 6488 deaths recorded, with the age of each decedent given. The aggregate of the ages footed up 90,336 years, or an average of 13.9 years for every individual decedent, old and young. Last year there were 22,897 deaths similarly recorded, with an aggregate of 672,540 years of life, or an average age for each decedent of 29.4 years. This is an increase of 111.5 per cent.

Meat Extracts of Vile Origin.—The *Lancet* of April 22d comments upon revelations which have recently been made concerning the preparation of meat extracts from filthy material such as putrid livers and offal. Modern chemistry has unwittingly placed at the disposal of those who prepare meat extracts in this manner deodorizers and subtle flavoring materials which disguise the substances from which these extracts are made. The *Lancet* considers that a system of control should be established by the State so that extracts might from time to time be subjected to chemical and bacteriological examination. Possibly many cases of gastro-enteric disturbances, the etiology of which has not been discoverable, may have been due to the ptomains generated in such preparations.

The "Koch Lung Cure" Establishment.—President Murphy of the New York City Board of Health will investi-

gate the "Medical Council and Koch Lung Cure Establishment" at 48 West Twenty-second street. This concern advertises extensively in the German newspapers, professing to cure "catarrh, all pulmonary diseases, diseases of the eye and ear, diseases of women, tumors, and cancers." It has advertising offices in Chicago, Boston, and Philadelphia. Complaint has been made by a woman whose husband was dying of consumption that a bottle had been given this patient, which, the doctor told him, cost $9 in Germany, and which, upon analysis, was found to contain three minims of chloroform to two ounces of water, and to have a market value, including the bottle, of 9 cents.

The New York State Board of Charities —Inspector of Almshouses Henry D. Kerr, was detailed on May 15th by the State Board of Charities to act as deputy superintendent of State and alien poor in New York City and vicinity. The incorporation of the Society for the Relief of Incurable Cancer in New York City has been disapproved by the Board, the proposed incorporators not having shown to its satisfaction the desirability of the establishment of such an institution. Robert W. Hebbard the secretary of the board, has been authorized to represent the President, William Rhinelander Stewart, during the latter's absence in Europe, in the preliminary work of arranging, in conjunction with a representative of the Comptroller, for the classification of positions in the State charitable institutions and the grading of salaries of their officers and employees.

International Congress of Gynecology and Obstetrics.— The third International Congress will be held at Amsterdam, August 9, 1899. The leading questions for discussion will be the following: (1) The surgical treatment of fibromyoma. (2) The relative value of antisepsis and improved technic for the actual results in gynecological surgery. (3) The influence of posture on the form and dimensions of the pelvis. (4) The indications for Cæsarian section compared with that for symphysiotomy, craniotomy, and premature induction of labor. Doyen, Howard Kelly, and Shauta will open the discussion of the first question; Bumm, Richelot, and Lawson Tait the second; Bonnaire, Pinzani, and Walcher the third; Leopold, Pinard, Pestalozza, and Fancourt Barnes, the fourth. Dr. J. D. Emmet, 91 Madison Avenue, New York, is the secretary for America.

An Army Vaccine Farm.—General Guy V. Henry and the medical officers serving under him are to be praised for their very efficient work in Puerto Rico. They have stamped out a threatened epidemic of smallpox, and have rendered that disease almost a nullity upon the Island. The surgeons put into operation a vaccine farm, produced their own vaccine, divided up the island into five districts, established vaccination stations in every village and city of any size, and vaccinated practically every Puerto Rican —some 850,000 people in all. The vaccination was practically compulsory, for the order was that people who were not vaccinated could not enter any public conveyance or public place. The population generally took very kindly to the measure. The cattle-owners on the Island lent their cattle to the surgeons for the purpose of producing the virus required.

Society for the Abolition of Vivisection.—Some of the members of the Liverpool Antivivisection Society, considering that the English National Antivivisection Association is not radical enough in its aims or drastic enough in its program have formed a branch of the British Union for the Abolition of Vivisection. The first annual meeting of this branch has just been held and the chairman dilated at great length upon the peril to society that all and every part of the practice of vivisection had become. The speeches made by eminent men at the opening of Liverpool School of Tropical Diseases were referred to with disapproval and the Union's opposition to every form of experimentation on animals or to any arrangement between antivivisectors and experimentors, even in the matter of giving hospital charity loudly proclaimed. The Liverpool correspondent of the *British Medical Journal* says that now that this society has thrown off the mask, it would be as well if it would style itself the Society for the Abolition of Medical Education.

Cancer Hospital in New York City.—*A propos* of a recent newspaper discussion, the directors of the New York Skin and Cancer Hospital have issued a statement designed by them to correct a wrong impression regarding the purposes and work of their institution that may have been made by the recently published appeals for funds to establish and support a home for cancer incurables. They declare that admittance to their clinics or general wards is in no case conditional solely on ability to pay, nor is a patient ever discharged for mere inability to pay. The Skin and Cancer Hospital is a free institution for the treatment of cancer as well as skin diseases. By far the greater number of the patients pay little or nothing for their board. There are no facilities, however, for receiving sufferers from cancer who are presumably or demonstrably not susceptible of cure or betterment. It is their especial purpose to pursue the scientific study of cancer with a view to removing the present deadline of incurability. Inoperable cases are objects of relief and study, and constitute a large number among the absolutely free patients. The hospital would cheerfully undertake the supplemental work of providing wards for incurable patients did their finances justify it in so doing. The directors point out that their institution is the proper organization through which to extend comfort to hopeless cases.

Obituary.—Dr. William H. McEnroe of 145 West Eighty-second street, New York, died suddenly at his home May 17th, of acute indigestion. He also suffered from heart trouble. Dr. McEnroe was apparently in good health, and before retiring at midnight ate luncheon. Shortly before 2 o'clock he became suddenly ill and died before medical aid could reach him. —Dr. Joseph W. Stickler of Orange, N. J., a leading lung specialist, died suddenly May 18th at the Fifth Avenue Hotel, New York, of heart disease. He was born in 1854 in Hoboken, and went to Orange in 1858.

He was graduated from the College of Physicians and Surgeons in 1879. Dr. Stickler took the only prize ever given by the New Jersey State Medical Society for the writing of an essay, the subject of which was "The Climatology and Diseases of Essex County." He was President of the Young Men's Christian Association of Orange for two years, and a member of a number of medical societies in New Jersey and New York. He leaves a wife and one child.—The body of Dr. Robert Storer Tracy, who had been missing since the night of April 1st, has been found in the Saranac River. He had incipient phthisis, and was an inmate of Dr. Trudeau's sanatorium in the Adirondacks. Dr. Tracy was a son of J. Evarts Tracy, Esq., of the law firm of Evarts, Choate & Beaman. He was twenty-seven years old, a graduate of Yale and of the College of Physicians and Surgeons of New York City, and had been an interne in the New York Hospital and in the Sloane Maternity Hospital.

English Tribute to Major-General Leonard Wood, M D.—In the MEDICAL NEWS of April 15th our London correspondent said that, now that the Sirdar has gone back, General Wood is decidedly the popular hero in England. A striking confirmation of this bit of news and of the opinion that General Wood's magnificent official success in other spheres was especially due to his medical training is afforded by an article in the succeeding week's number of the *British Medical Journal*. "The career," the writer says, "of Major-General Wood, the United States Volunteer Military Governor of the Province of Santiago de Cuba, is one of interest to members of the medical profession, as he is a conspicuous example of the special fitness for organizing an administrative work under new conditions which seems to be developed in a remarkable manner by medical training. * * * Perhaps more than any other man who played a prominent part in the war between Spain and the United States, General Wood has impressed his individuality on the minds of his countrymen as a strong man who can be trusted to do effectively whatever work may come in his way, whether it be treating a colic or governing a conquered province." The same authority characterizes his work at Santiago after the war was over in the words of a correspondent of *McClure's Magazine* as "the *tour de force* of a man of genius, for in the harder, more fundamental tasks that confronted him here General Wood had had no previous experience." This thorough-going appreciation of the work of our American medical hero cannot but be cordially welcome to members of the profession in this country.

Medical Department at Manila.—Surgeon-General Sternberg made public on May 13th a report by Major Henry Lippincott, Chief Surgeon at Manila, of the operations of the Medical Department in the Philippines, from February 4th to March 31st. With the former date began a prolonged series of engagements with the Filipinos, and from that time to March 31st, 182 United States soldiers were killed or died from wounds received in action. The number of wounded during this period not included in this number was 847. It is noted that "the effect of the firing was marvelous on the sick," many men who were hardly considered well enough for duty, leaving the hospital for the firing line. The medical staff were prepared for all emergencies. The first-aid packages proved of the greatest possible value. "Litters, pouches, and medical and surgical chests were in readiness, easily prepared articles of food, stimulants, and water were on hand, and the ambulance company did excellent service." The signal corps, by putting the hospitals in communication with the troops at the front, made it possible to send supplies at a moment's notice. The hospitals were supplied with an abundance of everything essential, "which was simply astonishing when the great distance from the United States was taken into consideration." The Corregidor Hospital, which is used for convalescents, has been of great benefit. Cases of typhoid and malaria have done well there, but patients suffering from dysentery and diarrhea, though improved, have rarely been cured. Rheumatism is obstinate in the climate of the Philippines. The total number of cases of smallpox up to March 31st was 151; deaths 77. There were 85 cases of varioloid with no deaths. There is "every reason to hope for a cessation of smallpox." The food-supply has been good. Two hundred and fifty-six wounded Filipinos, among whom were four women, were received into the hospital up to March 31st. Of these forty-five, including one woman, died. "These people receive the best of care and treatment and seem to appreciate the efforts made in their behalf." Among the Filipino wounded suppuration is the rule, whereas, among our soldiers it is the exception. Many causes account for the condition in the former, the chief being infection before coming into the hands of our surgeons. They have, moreover, an inordinate propensity to tear off dressings and finger their wounds when opportunity offers."

CORRESPONDENCE.

THE PURSE-STRING METHOD FOR TONSILLAR HEMORRHAGE.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your issue of May 20, 1899, page 619, my friend. Dr. Dawbarn, makes a passing criticism of mine (the matter has never even been alluded to in my lectures) the basis for an interesting exposition of his method of arresting obstinate tonsillar hemorrhage by means of a purse-string suture.

My first thought when reading the article was, Has the doctor ever seen a case of urgent, profuse, tonsillar hemorrhage?—probably, but it certainly was not the one that he describes, the only case, be it here said, in which he has practically demonstrated the application of his method for arresting hemorrhage.

A patient who *can* be anesthetized, deliberately placed in a recumbent position, with the bleeding tonsil uppermost, so that the blood obligingly and conveniently runs away by gravity from the surface that the operator wishes to see while he four times introduces, in a locality rather difficult of access, the needle, which places the constrict-

ing "purse-string" about the stump, is *not* a case of severe, profuse, tonsillar hemorrhage, such as I had in mind when I said, and now repeat, that I believe the "purse-string" method which certainly requires toleration, time, and deliberation, is impracticable, even impossible, of accomplishment in urgent cases.

Some years since I amputated with the bistoury a tough, hard, hypertrophied tonsil in an adult (the doctor is right in saying that these are the ugliest cases of bleeding--I add, *if* they do bleed, which is not certain). Immediately there was a profuse gush of blood—so rapid was its flow, so great its quantity, that the patient's fauces, pharynx, and mouth, quickly filled and refilled; the blood ran freely into his larynx and trachea, causing violent cough, which spattered blood widely, and dyspnea of such distressing grade that the strangling, half-suffocated and altogether frantic man fought me off wildly, and rushed about the room, gasping for breath, while throwing out mouthfuls of blood and more than once vomiting it in quantities.

To seize him by the hair, force him downward into a chair, shout for assistance to my dispensary collegues, crowd open his mouth, despite his struggles, compress the tonsillar wound "between the forefinger on the stump and the thumb outside" and thus control the situation, was the work of but a few rapid, exciting moments. In a short time he became faint, fainted, and the bleeding, as is so often the case, then ceased, not to recur. Was this an instance where the "purse-string" method could have been adopted?

There are other cases, instances of moderate hemorrhage, so called "obstinate" cases, in which, from the nature of the wound alone, its location, its depth, and other complicating circumstances, I believe that a purse string suture would be useless in controlling the bleeding even if it could be applied, which I doubt in such cases; also I have found simpler measures than the "surgical suggestion" of Dr. Dawbarn (see description, page 620) to usually answer the purpose, quickly and efficiently.

Unfortunately for all, patient and physician, the bleeding tonsillar-stump is not always as conveniently and favorably shaped and located and as easily reached as in the diagrammatic sketch accompanying the article. The operation upon paper is ideal.

Yours truly,

GEORGE M. LEFFERTS, M.D.

212 MADISON AVENUE, NEW YORK,

OUR LONDON LETTER.

[From Our Special Correspondent.]

COLONY FOR EPILEPTICS AT MANCHESTER—MILK FROM A SEWAGE-FARM—OPENING EXERCISES AT THE LONDON POLYCLINIC—REPLACING THE END OF A NOSE—AGAIN THE CANCER PARASITE—TAXATION OF THE COLLEGE OF SURGEON'S LIBRARY—ANGLO-AMERICAN HOSPITAL IN ROME.

LONDON, May 13, 1899.

THE example set by America in the Craig and Gallipolis colonies for epileptics has by no means been lost over here. The method had long been advocated upon theoretic grounds, and just recently the local authorities of Manchester decided to establish a colony and purchased an admirably situated farm for the purpose. Now, however, comes the discouraging news that the municipal council of the neighboring city of Liverpool has blocked the whole scheme by objecting to such use of the ground chosen, on the plea that it will result in the contamination of their water-supply. Of course, if an interest of such vital and paramount importance is really involved the colony must at once seek another site, but it is a little difficult to see why the colony would be worse in this regard than any other farm now on the watershed, and also why such a serious infringement of Liverpool's plain rights could not have been noticed and protested against before the land was actually purchased by a public body. Indeed, when it is remembered that the feeling between the two cities is even livelier than that between Chicago and St. Louis, or Buffalo and Cleveland, one cannot suppress a half suspicion that personal jealousies may have something to do with this apparent hygienic sensitiveness.

Another local sanitary war which is attracting a good deal of attention, is raging near Aldershot. The sewage from the great military camp of instruction there is pumped upon a sewage-farm of the most approved modern type, which bears such enormous crops of ryegrass that there is difficulty in finding a market for it. To utilize this surplus product a dairy which should supply the camp with milk was established, but when this applied to the local Urban Council for a milk-permit, as required by law, that sapient body refused it on the ground that milk from grass grown on sewage-farms could not be healthy. This wise pronouncement, however, was found to have been inspired by the local dairymen, who have been driving a large and profitable trade with the camp, and who have now succeeded in actually getting the trumpery charge before Parliament and a solemn commission appointed to investigate their ridiculous claim. Sewage that has been split up and digested three times, first by the soil-bacteria, then by the grass, and finally by the cow, passed through three stomachs in fact, is about as dangerous as a homeopathic dilution of the thousandth potency.

The Prince of Wales has appointed as delegates to the Berlin Congress for the Prevention of Tuberculosis, Sir Herman Weber, Malcolm Morris, Alfred Hillier, and C. Rube.

The London Polyclinic was formally opened with a *conversazione*, on Monday evening, May 1st. The clinical lecture-rooms, library, reading-room, and laboratories were open for inspection, with a large display of pathological specimens, drawings and photographs, and were well filled with visitors all the evening. The clinical demonstrations three times a week have already begun, as have the formal lectures and practical courses. All members of the profession visiting London are cordially welcomed at the clinical demonstrations and to the use of the Information Bureau.

The successful conclusion of a rather unusual piece of surgery has just been demonstrated by the most conclusive of proofs, a photograph of the face of a man, the tip

of whose nose had been replaced and sutured after complete separation. The case was reported a couple of months ago in the *Lancet* by Dr. Abbot Anderson. The patient had been his own executioner by the famous "whittling-toward-yourself" stroke of his own knife, against which all good little boys are warned. Dr. Anderson fortunately arrived promptly, picked up the *disjectum membrum* and carefully adjusted and sutured it, with the result that the photograph shows an apparently perfect nose, upon which the line of union can scarcely be made out.

And again the cancer parasite is to the fore. Dr. William Russell appears in the *Lancet* with a triumphant "I told you so," to the effect that the "fuchsin bodies," discovered and described by him in cancerous growths several years ago are identical with the organisms of Plimmer, and were originally regarded by him as yeasts, but in deference to the then prevailing opinion were described as sporozoa. What makes this naïve confession of unreliability the more amusing is that Plimmer himself has made the same *volte face* in the opposite direction, inasmuch as several of his plates are actually reproduced from a former paper, in which the organisms are described as protozoa (animals), under the frankly confessed influence of Metschnikoff, while he now regards them as saccharomycetes, under the influence of San Felice. It would really seem as if the final arbiter of questions medical, the level-headed, all round, family-physician, was justified in looking askance at reported discoveries of the cancer parasite, until its enthusiastic champions can agree not merely among themselves but *with* themselves for three years in succession whether it is a vegetable or an animal, and publish demonstrations free from such distressingly obvious taints of suggestion and expectation.

The appeal of the Royal College of Surgeons for relief from taxation on their magnificent museum and library on the ground, of course, that they are purely scientific collections, neither for profit nor for personal advantage, has been decided in a curious manner. The court held after careful deliberation that the museum was entitled to such exemption, but that the library, being for the personal advantage of the members, was not. A beautiful illustration of legal hair-splitting, for when it is remembered that under the legal requirements of a double qualification for practice, nearly two-thirds of the entire English profession are members of the college, the library becomes as public an institution as can well be found, to say nothing of the generous and courteous way in which it is placed at the service of visiting members of the profession from every part of the habitable globe.

The London medical press comments most favorably on the vigorous methods used in dealing with the smallpox-scare at Laredo, Texas. They are particularly impressed by the use of regular troops, and warn the anti-vaccinationists against dependence upon "democracy" for relief from compulsion, as a democracy in which a majority of the people are in favor of protecting the community in this way is likely to have even less scruple in enforcing its decisions for its own good than an absolute monarchy.

It is proposed to establish an Anglo-American hospital in Rome and an organization, of which the British Ambassador, Sir George Bonham is president, has been formed for that purpose. Its object is simply to provide a place where visitors of both nations falling ill in Rome, that hot-bed of disease, can obtain skilled nursing and the best of care. There is great need for such an institution, as the only resource at present is the convents, and the nuns, though kind and hospitable, are but little versed in modern methods of nursing, and rather resent any suggestions or trained assistance from without. Some $3000 has been raised already, but it is anticipated that its support will require about $1000 a year.

Not merely every dog has its day, but every insect as well, apparently. The despised and hated mosquito is in high honor just at present, and experts are hard at work devising foods upon which it may be kept alive. The most successful appear to be bananas and a mixture of equal parts of brown sugar and sherry. Which would appear to indicate that the mosquito's life though short is a merry one.

German.

ON THE DEVELOPMENT OF MILIARY TUBERCULOSIS—ACCIDENTS FOLLOWING THE DEEP INJECTION OF CORROSIVE SUBLIMATE—THE DECREASED MORTALITY IN HAMBURG FROM TUBERCULOSIS, AND SOME NEW INSTITUTIONS WHICH HAVE BEEN OPENED FOR THE TREATMENT OF INCIPIENT CASES.

AT the meeting of the Berlin Medical Society, March 15th, BENDA read a report of original investigations into the spread of miliary tuberculosis, taking the ground that the rupture of a tubercle into a blood-vessel is the immediate occasion of such a dissemination. He asserted that he had observed three cases of ulcerative endocarditis which he would have passed unnoticed had he not been making this special investigation, and intimated that there are doubtless many others of a similar character which have not been noted. He also described in support of his theory the progress of tubercular ulcers of the stomach as observed by means of the gastroscope.

The paper was the subject of a sharp criticism by Virchow. He said that he had never seen a single case of ulcerative tuberculosis of the endocardium, and that while he was ready to admit that he might have overlooked some cases he thought it impossible that they had been relatively frequent since he had never found one. He also expressed his disapproval of the habit into which many of the younger men have fallen of speaking of what they have seen through the gastroscope and similar instruments in exactly the manner that they would do had the surfaces been spread out before them. Every one is entitled to his own opinion of the value of such examinations, but it is certainly inadvisable to let them stand in the balance over against the observations of an organ after death, for instance.

At a recent meeting of the Charité physicians, LESSER reported three cases of extensive swelling and gangrene which followed the injection of from 15 to 30 drops of a

1-per-cent. solution of corrosive sublimate. The patients were all under treatment for syphilis, and had shown that they were not especially susceptible to mercury, or to this method of its administration, since they had received many doses without accident. Suddenly there developed an enormous hematoma, followed in all three patients by gangrene so extensive that repair was not complete for several months. This accident in his opinion was not due to puncture of a vein, as the needle was always allowed to remain open for a moment before adjusting the syringe for injection to see if any blood came from it. Furthermore a vein could scarcely pour out so much blood in so short a time. An artery was probably traversed by the needle, its eye passing clear though both walls, so that no blood could escape until the needle was withdrawn. While this was a rare accident it showed the risk that there is in deep injections, of whatever character. This risk can be greatly lessened by making the injections into the subcutaneous fat; it is to avoid the pain which often follows such injections that the needle is thrust into the muscles. All of the three patients were women.

At the Medical Union of Hamburg, March 21st, REINCKE showed that the mortality from tuberculosis in that city has fallen greatly since 1884. This improvement he ascribed to improved hygienic surroundings, better food, better dwellings, etc. He warned against a relaxation of effort on the part of the medical profession, as the aim ought to be, not merely to increase the resisting power of the well individual, but to cure every sick person or at least to treat him so that he shall not infect others. To obtain these results it is desirable that tuberculous patients shall be treated in institutions especially provided for them.

DEUCKE and RUMPEL described an institution of this character which has recently been opened near Hamburg. It was built by private capital on condition that the city conduct it for a period of years. It lies 200 feet above the Elbe, and has its own grounds, including a grove. One hundred patients can be accommodated. The usual charge is fifty cents a day, or less. It is especially intended for incipient cases in which the diagnosis is based upon a sputum examination, while physical signs are absent. The effect of treatment upon a patient at this stage presumably in the first attack, gives a valuable indication of the course the disease is likely to pursue in future attacks. Patients with fever, early hemoptysis, laryngitis and pleurisy, will not be treated in this institution.

RITTER described a simular institution which has been opened in Geesthacht, also for incipient and presumably curable cases. The period of cure is three months, and at its end, a free journey is to be given to poor convalescents.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Monday, April 24, 1899.

THE President, DR. S. O. VANDERPOEL, in the Chair.

The first paper of the evening, by DR. J. E. STUBBERT of Liberty, Sullivan County, N. Y., was entitled

SOME AUXILIARIES TO THE CLIMATIC TREATMENT OF PHTHISIS.

Dr. Stubbert said that we have about given up thinking that there are specifics for pulmonary tuberculosis. Creosote, which was the last remedy lauded in this respect, has proved to be a good cough medicine but scarcely more. As the result of the giving up of faith in drugs has come a misplaced confidence in climate alone with a resolve to keep away from doctors, but this is an error in the opposite direction since medical treatment can do a great deal. Climate alone will benefit incipient cases, but comparatively few incipient cases come for treatment.

Especially is treatment important for the complications of tuberculosis. Of the cases treated at Liberty more than 400 have had complications. The majority of these have been in the throat, nose, and pharynx. The chronic congestion induced by these irritative conditions can scarcely fail to react unfavorably upon the tubercular process in the lung. When promptly and persistently treated, too, these lesions may be arrested before ulceration has taken place. It is a conservative estimate to say that twenty-five per cent. of consumptives have some laryngeal tuberculosis while a large number have lesions in the pharynx or nose. For these conditions local treatment is indispensable. Albolene sprays should be employed, or Dobell's solution with occasional applications of lactic acid or of nitrate of silver. Tags of hypertrophic tissue give way to applications of suprarenal capsules.

For the successful local treatment of these tuberculous conditions in the nose and throat time and patience are necessary. In the larynx especially is improvement slow. In a recent case Dr. Stubbert had under his care, in which there was loss of voice, steady treatment was kept up for over eight months and improvement, especially at the beginning, was very tardy, but the patient is now practically well and has completely recovered her voice.

Anemia is a very common complication of tuberculosis, especially in the incipient stage. For this the stimulant effect of high altitudes upon the blood-making organs, and the constitutional effect of plenty of fresh air are the best remedies. At Liberty static electricity has given excellent results in anemia, better than any other single method of treatment. There is marked improvement usually manifested under its use, especially in cases complicated by neurotic conditions. An hour in the ozone-room and contact with the negative electrode, or a séance on an insulated stool always favorably affects such cases.

The ideal diet for tuberculous patients is to have them take three substantial meals a day. Gastro-intestinal disturbance not infrequently prevents this. It is probable that chronic gastritis with dilatation of the stomach is sometimes an etiological factor in the production of the lowered state of resistive vitality that has permitted the successful implantation of the tubercle bacillus. These conditions should be treated by accepted methods and Dr. Stubbert has found lavage and Einhorn's intraventricular electrode of special service. When tuberculous

patients suffer from biliousness a cathartic dose of calomel will be of service.

Dr. Stubbert has made a very satisfactory trial at Liberty of the antitubercle serum manufactured by the United States Government and has been pleased with the results obtained. It is of good service, especially in incipient cases, but seems to be contraindicated in advanced cases. It is better than creosote and a certain immunity to the disease seems to be established in patients who recover under its use, so that despite the fact that they go back to live under unfavorable circumstances relapses do not occur. Antistreptococcic serum seems to be indicated in certain cases, though they are not numerous and are mainly such as high altitude affects favorably by stopping the ravages of mixed infection.

A remedy that has given excellent results in Dr. Stubbert's hands is ichthyol in large doses—doses so large that they pass through the stomach practically unchanged. Thirty grains three times a day is given unless diarrhea or vomiting intervenes or the persistent taste of ichthyol in the mouth takes away the appetite. There is a marked gain in weight under this treatment and a general feeling of improvement. The sputum soon grows less and changes in color from green to yellow. From fetid and purulent the expectoration becomes mucous and frothy, and the pyogenic membrane becomes mucus-secreting once more. A cessation of the remedy too soon, *i. e.*, before certain changes have taken place in the lungs leads to a return of the old characters of the sputum. Of fifty-one patients treated by ichthyol 14 per cent. were cured, 55 per cent. improved, 19 per cent. were unimproved, and 12 per cent. died.

Another drug that has given good satisfaction is kolagra. Results with it were comparable to those obtained with ichthyol. The drug has been introduced from South America, where the native Indians had learned its virtues in pulmonary tuberculosis and had taken advantage of them. The Indians noticed long ago that cattle suffering from consumption, when allowed to wander off because no longer considered worth the caring for, often returned after some time, sleek and fat and entirely cured. It was noted that they ate this plant especially, so the hint was taken. It is antiseptic in its action, and under its use Dr. Stubbert has seen tubercular infiltration of the larynx disappear. It is given in doses of ½ to 1 c.c. The subjective symptoms very soon improve and the bacilli become less. For its prompt effect in changing the character of the sputum to a mucous, frothy secretion instead of a greenish purulent liquid it deserves to rank with ichthyol and creosote.

In discussion Dr. E. Le Fevre said that in the matter of treatment a sharp distinction should be drawn, especially between the two most usual forms of reaction of the organism affected by the tubercle bacillus. In one class of cases there is a connective-tissue overgrowth and very little destruction of tissue. The organism protects itself by encapsulating the bacilli. In a second class there is marked destruction of tissue, and the organism tries to eliminate in the material thrown off the invading micro-organism.

There is a hopeful field in medical treatment without climate and one of the important elements of it is attention to the auxiliaries mentioned by Dr. Stubbert. Especially is attention to the upper air passages necessary. Inflammatory conditions here set up pulmonary reflexes which lessen respiratory movement. There is imperfect inspiration that fails to fill the edges of the lungs, and a lagging respiration that predisposes to the invasion of the tubercle bacillus.

Dr. S. A. Knopf said that respiratory exercises increase the vital capacity of the lungs and act as a general stimulant. The number of blood-corpuscles increase and the oxygenation of the system is greatly facilitated. Lung exercises might be used every hour according to the patient's condition and are a most helpful remedy. Hydrotherapy is also of great value. A douche on the apices serves as a precious stimulant to metabolism here, which aids in the cure of diseased processes. The general spray is a good systemic stimulant and when a spray is directed frequently to points where old pleuritic adhesions exist the tendency to painful uneasiness at these points decreases and the adhesions gradually loosen, permitting freer play of the lungs.

As to serum he thought that while it may have a value in the treatment of tuberculosis, that value is not yet sufficiently determined to enable us to make any public announcement as to its effect.

In conclusion, Dr. Stubbert said that he is not an advocate of kolagra or of ichthyol or of the serum treatment, but that he is an advocate of a fair trial of remedies that come to us highly recommended by others. Our remedies for tuberculosis up to this are so ineffective that this open state of mind is the only rationally defensible one. Kolagra has come to us authenticated by the President of the United States of Columbia, and good results seem certainly to follow its use. The serum is supplied by our own Government and theoretically, at least, would seem to be indicated. Personally he has not seen relapses after its use and knows of none. He is not an advocate of particular new remedies but of judicious investigation of the good they may do.

The second paper of the evening was read by Dr. W. M. Leszynsky and was entitled

SOME OF THE ESSENTIAL FEATURES IN THE DIAGNOSIS AND TREATMENT OF SO-CALLED IDIOPATHIC EPILEPSY.

He said in brief: Epilepsy occurring without any recognizable cause in the skull or its contents is not a very uncommon condition. It is absolutely unamenable to surgical treatment and we have to depend on the medical management of the case. In dispensary practice with homes in tenement-houses it is extremely difficult to make any treatment successful. For such patients the best thing is living in a colony for epileptics. Craig Colony is already doing excellent work in this line, but already they are pressed for room and applicants must wait their turn. The institution eminently deserves the State aid it asks and the profession and the County Medical Society in particular should use their influence to obtain it.

The diagnosis of epilepsy is not difficult if an attack is

seen. The descriptions of non-medical friends are, however, very unsatisfactory, and very little reliance can be placed on the patient's own account of his seizures. Uremic attacks have caused mistakes, but should not if the heart and urine are carefully examined. A good deal of stress is laid on the differentiation of hysteria and epilepsy, but it must not be forgotten that hysterical symptoms may complicate genuine attacks of epilepsy, and that attacks of both may alternate for some time.

Sometimes the attacks may be so slight as to attract not very much attention even from the patient himself, or may occur during sleep and so remain latent for a long time. An actor who finally had to give up his profession because of frequently recurring attacks of petit mal, in which he forgot his lines and part and talked gibberish for a few minutes, proved on careful inquiry to have been having a series of attacks of grand mal at night for years which had remained unrecognized.

One of the fruitful sources of nervous reflexes that should always be carefully attended to in epileptic patients is the eyes. Suitable glasses should always be fitted whenever there is any error of refraction. For a time exaggerated claims were made for the curative effect of the correction of errors in ocular muscle balance, but these claims have not been substantiated. Correct the refractive errors rather than the muscular anomalies. The removal of uterine appendages in women was tried in some cases for epilepsy years ago, but the proceeding has now no supporters. Intestinal auto-intoxication undoubtedly plays a rôle in increasing the number and severity of epileptic seizures. Epileptics are habitually bolters of their food, and digestive disturbances are almost the rule. Dr. Herter has shown that intestinal toxins are excreted in the urine in greater abundance just before an attack showing there are more of them in the system. The acute infectious fevers often make the epileptic condition worse, and so do traumatic or surgical infections.

The first rule is to improve the general condition. That bromid is necessary whenever epileptic attacks occur is a mistake. If there are but three attacks a year, for instance, it is extremely inadvisable to keep the patients under the constant use of the bromid. Rather seek out the immediate cause or occasion of the attacks, and if possible influence that. Give the smallest dose of bromid that will keep the attacks under control. Arsenic may be added to prevent the occurrence of acne, and care of the skin will do much to keep off cutaneous reactions to the drug. Sudden withdrawal of the bromids after they have been taken for some time in any amount should be advised against as it has been known to produce the status epilepticus.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-fourth Annual Meeting, Held at Philadelphia, Pa., May 23, 24, and 25, 1899.

FIRST DAY—MAY 23D.

DR. DUER of Philadelphia, in a few well-chosen remarks, bid welcome to Philadelphia to the members and guests of the Gynecological Society, which has been the American parent of all advances in this branch of medicine and whose proceedings have had direct effect on the welfare of the women of every land. It has the approval of the whole world and has been the court of last resort for all mooted questions, setting the seal of approval or disapproval on all papers read before it. It is the sponsor of modern gynecology and many things that were a question on its foundation are not a question now. It was the earnest wish of all that this meeting should equal its predecessors in the brilliancy of its papers and discussions, and on behalf of the medical men of Philadelphia he extended a most cordial welcome to all,

DR. HUNTER ROBB of Cleveland read a paper, entitled "Sixty-five Consecutive Abdominal Sections without a Death; with Clinical and Pathological Reports," and said: Perhaps more can be learned from our failures than from any number of successes, but still much can be learned from success and from a careful macroscopic and microscopic study of the sections removed. There are three most important factors of success: (1) Careful operative technic. (2) Preparation of the patient. (3) Operative skill.

There should be a thorough organization of the staff that is to assist at the operation, each assistant thoroughly understanding his or her particular duties, and all should work together harmoniously. The first assistant should assist the operator directly, the second having charge of the instruments and handing them to the operator or first assistant as needed. The third assistant takes charge of the dressings, and makes any cultures or cover-slip preparations that are desired. The fourth assistant devotes all his attention to the giving of the anesthetic, while the nurses watch and are ready to be of service when called upon. Of course the most thorough asepsis of dressings, instruments, pads, the field of operation, and the operator and his assistants' hands is carried out in the usual manner.

The patient should be under observation for several days previous to the operation, and a thorough study of the excretions should be made. A careful physical examination should also be made, and the blood before and after the operation carefully studied. The patient's general condition should be improved as much as possible before the operation. Rubber gloves, sleeves, and skull caps, should be used by the operator and his assistants during all operations, for by their use the danger of infection is materially lessened. The sponges are best made of pads of gauze, thoroughly sterilized, which is a much easier proceeding in this case than when sea sponges are used. About 500 c.c. of hot sterilized normal salt solution should be used to flush out the abdominal cavity at the conclusion of the operation, and then about 500 c.c. or less should be allowed to remain in the cavity. When drainage is necessary it is best accomplished by means of a gauze drain.

The patient after the operation should be put to bed in the postural position, as in that position drainage is best obtained. Shock should be combated by hypodermic injections of strychnin and enematas of hot coffee. If thirst be extreme the patient may be given a few sips of

hot water, or this failing, an enemata of hot water should be administered. No morphin should be given unless there be a special indication for its use. The bowels should be opened on the second day by a moderate dose of calomel followed in two hours by an enema of glycerin and soapsuds. Unless the patient pass her urine voluntarily she should be catheterized every eight or ten hours. The postural position should be maintained at least for the first ten hours but should there be much pain or restlessness, the patient may be moved on her side for ten minutes and then the postural position be resumed. Should the tympanitis be extreme, a rectal tube should be passed, this failing, an enema of turpentine, sweet oil, and water should be administered. Turpentine stupes should also be given a fair trial.

The clinical and pathological report of sixty-five sections may be condensed as follows: The oldest patient was aged fifty-seven years, the youngest seventeen, and the average thirty-one years. Fifty-three were married, 16 were single, while 6 were widowed. The chief clinical symptoms were pain in the lower part of the back in 54 cases, backache in 30, dysmenorrhea in 40, and leucorrhea in 19 cases. In 2 of the latter it was of specific origin. There was menorrhagia in 19 cases and metrorrhagia in 1 case. Frequent and painful micturition was present in 6 cases, and irregular menstruation in 19 cases, being scanty in 2 cases. An organic lesion of the heart was present in 3 cases. Dyspareunia was present in 1 case.

The longest time of anesthesia was three hours and fifteen minutes, the shortest time was one hour and twenty minutes, the average time being two hours and nine minutes. The longest operation occupied two hours and fifty minutes, the shortest thirty-nine minutes, while the average time was one hour and thirty-eight minutes. In every case the abdominal cavity was thoroughly irrigated with a hot normal salt solution. In only one case was drainage necessary, and then a strip of sterile gauze was used.

Dr. Charles P. Noble of Philadelphia opened the discussion by saying that the technic used by Dr. Robb was the same as that generally used throughout this country. The postural position after filling the abdomen with hot salt solution, is an admirable addition to our means of treatment, and is especially valuable in pus cases. In a very large private and hospital experience no bad results have followed. The glass drain has now been given up as a routine procedure, most cases requiring no drainage at all, still it is a great question whether gauze is a better drain than the old-fashioned glass tube. The only use for the gauze drain is when injury to the bowel or gall-bladder has occurred, or when there is extensive hemorrhage. He is opposed to the teaching that gauze is the very best drain. It would seem that often it acts as a dam, preventing the discharge of serum, etc., which would otherwise have taken place. There seems to be no objection to the use of opium in these cases. His patients are given half a grain hypodermatically of phosphate of codein *ad libitum*. In not one case has any bad result followed its exhibition.

Eternal vigilance should be the watchword in these cases, and they cannot be watched too closely. Sponges would seem to be better than gauze pads. They are cheaper, and by their use it is much easier to thoroughly dry the field of operation. In every way they would seem to be more satisfactory. The rubber gloves are more useful when the hands of the operator have been in contact with suspicious cases, but they should be used always, for the operator never knows when his hands are not surgically clean, and after a little practice one can operate quite as well with them on as off, except that it is more difficult to handle and manipulate intestines when they are used.

Dr. J. Montgomery Baldy of Philadelphia said that there was a time when he never used morphin in these cases, but now he uses it whenever the patient is restless during the night after the operation. The good that has followed its use at this time cannot be overestimated. The bowels, as a rule, are not opened before twenty-four hours after the operation and by that time the effects of the morphin will have entirely passed away. Gauze is most valuable to drain serum, but it will not drain blood and at the best it is absolutely uncertain. With a gauze drain it is absolutely impossible to see an intra-abdominal hemorrhage, while if a glass tube be used the presence of the blood is manifested at once. The use of normal salt solution in these cases is by no means of recent origin and is most valuable in nearly all cases. There is nothing better for absorption than the thorough use of the sterile sea-sponge. They are dangerous if not properly prepared, but if they be thoroughly washed and then sterilized they are much better than the gauze pad. The rubber glove does not seem to be so useful for the reason that it spoils the tactile sense. It should only be used in cases of absolute necessity; that is, after the operator has been with a badly infected case and then has to operate on a clean one.

Dr. J. E. Janvrin of New York said that hot saline solutions were used thirty years ago by Dr. Peaslee and that the credit for being the first to use them should go to this American surgeon.

Dr. A. P. Dudley of New York said that to his mind it is a great question as to whether or not gauze is a true drain, and it would seem that it is not, as it will not act as a true drain through an abdominal incision. On the other hand, it is a most excellent drain when it is used by way of the vagina. The gauze should be left in place for five days because during the first few days it clings closely to the peritoneum and intestines and should not be drawn out while still held in this fibrin attachment. It is not possible to drain up hill which is what one does when an attempt is made to drain through an abdominal incision by a piece of gauze. It is most valuable in drainage by the vagina, allowing no air to enter the abdominal cavity, as often happens when the rubber drainage-tube is used.

Dr. Wathen of Louisville said that he generally operated though Douglas' cul-de-sac in preference to the suprapubic route. He finds it possible to remove everything by this route, and has not had a single death, and

every patient made an uninterrupted recovery. He generally employs gauze for drainage and finds it answers its purpose perfectly, especially so when the gauze is encased in a gum tube. In the majority of cases there is no need for a laparotomy, as everything can be removed per vaginam. The drainage is better, the time of operation is shorter, the danger of tearing the bowel is less, and the patients make a better and quicker recovery. In no case is there any indication for the use of rubber gloves as by the ordinary methods the hands can be made perfectly aseptic.

DR. LAPTHORN SMITH of Montreal said that he uses opium in every case in which there is restlessness during the first night after operation. The use of salt solution is a most valuable adjunct, and in three or four cases life has been saved by its use. It is especially valuable in those cases in which large tumors have been removed. In most cases drainage is not necessary after laparotomy, but if there is a direct indication for its employment it should be done per vaginam. When gauze had been used as a drain through the abdominal incision in three pus cases it was found to be useless, as in a very short time it not only did not drain, but dammed back fluids which otherwise would have made their escape. There is strong evidence in favor of the use of a rubber drainage-tube through Douglas' cul-de-sac, packing the vagina around the end of the tube with sterile absorbent gauze.

DR. BOUVE stated that he considered normal salt solution to be of distinct advantage in these cases. The preoperative treatment is a great drain upon the patients, the light diet and purgation causing the loss of much fluid, so that loss is made up by the salt solution, which also tends to relieve thirst, which is often the most distressing symptom after operation. The rubber gloves are a most valuable addition and help to the surgeon, as it is nearly impossible to make the hands absolutely sterile, and then to keep them so during the operation. They are made of the only material that is absolutely impermeable, and they should be used in every operation.

DR. J. RIDDLE GOFFE of New York said that he thought the after-treatment of these cases was most important, and that they cannot be watched too closely. It is most important that the patient be kept as comfortable as possible. She should be placed in any position agreeable to her just as soon as she is out of her anesthetic. If she becomes restless in any one position she should be changed at once, and if necessary, a hypodermic of morphin should be administered, and if there be an indication it should be repeated. By frequently changing the patient's position she is made perfectly comfortable, and so in many cases the use of opium is avoided.

DR. ROBB closed the discussion by saying that the salt solution tends to decrease the thirst, and is most valuable in the after-treatment. After a long experience he has found that gauze drains act quite as well as does the glass tube. The glass tube, as a rule, is usually filled with bacteria, and certainly causes much more trauma to he abdominal contents. As a rule, even in bad pus cases, a drain is not required for the reason that in nearly all cases this pus is sterile and absolutely free from micro-organisms. In eighteen cases of pyosalpinx in which there was abundant quantities of pus, the abdominal incision was closed up without drainage, and the patients made an uninterrupted recovery. Simply because pus is present is not an absolute indication for drainage. In nearly all cases this pus is sterile, but it is a good general rule to use rubber gloves and sleeves as they can be rendered absolutely aseptic, which is very difficult and often impossible in the case of the hands and arms. If virulent organisms be present in a pus case, it does not matter how much drainage you put in, the patient cannot be saved. The whole abdomen may be filled with drainage-tubes and be constantly irrigated, yet the result is the same. The hot salt solution is valuable in that it lessens toxicity of any micro-organisms that might be present and tends to relieve the thirst. The postural position is the best, as in that position drainage seems to go on better. The use of morphin as a routine treatment is not wise, other things being tried first. The deodorized tincture of opium was tried in many cases and proved most valuable. As it is so hard to properly sterilize sea sponges it would seem that gauze sponges are the best, as they can be rendered perfectly sterile, and are in reality not more expensive than sponges. One of the chief advantages of the gauze pad is that they can be made of any size desired, intestines can be walled off much easier in those cases in which they are used, and the operative technic thereby simplified.

DR. CHARLES P. NOBLE of Philadelphia then read a paper, entitled "Early Abdominal Sections for Fibroid Tumors, with a Tabulated List of All Operations Prior to 1865," in which he went very fully into the early history of this operation. In the majority of cases the operation was attempted after an error in diagnosis, the operator believing that he had to deal with some form of ovarian tumor, and when he discovered his mistake, abandoned further operative interference. In 1842 Charles Clay of Manchester did a supravaginal myomectomy but the patient died of hemorrhage. In 1844 Clay performed a total extirpation of the uterus, but the patient unfortunately died as the result of a fall. In 1863 Clay successfully performed a supravaginal amputation of the uterus.

ORIGINAL ARTICLES.

THE NEW DIAGNOSTIC SPOTS OF MEASLES ON THE BUCCAL AND LABIAL MUCOUS MEMBRANE.

BY HENRY KOPLIK, M.D.,

OF NEW YORK;

ATTENDING PHYSICIAN TO THE GOOD SAMARITAN DISPENSARY AND TO ST. JOHN'S GUILD HOSPITAL; ADJUNCT ATTENDING PHYSICIAN TO THE CHILDREN'S WARD, MOUNT SINAI HOSPITAL.

IT is now two years since my first communication on "The Diagnosis of the Invasion of Measles from a Study of the Exanthema as It Appears on the Buccal Mucous Membrane," appeared in the *Archives of Pediatrics*. It is strange how slowly this valuable diagnostic sign has made its way. It was first taken up by Professor Heubner in Berlin who wrote to me that he had learned of this sign of measles from my reprints, and the *Archives*. He then became interested in the sign, and Slawyk, his assistant, in a communication to the *Deutsche Medicinische Wochenschrift*, No. 17, 1898, not only confirmed what I had stated about the diagnostic sign of measles, but reiterated the great importance of the sign in aborting hospital epidemics. Since then the knowledge of this new diagnostic sign of the invasion of measles has spread in Germany and Austria. It is today firmly established as the most valuable pathognomonic sign of the invasion of this disease. Its value is felt when we are told that in many of the European ambulatory clinics this sign is sought for always in the routine examination of the little patients who come for treatment, and when found, whatever other symptoms may be present, the patient is at once isolated. Such is the statement which comes from Heubner's clinic in Berlin, and Gaughofner's clinic in Prague, the latter in an exceedingly interesting communication by D. Ludwig Knöspel (secondär arzt).

Here in America it is surprising to see how little recognition the sign has received. With the exception of the articles of my assistants and pupils, and one or two scattered communications in the journals, one finds nothing except the same old insistence of ambitious correspondents concerning the old textbook signs of measles to be found on the mucous membrane. In a recent discussion before the American Pediatric Society, A. Jacobi mentioned this sign, but since then one finds very little from the leading clinics. T. Escherich of Graz has sent me a personally unsolicited communication in which he says that he has found the sign of great value in the few cases he has since seen, but explains that his material at the time was limited, and permits the above use of his name for my writings.

In view of the above, I have been persuaded that a third article on this early sign of measles is not only called for, but will tend to cause a more active interest concerning it among those who have charge of large dispensaries, hospitals, and asylums, where the prevention of epidemics is the chief function of the physician.

One does not find this sign of measles described in any of the older or more recent text-books, nor to my knowledge, in any brochure. Slawyk cites the article of Jurgensen on measles; but a study of the work of Dr. Flindt therein mentioned will show that Flindt describes a vesicular eruption on the hard and soft palate, and not on the buccal and labial mucous membrane. Filatow, translated from the Russian by Slawyk, under the author's direct supervision, and inaccessible to me, is said to describe in his infectious diseases a desquamation of epithelium on the buccal mucous membrane in the prodromal stage of measles. Not only does Filatow not describe my sign of measles, but it will be seen to be entirely different in its ultimate picture. In the German work of Filatow no reference is made to this sign of measles. After years of comparison and study, my first article appeared in 1898. It may be stated with absolute confidence at the outset that this sign appears in measles only, and never in any other condition whatever, either in health or disease. Such a statement could only be made after study and comparison of an immense amount of material, and when it is stated that this conclusion has been arrived at after a routine examination, extending over twelve years, of the mouths of all infants and children coming to one of the largest ambulatory clinics in this country, it will at once be seen that the conclusion rests on a firm basis. It was some years before the sign was formulated in the mind and eye of the writer. It was tested for years and found invariable in its presence and reliability, and the discovery was then published. I had even gone so far as to examine microscopically and bacteriologically these spots before the publication of my first paper, but had not thought it

prudent to include a find more or less indefinite in the publication of a clinical entity, thereby clouding its value.

Time of Appearance.—This new sign of measles appears as long as twenty-four hours, forty-eight hours, and even *three* to *five days* before the appearance of the skin exanthema. It is present before the signs of conjunctivitis appear, and when little or no fever is present.

The material which I here publish is only a small fractional part of my measles material. It is brought forward simply as illustrative. All cases were studied at the homes of the patients. Of fifty-two consecutive patients examined in my clinic and subsequently studied at their homes the diagnosis of measles was made in thirty-two cases before any sign of an eruption appeared on the body—not even a spot of exanthema. In three of the thirty-two the diagnosis was made three days before any exanthema appeared. In nine cases my sign appeared forty-eight hours before the appearance of the exanthema. In the remaining twenty cases fully twenty-four hours elapsed before any eruption appeared on the skin. In none of the fifty-two cases was the diagnosis wrong.

The Sign.—The sign which I have described in my former articles appears preeminently on the mucous membrane which lines the cheeks and lips. It can also be studied on the mucous membrane lining the cheeks opposite the last molar teeth. It appears only on the buccal and labial mucous membrane and not on that of the soft or hard palate or on the mucous membrane covering the fauces. The eruption or sign runs through a sort of cycle. It appears, as stated, 24 hours, 48 hours, 3 to 5 days before the exanthema of the skin. It is at first discrete, then becomes numerous and confluent, and when the skin exanthema appears and is spreading it is at its height. It then begins to fade and disappear. If one looks into the mouth in a case of measles before the exanthema has appeared he sees the usually described redness of the fauces and in some cases a few indefinite spots of red on the soft palate. In a strong glaring daylight one sees at this period on the mucous membrane lining the cheeks (buccal) and lips (labial) a distinct, pathognomonic eruption. This eruption consists of small, irregular spots of a bright-red color; in the center of each red spot is the interesting sign which I have described, a minute bluish-white speck. There may at first be only two or three or six such rose-red spots, with the bluish-white speck in the center. The combination of a bluish-white speck with a rose-red background on the buccal and labial mucous membranes is absolutely pathognomonic of the invasion of measles. Sometimes the bluish-white speck is so small and delicately colored that only in a very direct and strong daylight is it possible to bring out the above effect, but the combination is always present.

Sometimes the number of the spots is very few, and again they may be quite numerous and cover the whole inner surface of the cheeks. When once seen they will always be remembered, but in order to see them they must be looked for by everting the mucous membrane of the lips and that of the cheeks by means of the thumb and index-finger, or with a spatula, and then allowing the strong daylight from a window to fall over the examiner's shoulder on the mucous membrane. Any passing shadow obscures the picture, so delicate is the nuance of these spots at times. They can then never be mistaken for sprue, for sprue is of an opaque-white color, coarser, and at times plaque-like, while my sign is bluish-white, delicate, and never forms plaques.

Ordinary manipulation cannot remove them, such as passing the examining finger over them, but such brushing as they would receive if the mouth were cleaned by the mother I find sometimes removes them. They can also be picked off with the forceps. If examined they are found to consist of bacteria, diplococci mostly, sometimes streptococci and epithelial scales.

The Cycle.—The sign which I have described remains at first discrete, but as the rose-red spots with their bluish-white centers increase in numbers, the *rose-red spots* coalesce and a peculiar appearance of the mucous membrane results, there being large areas of rose-red studded all over with minute raised bluish-white specks, relieved here and there by the normal hue of the uninvaded mucous membrane. Finally the whole buccal and labial mucous membrane becomes of a uniform rose-red color studded with myriads of these bluish-white specks. At this time the skin exanthema has appeared and is spreading. When the skin exanthema is at its efflorescence the buccal eruption has begun to fade and lose its characteristics. It will thus be seen that the sign I have described is a sign of the invasion of measles and of the greatest value from a diagnostic standpoint. It gives one an infallible sign of the appearance of the disease in advance of the skin exanthema, and one can thus lessen the exposure of the healthy to contagion by a much greater period of time than was formerly possible.

In my first and second paper I pointed out the great value of this sign of measles, not only in making the diagnosis of measles, but in differentiating the many skin eruptions which simulate the eruption of measles. Since then this has been con-

firmed, not only at home, through the publications of Libman, Sobel, and Lefetra, but in the large clinics abroad (Knöspel in Gaughofner's clinic, and Slawyk in Heubner's clinic).

Among the conditions included by me, in which the skin eruption at the outset or the general symptoms were apt to raise the question of differential diagnosis, were rötheln, forms of erythema and urticaria, drug eruptions, scarlet fever, forms of simple aphthous stomatitis, and grip. To these have been added in the realm of dermatology (Sobel) forms of syphilide, antitoxin eruption (Lefetra and Knöspel), and an attack of measles following the other exanthemata, or complicating the same (Knöspel).

Scarlet Fever.—The invasion of scarlet fever sometimes is puzzling and one is in a quandary as to the diagnosis. The fauces are injected and a few deceptive spots even occur on the soft palate. The buccal and labial mucous membrane, however, retain their normal pale aspect, differing in this respect from measles.

Simple Aphthæ.—In simple aphthous stomatitis, there is a slight febrile movement at the outset, and if the buccal or labial mucous membrane be examined one may find a minute red spot or two in this situation. On close inspection such a red spot will be seen to be supplied with a yellow or pale yellow central spot or vesicle (plate) which is easily differentiated from the measles sign.

Rötheln or German Measles.—Mild forms of measles are repeatedly labeled as rötheln. This has been unavoidable because hitherto the profession has had no distinctive sign of measles in the early period of the disease. Since I have made a study of this subject I have met mild forms of a skin eruption which had the outward characteristics of measles. It was, however, duskier and more discrete even at its height than the exanthema of measles. There was slight conjunctivitis, little or no coryza, and the temperature of the patients remained low even at the height of the eruption. A careful examination of the mouth seemed to give the key to the affection. The fauces had a suspicion of infection; there may have been a spot or two on the soft palate. The buccal and labial mucous membrane showed the absence of the measles sign and were of a normally pale pink hue.

I have diagnosticated these cases as cases of rötheln in this manner, ruling out even a mild form of measles. Subsequent study of such cases confirmed the diagnosis. True measles never developed. The eruption faded and the patients, some six or seven, watched in this way, recovered within a few days.

Grip or Influenza.—No condition so closely resembles the invasion of measles as the onset of an attack of the grip or influenza in children. In these cases there is the conjunctivitis, coryza, fever, and slight cough. It is here that the measles sign is absent; the buccal and labial mucous membranes have a pale normal hue, though the fauces are injected. In addition, I have seen eruptions from quinin or copaiba which were mistaken for measles, and also *vice versa*, an attack of measles in an adult, who at the time was taking cinchona diagnosed as a cinchona eruption. The presence of my sign showed the error, and led to prompt isolation of the patient.

In the realm of dermatologic diagnosis mild forms of erythema or urticaria are early classified apart from measles by a study of the buccal and labial mucous membrane. In other special dermatologic entities, I would refer the reader to the article of Dr. Sobel, which is very instructive.

Pearls of the Buccal and Labial Mucous Membrane.—In the general search for my sign of measles in the clinic by assistants and pupils, I have frequently found that they mistook the above for the measles sign. If one studies the normal mucous membrane in young children, where it covers the inside of the cheeks or lips, one sees in many cases minute yellowish-white specks shining through the epithelium. If these are studied it will readily be seen that they are not surrounded by red and that the shining normal epithelium passes over them. I have called these "pearls" of the mucous membrane, retaining the nomenclature of Epstein, though they must not be confounded with Epstein's pearls.

The differentiation of antitoxin rashes from measles exanthema by means of my sign has been well brought out by Lefetra and Knöspel. The latter also relates several interesting cases of two attacks of measles in the same subject.

Especially instructive are the cases of double infection of scarlet fever and measles in the same subject, in which the diagnosis would have been impossible without the aid of the new sign of measles. In my own practice the following case will illustrate how this sign may be of importance in making a differential diagnosis: Child, eight years old, female, suffering from typhoid fever. Seen in consultation in the middle of the third week of a well-developed and characteristic attack of the disease. She had been doing fairly well, her temperature having fallen to 101° F. in the evening. There had been roseola in the early history of the case. Her spleen was enlarged, and there had been diarrhea and the Widal reaction. Suddenly her temperature rose to 103½° F., her body became covered with a roseola, and there was some redness of her eyes. The physician was puzzled as to whether the eruption was a recur-

rent typhoid roseola or something else. Examination of the buccal mucous membrane showed the measles-spots described above. The case was then one of typhoid fever complicated by an infection of measles which appeared in the third week of the typhoid.

It will be seen that in the spots which I have described the profession has a pathognomonic sign of measles at an early stage of the disease of the highest diagnostic value. It enables one to isolate the measles patients with certainty at a much earlier period than was formerly possible. Epidemics both in hospitals and institutions can be promptly limited if not aborted. At the same time, one has a means of distinguishing measles from a variety of similar eruptions of the skin resembling the measles exanthema.

OROSCOPY: ITEMS OF INTEREST FROM A DERMATOLOGICAL AND GENERAL STANDPOINT.

By JACOB SOBEL, M.D.,
OF NEW YORK;
ASSISTANT, DEPARTMENT OF DERMATOLOGY, GOOD SAMARITAN DISPENSARY.

INSPECTION of the mouth as an important part in the physical examination of a patient does not as a rule receive that attention and thoroughness which it would seem to merit from the fund of information one may thus obtain. The term oroscopy is not intended to imply a superficial survey of the oral cavity, a mere "looking into" the mouth, as it were, but rather a thorough examination under good illumination of the mucous surfaces of the lips, gums, cheeks, hard and soft palates, floor of the mouth, and tongue. Who will deny that with such a scrutiny many general diseases may be diagnosticated in their incipiency, others may find corroboration in the oroscopic examination, while numerous local diseases may thus be brought to light?

To discuss all the pathologic lesions which might occur in the oral cavity would carry me far beyond my original intention, which is simply to refer to a few of the most important conditions observed for the most part within the past year, especially to those which are likely to prove of interest to the dermatologist and general practitioner.

Lips.—The most common affection met with in this situation is herpes. True this attacks the skin surface more frequently than the mucous membrane, but the latter is often sufficiently involved to deserve attention. Any part of either lip may become affected, but the angle of the mouth is the favorite site. This herpes labialis — "fever-sore," "cold-sore," or "fever-blister," as it is commonly termed—may be but a manifestation of a slight systemic disturbance, to wit, constipation, coryza, bronchitis, tonsillitis, or menstruation, or it may be concomitant of cerebrospinal meningitis, pneumonia, or malaria. Indeed, it may sometimes prove of worth in differentiating the latter diseases respectively from tuberculous meningitis, pleurisy, and typhoid fever, in which conditions it rarely, if ever, occurs.

Mucous patches are observed to a greater or less extent on the mucous surfaces of the lips, most frequently at the angle of the mouth or in the groove between the gums and lips. They are usually superficial, not elevated, and present the appearance as if a nitrate of silver stick had been drawn across the surface; the latter circumstance has given rise to the term "opaline patches." When situated at the angle of the mouth they may become fissured, painful, and bleeding. Their surrounding area lacks the semblance of acute inflammation, being somewhat dull and congested; this fact proves important in differentiating them from the patches of aphthous stomatitis. The previous history, the adenopathy, the presence perhaps of a cutaneous lesion, and the resistance to ordinary local treatment would serve to render the diagnosis clear.

Stomatitis aphthosa, also known as vesicular or follicular stomatitis, forms a large part of the mouth affections in childhood. A group of vesicles constitutes the early stage; the latter soon suffer irritation and form small, superficial, grayish-yellow ulcerations with a surrounding inflammatory and reddened areola. This form of stomatitis is most commonly observed on the mucous membrane of the lips, cheeks, and tongue, and does not attack the gums for the reason that these do not contain any muciparous glands; a follicular stomatitis may extend all over the mouth and yet not touch the gums. When a stomatitis is directly on the gums it is of the ulcerative character (Jacobi). Koplik's spots,[1] those minute bluish-white spots on a reddish punctate area, which are observed in the preeruptive and early eruptive stages of measles, are occasionally seen on the upper and lower lips. Being precursors of the measles exanthem, their significance and importance from a prophylactic standpoint, particularly with reference to hospitals, schools, and institutions cannot be overestimated.

Purpuric spots on the mucous membrane of the lips are by no means uncommon; their differential value will be spoken of in connection with the hard palate. Perlèche is a contagious affection of the commissures of the lips, which is most frequently observed in schools and institutions; it occurs in in-

[1] Koplik, "A New Diagnostic Sign of Measles," *Medical Record*, April 9, 1898; Sobel, "Koplik's Spots as an Aid in the Diagnosis of Skin Lesions," *New York Medical Journal*, October 15, 1898.

fants and children. The sides of the lips are inflamed and macerated, and at times painful and bleeding fissures result. The condition may be confounded with periorbicular eczema and the rhagades of syphilis, both of which are distinguished by the history and the involvement of other parts.

In rare instances, verrucæ or warts are seen on the lips. Allen[1] has reported a case in which there were twenty on the buccal mucous membrane, with a partial involvement of the lip. Molluscum contagiosum or molluscum epitheliale, while usually occurring on the skin surface, and mostly in children, may involve the vermillion border of the lips.[2]

The pigmentation of Addison's disease may be visible on the mucous membrane of the lips before the skin lesion makes its appearance (Ortner). Chapped lips, which are nothing more than a superficial eczema with cracking, needs but a passing mention.

Nævi are now and then observed in this region. They may vary in size from that of a pin's head to an entire involvement of the lip, and may be superficial or deep. Occasionally nævi, situated near the angle of the mouth, invade the mucous surfaces of the lips.

Mucous cysts are not infrequently seen on the lips, and result from the retention of the contents of the mucous follicles. They usually form small, sessile, circumscribed, semi-elastic tumors, and appear to be situated in the midst of the soft, natural tissue. Their growth is slow, their character benign, and only when they become large do they cause any inconvenience.

Epithelioma is the form of cancer which most frequently attacks the lips, and the lower one far more frequently than the upper. It is a disease of advanced life, and occurs in males more frequently than in females. It may have its origin in a wart, papule, crack, or fissure, or in a thickening and opacity at the vermillion border of the lips. These do not disappear, but are followed by induration and ulceration, with the formation of a scab. The ulcer is excavated, with a slight exudation of a thin, seropurulent character, with a hard indurated base and everted margins. While the diagnosis of epithelioma is simple, as a rule, still it must be differentiated from papilloma and chancre. A papilloma does not usually ulcerate, the surrounding tissues are soft, the base is not indurated, and the neighboring glands are not involved. Chancre attacks females[3] more frequently than males, and may occur at any age, the cervical and submaxillary glands being early involved—six to eight weeks after the initial lesion; it is followed by secondary lesions in the throat and skin, lasts but a few weeks, ulcerates at an earlier date, and responds kindly to antisyphilitic treatment. A history of contagion may possibly be obtained. In very doubtful cases it is perfectly justifiable to excise a portion and subject it to microscopic examination.

Hypertrophy of the lips (macrocheilia) may be either congenital, transient, or permanent, and may involve the entire substance, or only the mucous and submucous tissues. Repeated attacks of eczema, chronic rhinitis or angioneurotic edema may give rise to a hypertrophy which disappears with the alleviation or cure of the etiologic factors. The strumous diathesis, myxedema, and acromegaly are usually associated with general hypertrophy of the lips.

Furuncle and carbuncle may attack the lips, the upper one far more frequently than the lower. Both conditions are associated with marked induration and inflammatory edema, and occasionally give rise to a fatal sepsis. The pale lips of anemia and the cyanotic lips of cardiac and pulmonary disturbances are recognized at a glance. Dry, coated, and fissured lips often indicate a febrile process.

Erythema multiforme exudativum may attack the lips, or, indeed, any part of the mouth, and may be mistaken for syphilis. It may occur in the form of single bullous lesions of a flabby or firm-walled nature, or, as I have seen it recently, in the shape of plaques resembling mucous patches. The latter result from the coalescence of the smaller lesions which have ruptured spontaneously. In differentiating from mucous patches, the main reliance must be placed upon the history, the absence of glandular enlargement, and especially upon the occurrence of other lesions of multiform erythema on the cutaneous surface. Rosenbach[1] has pointed out that erythema bullosum of the tongue is often associated with a similar eruption on the genitals. In a patient whom I recently saw at Dr. C. W. Allen's Good Samaritan Dispensary Clinic, the bullous lesions of the lips and tongue were associated with the occurrence of numerous firm, single-walled bullæ on the under surface of the penis and scrotum, giving to the latter region the appearance of a bunch of grapes.

Gums.—This region may present a number of interesting conditions. First of all, that common affection, ulcerative stomatitis or fetid sore mouth. Needless to say this is most frequently observed in bottle-fed babies, in whom cleanliness of the mouth is not rigidly enforced. It is not limited to childhood, however, for it has been seen in adults who

[1] *Deutsche. Medicin. Wochenschrift*, June 28, 1894.

were crowded together in poor hygienic surroundings. It may vary from a slight ulceration with redness and swelling to the formation of marked fetor and gangrene. There is hypersecretion of saliva, and mastication is exceedingly painful.

The spongy gums of mercurial salivation are familiar to all. This objective appearance is combined with the subjective sensations of a sweetish, metallic taste, pain on closing the teeth, and fetor of the breath. How often is the bluish-black line at the margin of the gums the first intimation that the patient is a subject of saturnism? This line is *in* and not *on* the gums, and cannot be removed by cleansing the teeth. In scorbutus and morbus maculosus of Werlhof the swelling, fragility, and bleeding from the gums are prominent features.

When a patient presents himself with an inflamed and indurated cheek, with perhaps swelling and even closure of the lids, is not the source of the trouble frequently a small alveolar abscess?

Swelling of the gums with falling out of the teeth may be the initial symptom of diabetes mellitus. Gingivitis is the general term for inflammation of the gums. Papillomata are rarely seen in this situation.

Simple epulis is a small, round, elastic, benign tumor resembling in appearance and structure the normal gum. Exceptionally an epulis is of malignant nature. Finally, from the accumulation of tartar due to improper mouth hygiene small abscesses may form along the junction of the teeth and gums.

Buccal Mucous Membrane.—This is the favorite site of Koplik's spots, which are pathognomonic forerunners, by three or four days, of the measles exanthem, and which also serve to differentiate this disease from other morbilliform eruptions, from German measles, antitoxin rashes, etc. Lately their importance in diagnosticating a beginning measles during the convalescent stage of scarlet fever and diphtheria, or in determining a second attack of measles in the same patient has been dwelt upon.[1]

Aphthous stomatitis, mucous patches, leucoplakia, and purpuric spots are observed in this situation. The pigmentation of Addison's disease often lurks on the mucous membrane of the cheeks. Papillomata[2] have lately been reported as occurring in this region. The simple ulcer following the irritation of a diseased and ragged tooth—dental ulcer, so-called—can hardly escape one's notice.

Thrush, sprue, or parasitic stomatitis often involves the buccal mucous membrane. It is a superficial stomatitis consisting of small, creamy deposits which coalesce and rarely result in the development of ulceration. As its name implies, it is parasitic in nature, and is dependent upon a fungus, the oidium albicans.

Noma or cancrum oris is the gangrenous form of stomatitis, which begins as a small dark spot or ulcer upon the inner side of the cheek or gum, and finally gives rise to sloughing and gangrene, with marked constitutional symptoms, and eventually death. It is usually a sequel of measles or scarlet fever, and both cases which I observed followed an attack of measles.

Hard Palate.—Varicella may often be diagnosticated by the lesions on the hard or soft palates. In the early stages, when the skin lesions are scant, indefinite, and apt to suggest a papular urticaria, the occurrence of flattened vesicles or yellowish excoriations with a surrounding reddened areola will remove all doubt. At times, these lesions are in groups of two and three, as on the skin surface.

Variola, it is said, may show the initial vesicles on the palate. Icterus is sometimes seen along the raphe of the hard palate before the cutaneous surface is affected.

The hard and soft palates often present a spotted red appearance at the invasion of measles. This is simply a papular eruption similar in every respect to the cutaneous outbreak, and while strongly suggestive of measles, when combined with other symptoms, is by no means pathognomonic.

Anomalous epithelial pearls (Epstein's pearls), consisting of slightly elevated, yellowish-white, irregular masses, may be seen scattered on either side of the median line in very young children. They have no particular significance, and unless ulcerated cause no inconvenience.

Mucous patches are occasionally observed in this situation, and are of especial interest because they may give rise to the same lesion on the corresponding part of the tongue, as was pointed out several years ago by Dr. Allen. When the mouth is closed the tongue rests against the hard palate, even more so when an attempt is made at deglutition; the result is that these patches being auto-inoculable, infection takes place by contact of tissue. Treatment in these cases must be energetic on account of the danger of perforation.

Bednar's aphtha is an affection of infancy which consists of a bilateral, superficial, round ulceration at the posterior alveolar border of the hard palate, at the point where the pterygomaxillary ligament is "put on the stretch" during the act of nursing or opening the mouth. It generally occurs from the second to the fourth week.

[1] Ludwig Knöspel, *Prager Med. Woch.*, xlii., 1898.

[2] Allen, "Impressions and Conclusions Based upon the Study of 5000 Skin Cases Treated During the Year," *Medical Record*, October 22, 1898.

Purpuric spots on the mucous membrane of the hard palate may prove the differentiating factor between purpura simplex and purpura hemorrhagica. Again, there are some cases of purpuric "bites" from fleas and body lice which are difficult to distinguish from purpura; the former are generally of the petechial, the latter of the maculæ ceruleæ type. In such instances the mucous membrane eruption furnishes the final test.

Soft Palate.—Aphthous and parasitic stomatitis may involve this region in severe cases. Bifid uvula, though rare, is occasionally observed. I have recently seen a number of such instances at the Good Samaritan Dispensary.

Edema of the uvula, either as an idiopathic affection, as part of a general pharyngeal inflammation, or the result of urticaria,[1] following irregularities in diet or drug medication, is not as infrequent as is generally supposed. It varies from very mild cases to those in which numerous and heroic punctures, and even amputation, become necessary. Angioneurotic edema may be classified in this group.

Elongation of the uvula is immediately perceived. The participation of the soft palate in a membranous throat is strong presumptive evidence that the lesion is diphtheritic.

Floor of the Mouth.—Tongue-tie, due to an abnormally short or broadly attached frenum, is the most common affection and is seen at birth. There may exist an arching of the dorsum of the tongue, and inability to protrude the organ beyond the incisors. In early life this prevents the proper adaptation of the tongue to the nipple, and later gives rise to impediment in speech. The treatment is surgical, division with a blunt scissors toward the teeth (to avoid cutting the ranine artery) being the preferable method.

Ranulæ or cystic tumors of various size are observed on either side of the frenum. They are due to obstruction of Wharton's duct, or of the sublingual ducts, the ducts of Rivini.

Salivary calculi are most frequently found in the submaxillary duct. They vary in size from that of a pea to that of an olive. Clinically, they give rise to irritation, with pain, and a soft tender swelling on the floor of the mouth, which recurs with a certain periodicity.

In children who have "cut" their lower central incisors and who suffer from pertussis it is not uncommon to find an ulcer on the under surface of the tongue near the frenum; this ulceration is traumatic in nature and results from the irritation which is produced at every paroxysm, when the tongue glides over the surface of the teeth.

Tongue.—This organ, *speculum primarum viarum*, furnishes such a vast amount of information that it would require a special paper to discuss it; for that reason it can be dealt with now only in a general manner. The tongue seems to be a general index whether the condition is a local manifestation of a constitutional disturbance or whether the process is a limited affair. The coated tongue of certain gastric disorders, the reddened tongue of fever, the strawberry tongue of scarlatina, the brown coating and fissuring of the typhoid tongue, the hypertrophic and thickened tongue of myxedema and acromegalia, and the pigmented tongue of morbus Addisonii are all general diseases with a local manifestation. These, however, pale into insignificance when compared with the number of local lesions. Many of them are so rare as to deserve a place in the category of curiosities. It is the more common affections of every-day practice that are of most interest here. Herpes febrilis, mucous patches, aphthous stomatitis, and thrush often have their starting-point in this organ. Simple or dental ulcer of the tongue is rarely mistaken for anything else. Its superficial character, its lack of induration, its situation opposite a sharp tooth, and the absence of glandular enlargement would serve to clear any doubt.

Leucoplakia or leucoma consists of glossy, milky-white patches of various size, shape, and thickness, which occur most frequently on the tongue and buccal mucous membrane. When the patches are scattered leucoplakia is the term applied; when they coalesce leucoma is more appropriate. This condition is of especial interest on account of its relation to syphilis and carcinoma. That these plaques may occur during the course of syphilis no one will deny; that syphilis is the direct cause of them is, however, very doubtful. The abuse of alcoholics, decayed teeth, and excessive smoking are the etiologic agents in some instances. They have even been called "smokers' patch," but, inasmuch as they are seen in women and non-smokers, this term is not strictly applicable. Its connection with cancer is important because after existing for a certain period of time these patches may assume all the appearances of malignancy.

Geographical tongue or exfoliatio areata linguæ requires mention,[1] not account of any great significance or importance that it may possess, but because of the danger of confounding it with other affections and becoming alarmed at its presence. It consists of a peculiar serpiginous or map-like ar-

[1] Allen, "The Tongue," Wood's "Reference Handbook of the Medical Sciences."

rangement on the upper surface of the tongue, with central reddened areas surrounded by slightly elevated yellowish borders. It occurs for the most part in children and may be observed in the exanthemata, eczema, psoriasis, miliaria, impetigo, syphilis, tonsillitis, constipation, and a variety of other conditions. On account of its evanescent and recurrent character it has been styled "wandering rash." It is distinguished from the syphilitic plaque by its constant change of position and by the yellowish margin.

Nævi, generally of the angiomatous type, are occasionally found in the tongue. They are venous, soft, and somewhat elevated, bluish tumors, which pale on pressure.

Papillomata may appear on the dorsum of this organ. They consist of hypertrophic papillæ, their base is soft and they rarely ulcerate. They may be the beginning of a cancerous process.

A question which is often asked and which is not always so easily answered is: Does this tongue lesion appear syphilitic, cancerous or tuberculous? The syphilitic lesions of the tongue embrace mucous patches, fissures, chancre, ulcers and gumma. Mucous patches and fissures are easily diagnosticated for the reason that other secondary manifestations usually exist. As has been previously stated, the mucous patch on the dorsum may have a corresponding plaque on the hard palate. Fissures as a rule are situated laterally, are sensitive to the touch, and may be single or multiple.

Chancre of the tongue may be single or double; it usually occurs at or near the tip; it commences as a hard "lump," which soon softens and ulcerates. It attacks both sexes. The lymphatic glands in anatomic relation are soon involved. The history, the occurrence of secondary lesions, and the response to antisyphilitic treatment give a further cue in doubtful cases.

Gummata may be single or multiple, superficial or deep, and are usually located on the dorsum of the tongue. They may either fade away under appropriate treatment or lead to deep destructive and ulcerative processes. The lymphatic glands are rarely affected as compared with chancre and carcinoma.

Carcinoma of the tongue attacks males more frequently than females and is usually situated at the sides; it is single, with a hard, indurated base and with everted margins, occurring at an advanced period of life. The lymphatic glands in the neighborhood are enlarged.

Tuberculous ulcerations occur in patients with a phthisical history, and are generally situated near the tip; they may be single or multiple and are usually, though by no means always, painful. Their edges are ragged, irregular, undermined and not surrounded by induration. The lymphatic glands may or may not be involved. The presence of the tubercle bacilli dispels all doubt.

But with all this differentiation one must often have recourse to the microscope in order to settle definitely the syphilitic, cancerous or tuberculous nature of certain ulcerations of the tongue.

In conclusion, the oral cavity may be the seat of such rare conditions as lupus vulgaris and erythematosus, erysipelas, angioneurotic edema, lichen planus, xeroderma pigmentosum,[1] and lesions of zoster, pemphigus, and leprosy.

GASTRO-ENTEROSTOMY WITH ENTERO-ANASTOMOSIS BY BRAUN'S AND GALLET'S METHODS. REPORT OF FIVE SUCCESSFUL CASES.[2]

By ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

In March of last year, and before this Section, I presented a specimen illustrative of gastro-enterostomy, performed on the posterior wall of the stomach, and supplemented by an additional opening (entero-enterostomy) between the ascending and descending portions of the jejunum, some four to six inches from its attachment to the stomach.[3]

FIG. 1.

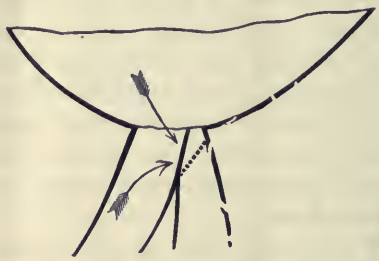

FIG. 2.

This was the suggestion of the German surgeon, Braun, and was intended to obviate the risks of the bile and pancreative obstruction that so often obtained in the ordinary gastro-enterostomy, and more

[1] Hallock, "Angio-Neurotic Edema of the Tongue," *Atlantic Medical Weekly*, July 16, 1898. Haynes, *New York Medical Journal*, December 25, 1897.

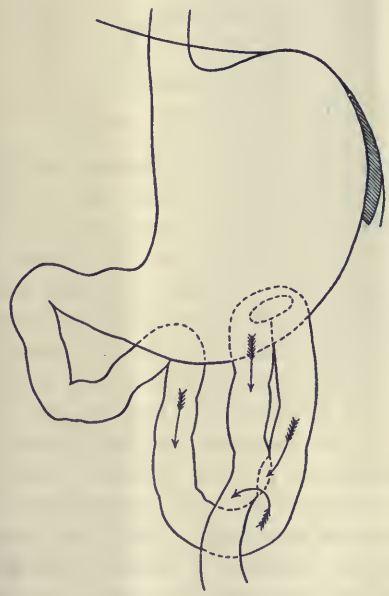
[2] Read at a Meeting of the Surgical Section of the New York Academy of Medicine, March 13, 1899.

[3] "On the Operation of Gastro-enterostomy, Combined with Entero-anastomosis," *Medical Record*, April 16, 1898.

particularly when this opening was made on the anterior face of the stomach. A report by Kappler[1] since that date has explained more clearly why every method of simple gastro-enterostomy is liable to produce obstruction. This mishap is easily understood by the diagrams that he gives, and which are here reproduced in outline. (Figs. 1 and 2.)

It will be seen that the pressure of the filled afferent bowel tends to shut off the mouth of the descending jejunum, owing to the mobility of the spur necessarily formed by the pendant intestine. Moreover, the outflow from the stomach, unless the spur hangs true in the middle or inclines to the afferent or upper opening, is also likely at times to be shut off by the same valve-like action. This, with the other reasons advanced in the paper then presented to this Section, led me to strongly advocate Braun's suggestion of a supplementary anastomosis (Fig. 3) which was also advised by the French surgeon Jaboulay, with the remark in reservation that time and experience could alone determine whether the additional opening made in the intestinal walls by the second or safety button added seriously to the surgical risk of the patient. In the specimen I then presented of carcinoma of the pylorus, for which a

FIG. 3.



Braun-Jaboulay's gastro-anastomosis with entero-anastomosis.

gastro-enterostomy had been supplemented by an enterostomy, death resulted four days after the operation, from pneumonia of supposed ether origin (though such a termination has also been remarked after a cocain operation). The field of operation was found absolutely free from any evidence of inflammation, and no signs of biliary or pancreatic obstruction had shown themselves by vomiting, etc., during life. Since that time I have had occasion to resort to gastro enterostomy in five instances. In one

FIG. 4.

Method of posterior gastro-enterostomy of Van Hacker.

of these a simple posterior gastro-enterostomy by Von Hacker's method was resorted to (patient shown). In this case there was a marked pyloric stenosis of a benign character, without appreciable tumor, due to healed ulcerations, and with extensive thickening and posterior external adhesions. Large fibrous pyloric stenosis with posterior adhesions with much dilatation of the stomach were found at the laparotomy, March 2, 1898. The Murphy button used was evacuated on the thirteenth day, and the recovery was without an untoward symptom. The patient has since gained twenty-two pounds in weight, and now, eleven months after the operation, is in good health and condition.

In the other cases, four in number, not only was the regular posterior gastro-enterostomy (Fig. 4) done, but an entero-enterostomy was added to this surgical procedure. Recovery took place in all of these, and in none was there the slightest gastric disturbance or other evidence of bile obstruction or overflow. The Murphy buttons, medium and small, that were employed were discharged, in all save in one case, from the tenth to the fourteenth day, and in each case the modified button,[1] with its enlarged intestinal end, was used to prevent slipping into the stomach. In the case excepted, though the feces were ordered to be inspected after the seventh day, the buttons did not appear, and one month later,

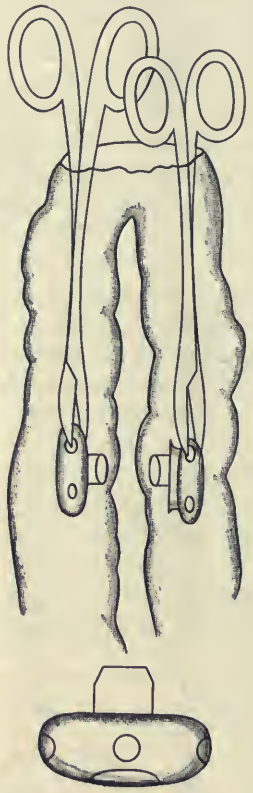
[1] *Op. cit.*, *Medical Record*, April 16, 1898.

though no gastric or intestinal symptoms presented themselves, the patient was tested by an X-ray picture, and at first no button could be found, but a better exposure revealed it subsequently to be in the stomach. He is yet in good condition, and without gastric symptoms.

Of these four cases two subjects had benign pyloric stenosis with corresponding dilatation of the stomach, and without any external evidence of a tumor. The two others had carcinoma of the stomach, in one affecting and stenosing the pylorus, and in the other mainly involving the adjacent greater curvature near the pylorus, which it invaded to a moderate degree. In this latter case, which had been, as were the others, previously accurately diagnosed by Dr. C. S. Fischer, who kindly referred the patients to me, there was but slight dilatation of the stomach. This, with the fact that posterior adhesions existed, rendered the posterior gastro-enterostomy part of the operation the most difficult one I have yet encountered, but his subsequent progress was as good as that of any of the others. In his case, operated on in November, 1898, there are now some signs reappearing of gastric irritation after a decided absence and after a gain of thirty pounds in flesh. In the other malignant case the patient gained some thirty pounds, but four months afterward succumbed from an extension of his disease. In all these cases, too, was Carle's [1] rather than Murphy's method resorted to in closing up the intestinal opening about the button. In other words, instead of using a purse-string suture, as Murphy advises, Carle employed one or more Lembert sutures for this purpose. This makes, and I found it to be so, smoother surfaces to be apposed to each other than by the purse-string method, and occupies no more time.

In the last case but one in which I operated by this method of Braun I ventured on some modifications. It was in the one alluded to in speaking of a lost button, and where benign pyloric stenosis with dilatation existed. Usually the loop of the jejunum is opened first, the enlarged half of the button is inserted, fastened by sutures, and held by forceps in the hand of an assistant until wanted, and then the opening in the stomach is similarly made, and the gastro-enterostomy completed. After this is done the insertion of the second button, the entero-enterostomy, is accomplished by duly incising and treating each wall of the chosen part of the jejunum. Gallet of Brussels has, however, recently [2] suggested that as soon as the opening has been made in the loop of the jejunum for the initial step of the gastro-enterostomy, through this should be carried on a catch forceps (Fig. 5) one-half of the smaller button

Fig. 5.



Gallet's method of entero-anastomosis.

for the entero-enterostomy, down one leg of the loop to a desired depth, and the other half of the button on another catch forceps down the other leg of the loop, and when opposite to each other they should be pushed together, crushing or cutting, as it may be, through the intervening doubled intestinal walls. This I found could be easily done, especially as I had taken the precaution to have the invaginating cylinder ends of the buttons bevelled to almost a cutting edge (see diagram) which allowed a very ready perforation of the intestinal walls. This maneuver did away with the preliminary incisions and the need of subsequent sutures, and saved time. Then the gastro-enterostomy proper was proceeded with. In opening the stomach I also made a variation in the technic. Instead of incising the stomach an inch or more, which is demanded by a 27 mm. or medium-sized button, and which, as in the intestine, is generally found to be overlarge, I made a very small cut the width of a knife-blade, and then enlarged this opening by a uterine dilator, and with it *in situ* pushed into the stomach half of the button held securely by the proper forceps. This scheme

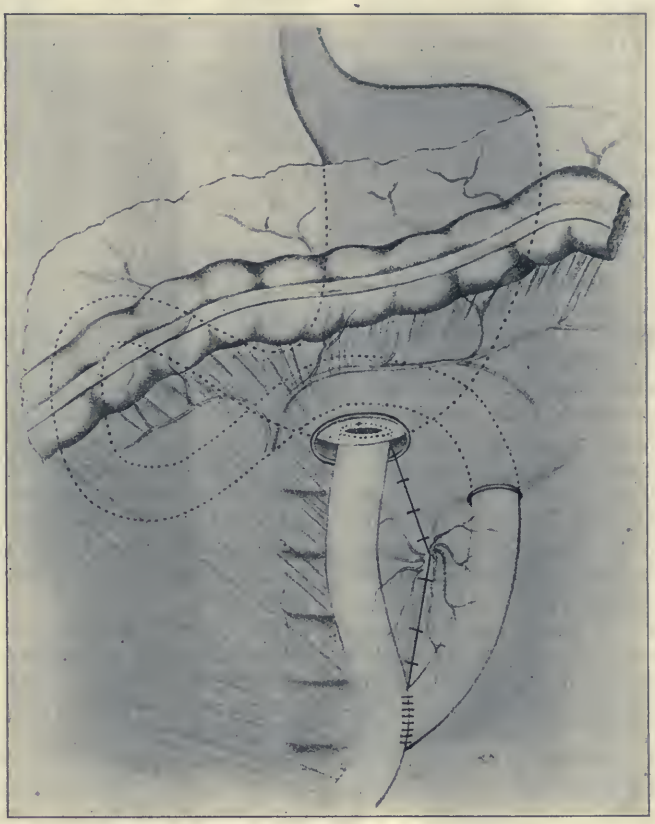
answered well in this instance at the operation itself, but whether it will prove of material service in other cases remains to be seen, and whether it contributed by its laceration to the dropping of the button into the stomach, which occurred, I cannot say, but this outcome will prevent my repeating this maneuver.

So far, the preceding experience, though not great, leans strongly in support of the dictum of Chaput, Roux, and other French surgeons, that a special route should always be provided for the carrying off of the pancreatic and biliary discharges when a gastro-enterostomy is resorted to. Whether this shall be done by an entero-enterostomy, by a Murphy button, which I prefer myself, or by a special intestinal suture-implantation, as Roux advises (Fig. 6), is to be determined in the future. It certainly is a marked contrast to my seven previously reported anterior and posterior gastro-enterostomies wherein I had four deaths, three of which resulted from the obstruction arising from a faulty technic; in other words, from the absence of an additional or safety opening into the jejunum below the stomach opening.

The following is a synopsis of the preceding cases:

CASE I. *Benign Pyloric Stenosis with Dilatation. Posterior Gastro-enterostomy.* — Male, aged forty-four years, cigar-maker. Severe intermittent gastric pains aggravated by eating. Duration four years. Loss of weight fourteen pounds. Vomiting occasional. Stomach dilated to two inches below umbilicus. No tumor to be felt. Lavage showed residue of meals of the day before Hyperacidity present, ranging from 0.7 to 1.5 per 1000 hydrochloric acid. Gastric muscular movements active on tube stimulation. Diagnosis by Dr. C. S. Fischer of benign pyloric obstruction and spasm.

FIG. 6.



Roux's method of gastro-enterostomy.

Laparotomy; median incision; March 26, 1898. Pylorus fibrous, 1½ inches in diameter; adherent posteriorly. Posterior gastro-enterostomy with medium-sized Murphy button resorted to. Excess of wounds closed by Carle's method. After the gastro-enterostomy was completed, an entero-enterostomy was done with the smallest Murphy button in the portion of the jejunum ascending and descending from the gastro-enterostomy, and distant from it about four inches. The patient did well. Both buttons were discharged on the thirteenth day. Since then patient has gained twenty-two pounds in flesh, and is free from gastric symptoms. Gastric dilatation very much lessened.

CASE II. *Carcinoma of Pylorus. Gastro-enterostomy with Entero-anastomosis. Recovery.*—Male, aged forty five years, under the care of Dr. McCoy of Paterson, N. J. Symptoms of gastric pain and vomiting had existed for more than a year, with loss of flesh and strength. For the previous three months a movable, irregular-shaped tumor to right of median line, above the umbilicus, was found. With this a markedly dilated stomach existed. No hydrochloric acid found in lavage after a test meal. Diagnosis of malignant stenosis of pylorus with dilatation.

May 16, 1898, an exploratory laparotomy was performed. A neoplasm of the pylorus, 1½ by 3 inches in size, nodular and attached to the transverse colon, and with glandular involvement and infiltration in the adjacent tissues was found. Advised and performed posterior gastro enterostomy with an additional entero-anastomosis after Braun's method. The patient did perfectly well. The buttons were discharged on the thirteenth and fourteenth days, respectively. His weight increased during the next five months more than thirty pounds. Then he began to have some recurrence of gastric irritation. This persisting, his surgeon explored by laparotomy, hoping to be able by a pylorectomy to further relieve him, but so much infiltration had occurred that the operation was properly abandoned and the wound was closed. The patient did not long survive this surgical effort.

CASE III. *Carcinoma of Stomach. Gastro-enterostomy with Entero-anastomosis.*—Male, thirty-three years old. For three years past had had more or less persistent vomiting, usually without pain, with, of late, increasing weakness and loss of weight. Paroxysmal epigastric pain had come on, which was aggravated by eating. Occasionally slight amount of blood in vomited matters and in the stools. Food remained abnormally long in the stomach, twelve to fourteen hours. A small, movable tumor was recognized slightly to the left of the median line. Stomach apparently but little dilated. Entire absence of free hydrochloric acid. No peptic ferments. Abundant lactic acid. Gastric motility impaired. Diagnosed by Dr. Fischer to be a neoplasm of the stomach but slightly involving the pylorus and without dilatation.

Operation, November 19, 1898. Median incision. Nothing felt at pylorus or on anterior wall, but on tearing through gastro-colic omentum for exploration a mass, thick and irregular, 2 by 2½ inches, was found on the posterior gastric wall reaching up to, and only moderately involving the pylorus. The rest of the stomach was much contracted and held down at its lower part posteriorly by adhesions. A posterior gastro-enterostomy was undertaken through the usual route of the colic mesentery, but its accomplishment proved to be very difficult from the inability to draw the stomach forward. After it was performed an entero-anastomosis was resorted to some 5 inches from the stomach, and the abdominal wound closed. The patient reacted well and progressed most favorably. The buttons were discharged on the tenth and eleventh days. He has gained since then more than fifty pounds in weight.

Here it was proposed to first establish the gastro-enterostomy and then to perform later, if it was deemed best, a resection of the stomach. The man's improvement has been so marked, and so thoroughly free from symptoms of gastric difficulty that the possibility of an error in diagnosis comes up and the idea can now be entertainedt that the area of supposed neoplasm was made up of the inflamed base of one or more peptic ulcerations, or, possibly, of a gumma, as he had had syphilis.

CASE IV. *Benign Stenosis of the Pylorus. Gastro-enterostomy and Entero-anastomosis by Gallet's Method.*—Male, thirty-four years of age, with a history extending over nine months of gastric paroxysmal pains and distress, which were most felt after meals. Pains were cramp-like. Vomiting large in quantity. When the stomach was distended it reached some three inches below the umbilicus. Motility was marked and could be seen to run in waves transversely across the stomach. Food was found in the stomach after twenty-four-hours' fasting. Free hydrochloric acid 0.5 to 2.0. Pepsin normal. Putrefaction and fermentation of the stomach contents were marked. Diagnosed by Dr. Fischer as a benign pyloric stenosis with dilatation, and either hypertrophic or spastic stomach. This was confirmed at a laparotomy, December 15, 1898. A posterior gastro-enterostomy with entero-anastomosis was resorted to; but the latter step was carried out first by the plan suggested by Gallet of Brussels and described in the text (see Fig. 4). For the stomach opening a small puncture was made with an ordinary scalpel, and through this was introduced a uterine dilator and its lumen stretched until the Murphy button, 27 mm. in diameter, could be introduced into the stomach. The approximation of the two halves of the button was then completed.

The patient, for two or three days after the operation, had some temperature elevation and gulping of wind, but nothing wrong was felt in the epigastrium. Beyond this he progressed satisfactorily, but though after the seventh day the stools were daily inspected no trace of the two Murphy buttons employed, one for the gastro-enterostomy and one for the entero-anastomosis, was discovered up to six weeks after the operation, when the patient, being in fine condition, was eating and digesting well, and gaining rapidly in weight and strength. An X-ray examination revealed the larger button, recognized by its flange, to be held just above the edge of the ribs on the left side in the posterior portion of the normal splenic flexure of the colon. This, however, would represent also the situation of a yet dilated stomach, so that in all probability the lost button is in the patient's stomach, where it is doing no harm. Concerning this it may be remarked that they have been left in for two years without damage. No trace was obtained of the smaller button.

CASE V. *Dilatation of the Stomach, without Pyloric Stenosis, with Movable Kidney. Gastro-enterostomy and Entero-anastomosis by Gallet's Method.*—Mrs.

B., forty years of age. For twenty years the patient had had remittent attacks of distress after eating, associated with large eructations, vertigo, headache and lassitude, though without much loss of strength or weight. Stomach was dilated vertically; its great curvature was 2½ inches below the umbilicus and to the left. Lesser curvature normal. Slight peristaltic action at times visible. Motility greatly impaired. Quantities of putrefying and fermenting material found in the stomach when it normally should have been empty. Total acidity 2.0–2.4 per 1000. Free hydrochloric acid 0.1–1.1 per 1000. Organic acids, butyric and lactic, always present.

FIG. 7.

Forceps designed by Dr. Turnure for use in Gallet's method of entero-anastomosis.

Peptic ferments normal. Diagnosis by Dr. Fischer: dilatation from atony without pyloric obstruction, probably of neurotic origin. The patient also had an enlarged, tender and movable right kidney with a small amount of pus in her urine.

March 7, 1899, median laparotomy revealed no abnormality of the pylorus but a greatly dilated stomach. A Gallet's entero-anastomosis was first performed after opening the desired loop of the jejunum, and then a gastro-enterostomy, and the parietal wound closed. Her progress was satisfactory and uneventful.[1]

It is yet too early to speak of the outcome of this interesting case, which is a type of many that are only temporarily relieved by lavage and other methods. It is possible from the existence of the kidney dislocation that this displacement has begotten the gastric trouble, and that a secondary nephrorrhaphy may be necessary, but it was judged best to attack the stomach difficulty first. As the lesser gastric curvature was normally situated no attempt was made to raise the stomach or to anchor it in view of the possible action of a gastroptosis. It may also be recorded as corroborating the experience of others that in the two other cases of benign stenosis since the operation the size of the stomach has materially lessened and the motility has increased, demonstrating the diminution of the atonic condition. It is the thorough emptying of the stomach in the last detailed case that gives hope of a restored or improved functional activity of the previously overstretched viscus.

I submit also a diagram (Fig. 7) of a forceps, designed by Dr. Turnure, one of my hospital internes, as an aid in carrying out Gallet's method of entero-anastomosis. The instrument is a simplification of that proposed by Duroque in 1897.

A CONTRIBUTION TO THE STUDY OF CEREBROSPINAL MENINGITIS.[2]

BY LEWIS A. CONNER, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE HUDSON STREET HOSPITAL; ASSISTANT PATHOLOGIST TO THE NEW YORK HOSPITAL; INSTRUCTOR IN MEDICINE IN THE CORNELL UNIVERSITY MEDICAL COLLEGE.

EVERY year in any of the large hospitals in this city there may be seen a certain number of cases of cerebrospinal meningitis which are manifestly primary, or idiopathic, in origin. In certain years these cases are so considerably increased in number as to constitute a distinct epidemic. This was the case in 1893. This paper is based upon the study of 60 such cases, 13 of which have occurred during the last four years in my own service at the Hudson Street Hospital, and the remaining 47 cases during the last six years at the New York Hospital. It is through the courtesy of the attending physicians to the latter institution, Drs. G. L. Peabody, A. B. Ball, H. P. Loomis, and S. W. Lambert, that I am able to add this second series of cases to my own. Every effort has been made to exclude from this list all cases in which there seemed any ground what-

[1] The larger button was discharged per rectum on the twenty-first day. The smaller one has not yet been found in the feces.

[2] Read before the New York Neurological Society, January 3, 1899.

ever for the belief that the meningeal inflammation was secondary to infective processes elsewhere in the body. In this way a large number of cases of meningitis following pneumonia, empyema, ulcerative endocarditis, middle-ear disease, pyemia, and tuberculosis have been discarded.

By far the most important work of recent years on the subject of epidemic meningitis is that which recently appeared as a report of the Massachusetts State Board of Health upon the recent epidemic in the vicinity of Boston by Councilman, Mallory, and Wright.[1] In this report the very elaborate and careful description of the histologic and bacteriologic findings is especially valuable, and will be referred to later.

The post-mortem examinations in the cases here reported were made either by Dr. George P. Biggs, the pathologist of the New York Hospital, or by myself.

Etiology.—Of the 60 cases, 21 occurred in 1893 (a year in which the disease seemed especially prevalent in various parts of the country), 5 occurred in 1894, 8 in 1895, 6 in 1896, 10 in 1897, and 10 have occurred during the year just past.

Season.—One-half of all the cases developed during the spring months of March, April, and May. Twelve cases appeared during the summer months, 10 in the fall, and 8 during the winter months.

Sex.—Forty-two (or seventy per cent.) of the cases occurred in the male sex.

Age.—Thirty-two per cent. of the patients were under fifteen years of age; forty-three per cent. were between the ages of fifteen and thirty, and twenty-five per cent. were over thirty years of age. The youngest case was that of a child of two months;* the oldest was that of a woman of sixty-five years. The male patients were, as a rule, vigorous, robust persons whose occupations kept them out of doors much of the time—laborers, longshoremen, etc. In only one case was there a distinct history of exposure to cold or wet preceding the attack. In this case the exposure had occurred on the day before the onset. Two of the patients were hospital nurses, but neither had been in attendance upon a case of meningitis. No two of the cases came from the same family, but two young negro laborers who occupied the same room in a lodging house were attacked by the disease within a few hours of each other, and both died within four days of the onset. In two cases (XIII. and XXXVIII.) the symptoms developed after exposure to the hot sun. One of these cases behaved like a case of sunstroke. The patient was brought to the hospital in deep coma, with a temperature of 105.6° F., and the symptoms of meningitis were not recognized until the following day. He died at the end of two months, and the diplococcus intracellularis was found in the meningeal exudate at autopsy.

Post-mortem Appearances.—A post-mortem examination was made in eighteen of the forty-one fatal cases. The appearances of the meninges varied greatly in the different cases, as might be supposed. In the very acute cases marked injection of the meningeal vessels was the most noticeable feature, while the exudate was usually slight in amount, and sometimes was hardly apparent to the naked eye. Cases lasting a week or two usually showed an abundant purulent or fibrino-purulent exudate over the base, beneath the arachnoid, in the sulci, and along the course of the vessels of the convexity; but great variation was seen in the quantity, the distribution, and the character of the exudate.

In the two chronic cases examined the purulent exudate was less abundant, and the thickening and opacity of the arachnoid more evident. In all the cases the exudate over the convexity was seen chiefly in the meshes of the pia, in the sulci, and along the course of the blood-vessels. The lateral ventricles in many of the cases were distended with clear or slightly turbid fluid to such an extent as to cause noticeable flattening of the convolutions, and the ependyma was granular, opaque, and evidently involved in the inflammation. The choroid plexus often showed infiltration of pus and fibrin.

In the cord the greatest involvement was usually in the dorsal and lumbar portions, and always upon the posterior surface. Microscopic examination showed in addition to the meningeal exudate an often extensive involvement of the subjacent brain tissue as seen in the engorgement of the vessels and in the round-cell infiltration, especially along the course of the smaller vessels. The constant involvement of the cranial nerves in the inflammatory process was shown in the few cases in which they were examined. Councilman, Mallory, and Wright, in their very careful description of the microscopic changes, describe the lesions of epidemic meningitis as differing from those of other forms; in the smaller production of fibrin, in the presence in the exudate of a considerable number of large cells often enclosing several leucocytes; in the relatively small amount of endarteritis, and finally, in the greater participation of the brain substance in the inflammatory process, with proliferative changes in the neuroglia and degenerative changes in the ganglion cells and the nerve fibers.

* The character of the meningitis in this case was not proven by autopsy, but since writing this paper a child, aged two months, has died at the New York Hospital, in whom the primary nature of the meningitis was shown by the post-mortem findings, and in which cultures of the diplococcus intracellularis meningitidis were obtained.

Bacteriology.—Councilman and his associates, as a result of their investigations, are convinced that the specific cause of epidemic cerebrospinal meningitis is the diplococcus intracellularis meningitidis, first accurately described and named by Weichselbaum in 1887. In thirty-five post-mortem examinations made by them this organism was found in all but four cases in cultures, in cover-slip examinations of the exudate, or in sections. The organism is found almost altogether in the pus-cells of the exudate. It is composed of two hemispherical portions separated by an unstaining interval and resembles closely the gonococcus. It shows no capsule and is decolorized by Gram's method of staining. It is an ærobic bacterium, but grows scantily and with difficulty on most media. Blood-serum agar was found to be the medium best suited for its growth.

Earlier investigators, Weichselbaum,[2] Jäger,[3] Heubner,[4] Peterson,[5] and others, found the same or a very similar organism in certain of the epidemics, but the weight of evidence hitherto has seemed to support the belief that the specific organism in most of the epidemics and in most of the sporadic cases is the micrococcus lanceolatus or pneumococcus.

Flexner and Barker[6] in their admirable account of the Lonaconing epidemic in 1893 summarize the matter as follows: "The number of bacteriological examinations of uncomplicated cases of meningitis occurring either sporadically or in epidemic form is, up to the present time, not large. There is, however, such uniformity in the results obtained that while it is, perhaps, not to be considered as established for all, yet the majority of cases appear to be caused by an organism which, in its morphological characters and biological properties, is not to be distinguished from the micrococcus lanceolatus." Latimer,[7] writing as late as 1896, arrives at the same conclusion.

A bacteriological examination was made in ten of the present cases which came to autopsy. In three of these the cultures remained sterile; in one case a pure growth of streptococci was obtained; in one (associated with hemorrhage into and about the pancreas) a mixed growth of pneumococci and streptococci was found. In one case the diplococcus intracellularis was found in cover-slip examinations, but the cultures remained sterile. In the remaining four cases examinations of the pus and culture growths showed a micrococcus which, in its morphologic and culture qualities, appeared identical with the pneumococcus. In two recent acute cases in which there was no autopsy, lumbar puncture was made. In one, cover-slip examinations showed a very few diplococci intracellulares. In the second case no organism could be found. A considerable number of cultures from both cases upon blood-serum, glycerin-agar, and plain agar, and in bouillon were made with negative results. In the three autopsies in which the culture results were negative only the ordinary culture media were used, and in view of the now recognized difficulty of growing the diplococcus intracellularis in such media it seems not unlikely that these were all cases of that form of infection.

There can be no doubt that certain epidemics have for their specific micro-organism the diplococcus intracellularis. There seems to be, however, incontrovertible evidence to show that in certain other epidemics the micrococcus lanceolatus stands in causal relation to the disease; while in the sporadic cases reported the micrococcus lanceolatus has been found in much the greater number. Councilman and his associates believe that in every case of epidemic meningitis the exciting agent is the diplococcus intracellularis and that the pneumococcus bears no relation to this disease but that *it* excites a meningitis which is usually secondary to pneumococcus inflammations elsewhere in the body, and that this type of meningitis can be distinguished histologically from the epidemic form.

It seems to me that this view cannot be accepted unreservedly without disqualifying the results of many trustworthy observers, and that at the present time there seems reason to believe that both the diplococcus intracellularis and the micrococcus lanceolatus can give rise to primary cerebrospinal meningitides, which clinically cannot be differentiated, and which, under certain favorable conditions, may appear in the form of epidemics.

Types of the Disease.—All the varieties usually described—the fulminant, the abortive, the acute, the intermittent, and the typhoid or chronic—were represented in the present series of cases. Including in the fulminant type those cases which run a fatal course in about two days, or in less, there were seven cases of that form. The shortest was one lasting twenty-one hours. These cases were all marked by violent and early delirium and coma. Of the abortive type there were two fairly typical examples. Twenty-six cases ran their course within two weeks and may be termed *acute.* No one of these recovered. There were two examples of the intermittent type in which, during the latter part of the disease, the gradual improvement was interrupted periodically by a return, for a short time, of all the symptoms. Thirteen of the cases extended over periods longer than one month and are to be classed with the chronic type. Of these thirteen patients eleven recovered. The longest case, a child of five, recovered at the end of three and one-half months.

Onset.—The onset was sudden in thirty-nine of the cases. The first symptom in four cases was one or more general convulsions. In one case it was sudden violent delirium; in two cases, sudden unconsciousness and coma. Four of the cases began with sudden development of a peculiar mental state in which violent, irrational acts alternated with periods of quiet and apparent rationality. One of these patients (No. IV.), while apparently well, began to destroy the furniture in his room. When taken to the hospital by the ambulance he would be, for some minutes, quiet and obedient and would talk rationally, and then suddenly would begin to fight and struggle violently. His temperature remained normal for some hours after admission, and as there was a history of severe mental shock on the day preceding, the case was not unnaturally looked upon at first as one of hysteria. His temperature soon rose, however, coma developed, and the patient died forty-six hours after the beginning of the attack. Autopsy confirmed the later diagnosis of meningitis. In another of these four cases the admission diagnosis was hysteria.

One or several attacks of vomiting ushered in the disease in six cases. In fourteen cases the disease began with a distinct rigor. In seven it began with sudden and violent headache. In one case an attack of dizziness was the first symptom.

When the onset was gradual the symptoms, in children, were usually restlessness, irritability, fever, prostration, and gradually increasing pain in the head and neck. In adults there was a gradually increasing headache, prostration, pain in the neck, and often vomiting.

Temperature.—Although the temperature curves in the different cases varied enormously, and although on most charts the irregularity was the most striking feature, yet it has seemed possible to recognize several fairly distinct types.

1. A number of cases were seen in which the temperature was normal or subnormal throughout the disease or up to within a few hours of death. None of these patients recovered.

2. Cases in which the temperature was high from the onset, and continued so until death or gradually fell until recovery.

3. Those in which the temperature rose gradually, maintained for some days a moderate height, and gradually fell whether the patient died or recovered. These charts occasionally resembled those of typhoid fever, but they usually displayed a less regular diurnal variation with a greater excursion. Not infrequently would the highest temperature be in the morning.

In the chronic cases the temperature usually ran a low course in the latter part of the disease. In the fulminant cases, when the patients had been brought to the hospital, their temperature was sometimes normal for a few hours, but in every case it rose rapidly, and remained high until death.

Pulse.—The pulse displayed the same marked variation in the different cases as did the temperature, but its behavior, as a rule, seemed to bear no relation to the height of the temperature. Usually, it was very considerably increased in rate, and diminished in force. Retardation of the pulse was by no means a common occurrence. In only four or five cases was it present for any length of time. In two cases, however, it persisted throughout almost the whole course of the disease. Toward the latter part of the disease great irregularity of rhythm and sudden violent changes in rate were common. The pulse was usually of very low tension, and often showed great irregularities of force as well as in rhythm.

Respiration.—In patients displaying active symptoms a very considerable increase in the respiratory rate was an almost constant symptom. This was especially noticeable, as might be supposed, in children, and respirations of 50 or 60 per minute were by no means uncommon in them. In the chronic cases the respiratory rate varied but slightly from the normal. Toward the end of the disease, in fatal cases, Cheyne-Stokes breathing and irregular types were not infrequently seen.

Vomiting was present at some time in the disease in more than one-half of the cases. In twenty-five it appeared at he onset; in thirteen cases only at that time. In fourteen cases it persisted throughout and constituted an important feature of the disease. In some cases it seemed to bear no relation to an ingestion of food, recurring at irregular intervals, and without evident exciting cause. In one case, which at the onset resembled acute gastro-enteritis, there was vomiting of blood. In no case was the vomiting described as "projectile."

Constipation was the usual condition, but diarrhea, sometimes severe, was present in some cases.

Sensory Phenomena.—Pain of greater or less severity was present at some time in almost every instance. Headache was much the commonest form. This usually appeared very early, and was apt to be constant and severe. Occasionally it would be slow in its development, and would never become a prominent symptom. It was most often occipital; sometimes it would seem to involve the whole head, and occasionally it was chiefly frontal. Pain at the nape of the neck usually accompanied the headache, and sometimes was the more prominent of the two symptoms. Aside from these two

common sites of pain, it was not infrequently referred to the back, limbs, joints, abdomen, and chest. Occasionally it was confined to, or was more marked upon, one side of the body.

Tenderness on deep pressure over the upper cervical vertebræ was extremely common. Sometimes it was present over the whole of the vertebral column, and not infrequently it was evident upon tapping the head. In a certain number of cases, especially among children, general hyperesthesia was a conspicuous symptom.

The *reflexes* presented no constant feature. In many instances they seemed quite normal; in others both the deep and superficial reflexes were lost; in still others they were exaggerated.

Photophobia appeared as a prominent symptom in six cases, and was present in lesser degree in many others.

In one case there was anesthesia of the whole of both lower extremities.

Motor Symptoms.—Greater or less rigidity of the muscles of the neck and back was present in almost every case. It usually appeared very early and persisted throughout the course of the disease. In twelve cases there was marked retraction of the head, in addition to the rigidity, and in two cases distinct opisthotonos. A certain amount of rigidity of all four extremities with flexed position of the limbs was common. Rigidity of one-half of the body, with convulsive movements of the other half, occurred in two cases. Severe general convulsions were present in eight cases; in four of these the convulsions ushered in the disease. Muscular twitchings, general, or confined to one side, were observed in nine cases.

The paralytic phenomena included paralysis of all four extremities, of both lower extremities, two cases of hemiplegia (one with involvement of the face and tongue), and paralysis of both upper extremities alone. The motor symptoms of the eyes included convergent strabismus in seven cases, divergent strabismus in two cases, lateral nystagmus in five, conjugate deviation in four, and slight ptosis in one case. The pupils often showed no abnormalities. They were much more apt to be contracted than dilated. Occasionally, they failed to react to light. In a few cases there was marked inequality.

Mental Symptoms.—These included almost every grade of abnormality from simple drowsiness to profound coma, and from slight "flightiness" at night to constant violent delirium. In the case of one patient who recovered consciousness was preserved throughout; in another case, lasting two weeks, there was perfect consciousness up to within a few hours of death. In the fulminant cases delirium or coma was present almost from the beginning. In most of the chronic cases, even of the fatal ones, there were apt to be considerable periods of consciousness during the middle and latter part of the illness. In a large proportion of the cases there were alternating periods of delirium and stupor. The onset of the disease was marked in four cases by a peculiar mental state which was twice mistaken for hysteria.

Eruptions.—Skin lesions of some sort were observed in sixteen of the cases (twenty-seven per cent.). These were most frequently in the form of an eruption of herpetic vesicles confined, usually, to the lips and nose, but occasionally involving a considerable portion of the face and head, and in one case appearing on the back as well. Large urticarial wheals over the entire body were present in one case during the first three days of the disease. These could be produced anywhere by drawing a fingernail over the skin. A hemorrhagic eruption was seen three times. In two cases it consisted of a profuse petechial rash extending over the trunk and extremities. In the third case a macular rash appeared over the trunk, extremities, and very profusely over the face. This became hemorrhagic over the hands and feet, and small hemorrhagic spots appeared in the mucous membrane of the hard and soft palate. Another eruption appeared on the twelfth day as a profuse papular rash over the chest, abdomen, and neck. This soon became vesicular and later pustular, resembling considerably the rash of smallpox, but without umbilication. *Tache cerebrale* was present in many of the cases. A slight jaundice was once seen.

The Blood.—While the blood was not examined in many of the earlier cases, in all the later ones in which it was sought a distinct leucocytosis was observed. Occasionally this was only slight, but usually there was a very considerable increase in the white cells. Blood-counts were made in thirty-three of Councilman's cases, with the result of finding a leucocytosis in every case. This leucocytosis is probably present in all cases of purulent meningitis, from whatever cause, and is not distinctive of the epidemic or primary form.

Spleen.—In fourteen of the cases (twenty-three per cent.) a distinct enlargement of the spleen was recognized clinically or at autopsy. The increase was usually only moderate, but in several instances it was very considerable and the organ could readily be felt some distance below the free border of the ribs. It was usually very soft.

Eyes.—The motor phenomena observed have already been mentioned. In none of the patients who recovered was there disturbance of vision subse-

quently. Unfortunately an ophthalmoscopic examination was made in only a very few cases. In one of these, a chronic case, there was a well-marked optic neuritis which developed four weeks after the onset. No other eye lesions were recorded.

Ears.—Pain referred to the ears was present in several cases, but in none did examination show evidence of middle-ear disease, although observers have mentioned this as a not infrequent complication. In two cases there was bilateral deafness. One of these patients recovered completely and the other had improved somewhat when discharged from the hospital.

Complications.—Involvement of the joints was seen in four cases. In three of these the appearances were those of acute articular rheumatism, with involvement of several of the large joints, and the cases were looked upon as such when first seen. In the fourth case there was a large serous effusion into the right knee-joint which disappeared at the end of ten days. Cultures from this fluid, in the ordinary media, remained sterile. The joint symptoms in every case appeared very early in the attack, usually at the onset.

Pneumonia.—Some form of pneumonia was present in seven of the cases. Two of these were apparently instances of hypostatic pneumonia and occurred as a terminal condition. The other five cases gave the usual physical signs and symptoms of lobar pneumonia. This developed in every case *after* the onset of the meningitis. In one case the pneumonia developed after convalescence had become established. Two of these patients recovered, two died without autopsy, and the fifth was removed from the hospital during the illness, so that in none of the cases was it possible to determine positively the character of the inflammation and of the exciting organism.

Nephritis.—Traces of albumin were found in the urine of a large proportion of cases. In ten of them (seventeen per cent.) there were evidences of an acute nephritis of greater or less severity. This regularly made its appearance late in the disease. In one case, a child of ten years, there suddenly developed during convalescence a violent attack of hemorrhagic nephritis, which was eventually recovered from.

Hemorrhage into the Pancreas.—A very remarkable complication (or association) was that of extensive hemorrhage into and about the pancreas. The patient (Case X.), an Italian male, aged forty-five years, after having violent headache with pain, tenderness, and rigidity of the neck for three days, became delirious, and later comatose, and died on the sixth day. The autopsy showed, beside extensive purulent exudate over the convexity, base, and cord, extensive and very recent hemorrhage into and about the head of the pancreas, the whole forming an irregular mass as large as an orange. There was neither necrosis of the pancreatic tissue nor suppuration. Cultures from the meningeal exudate showed a mixture of pneumococci and streptococci. Cultures from the blood, kidneys, liver, spleen, and pancreas remained sterile.

Diagnosis.—When the symptoms are well developed the recognition of cerebrospinal meningitis offers no difficulties. In the early days of the disease, however, a case may be very puzzling. In this series two of the cases were at first looked upon as acute articular rheumatism. Two other cases were for a time believed to be typhoid fever, and were treated as such, and two others when first seen were thought to be cases of hysteria.

The symptoms, it has seemed to me, which are most constant and most to be relied upon in the beginning of the disease are rigidity of the muscles of the back of the neck and tenderness on pressure over the cervical vertebræ. These were rarely absent.

In differentiating the cases of meningitis with gradual onset from typhoid fever, the presence of a leucocytosis and the failure of the blood to respond to Widal's reaction may furnish valuable aid, as was the case in Case LX. of this series, in which the symptoms very closely simulated those of typhoid fever, and in which the meningeal symptoms were not prominent until late in the disease.

The spleen is so frequently enlarged in meningitis that the recognition of its enlargement should not be given much weight as favoring typhoid fever. Confusion between meningitis and hysteria can, of course, exist only at the outset.

The separation of the primary form of meningitis from those which are secondary depends upon the exclusion of the various conditions which may give rise to the secondary forms, or upon the detection in the fluid obtained by lumbar puncture of the organisms associated with the primary form. The age of the patient, I believe, usually offers but little help. While it is doubtless true that in children tuberculous meningitis is more common than is the primary cerebrospinal form, yet the latter is by no means uncommon, as may be seen from the fact that thirty-two per cent. of the present series of cases occurred in children below the age of fifteen years. In a child who is free from all hereditary taint of tuberculosis, and in whom a careful examination fails to reveal evidences of tuberculosis of the lungs, lymph glands, or other structures, the chances are, I believe, in favor of a meningitis being of the primary cerebrospinal form.

Lumbar Puncture.—Much the most reliable means of diagnosis exists in the examination of the fluid obtained from the spinal canal by puncture between the lumbar vertebræ. This has now become a recognized method of diagnosis, and will often furnish valuable information at the time when it is most desired, that is, at the beginning of the disease. The procedure is not difficult, and if carefully performed is free from danger. Lumbar puncture was carried out in sixty-five of the cases of Councilman, Mallory, and Wright. In thirty-eight of these the diplococci were found either in cover slip examination or in cultures. Great difficulty was had in obtaining growths in the cultures except when large quantities of the fluid were used and many tubes inoculated, and even then the colonies were usually very few.

In both of my cases in which lumbar puncture was made the cultures remained sterile. In one a few diplococci intracellulares were found in the cover-slip preparations.*

Prognosis.—Of the patients whose cases are here reported nineteen recovered, a mortality of sixty-eight per cent. This, curiously enough, is exactly the mortality in the 111 cases reported by Councilman and his associates. Flexner and Barker state the mortality in the Lonaconing epidemic as forty per cent. In other epidemics the death-rate has ranged from twenty to seventy per cent. Most of the cases in which recovery takes place belong to the chronic type. Cases beginning with general convulsions and in which delirium and coma appear at the onset are almost always fatal. A continuous low temperature is by no means necessarily a favorable sign. In every case of this series in which the temperature was normal or subnormal throughout most of the disease the patient died.

In conclusion I wish to call attention to the comparative frequency of cerebrospinal meningitis in this city; a frequency greater than seems to be commonly supposed. These cases are by no means confined to periodical epidemics, but occur in relatively uniform numbers year after year. If they are all merely sporadic cases of the epidemic form then it must be admitted that that disease is endemic with us. The determination of the relation of these cases to the epidemic form rests almost wholly upon the careful bacteriologic examination of cases coming to autopsy and of the cerebrospinal fluid obtained during life, and it should be possible within a few years to settle the matter definitely and conclusively.

* Since this paper was written lumbar punctures have been made in two cases of meningitis at the New York Hospital and in one at the Hudson Street Hospital, and from all fairly abundant growths of the diplococcus intracellularis were obtained.

CLINICAL LECTURE.

BRAIN INJURIES, THEIR DIAGNOSIS AND TREATMENT.[1]

BY CHARLES PHELPS, M.D.,
OF NEW YORK;
VISITING SURGEON TO BELLEVUE HOSPITAL.

I PRESENT to you two cases of brain injury, both of recent occurrence, and in both of which symptoms have been typical.

This patient, the first, a boy ten years of age, fell down a flight of stairs two days ago. He was found by the ambulance-surgeon, profoundly unconscious, with widely dilated pupils, which were irresponsive to light, a cold, pale, but not moist skin, frequent stertorous respiration, a feeble, irregular pulse of 140, and a subnormal temperature of 97°. On immediate admission to the hospital he was conscious, but could be aroused only for an instant; his pupils were moderately dilated and were responsive to light; fecal and urinary control were lost, and there was a hematoma in the right frontal region. After reaction was established, some hours later, he had several attacks of vomiting, after each of which his mental condition became brighter.

Yesterday he slept a greater part of the time, and was less stupid when awake; fecal and urinary control had been regained with the restoration of consciousness, and the pupils were normal.

To-day his temperature, pulse, and respiration are normal, and beyond a little vertigo and some weakness he is without symptoms.

There can be no doubt that this was a case of simple general contusion of the brain, with severe general shock, upon which the most urgent symptoms depended. The loss of consciousness and succeeding mental torpor, the pupillary conditions, and the later attacks of vomiting were of cerebral origin, but the feeble pulse, rapid respiration, and subnormal temperature, and the loss of fecal and urinary control may be attributed to lesion of the spinal and sympathetic centers. At first, while the extent of brain lesion was obscured by the condition of general shock, prognosis was uncertain; but the speedy return to consciousness and to normal pulse and temperature conditions without the supervention of new symptoms referable to cerebral injury, minimize the possibility of any unfavorable development in the case, though a longer time must elapse before all danger is past. Some instability of the cerebral circulation is likely to continue for

[1] A clinic conducted at Bellevue Hospital, May 23, 1899.

months, or even longer, and during that time the patient's resistance to the effects of ordinary cerebral excitement, as mental exertion or excitement, exposure to the sun's rays or to movements which may cause vertigo will be diminished.

The second patient, a man fifty years of age, was found unconscious in the street and at once brought to the hospital. He was still unconscious and there was a rather profuse hemorrhage from the right ear. The right pupil was moderately dilated and irresponsive to light. His temperature was 99.2°, his pulse 68, and his respiration 36 and a little stertorous. Consciousness was restored an hour later, and at the end of four hours hemorrhage from the ear had ceased and temperature had risen to 100°. The following day there was a general paralysis of the right side of the face which still continues. No other symptoms have been developed. Pulse temperature and respiration have been, for some days, practically normal.

The diagnosis in this case is not difficult, A fracture of the cranial base extending through the right petrous portion, some slight supradural hemorrhage in the right middle basic fossa, and probable cerebral contusion without laceration.

The fact and situation of the cranial fracture is indicated with certainty by the hemorrhage from the ear. The absence of such hemorrhage does not exclude the possibility of a fissure of the petrous portion, for the auditory canal and tympanum may remain intact, but, as a positive symptom, I believe it to be pathognomonic. I have never failed in post-mortem examination to find this fracture when there had been hemorrhage from the ear during life. I have seen but one exceptional case in which there was ruptured tympanum and external hemorrhage, from concussion, and without basic fracture; this was from a pistol-shot wound at close contact just in front of the ear. Such an instance may be regarded as belonging to a special class of fractures and constituting the sole exception to an otherwise absolute rule. Falls from enormous heights or crushing violence inflicted upon the head, so long as no fissure lays open the auditory passages, never occasion this symptom if the necropsic examination of a very large number of cases may be trusted. The one source of possible error in estimating this symptom may be excluded by a sufficiently careful examination of the external meatus in order to determine that the blood has neither trickled into the ear from the wound of the scalp nor been derived from a wound of the canal itself.

The fracture of the cranial base in its petrous portion is confirmed by the occurrence of another symptom, the facial paralysis. This condition might be due either to a central lesion or to an injury of the facial nerve during its passage through the aqueductus Fallopii. Its central origin in this instance is impossible from its late appearance and from the absence of general symptoms of cerebral laceration or limited contusion. It is evidently not due to compression by osseous displacement from the fact that it was not a primary symptom. Its occurrence on the second day after external hemorrhage had ceased points to the compression of the nerve by coagula formed in the osseous canal through which it passes to its cranial exit.

The dilatation of the pupil might be referred to a general cerebral contusion or to pressure of blood upon the third nerve in the middle fossa as described by Mr. Hutchinson. In this case it probably results from blood-pressure as the cerebral injury is slight.

A cerebral lesion undoubtedly did exist—it always exists when unconsciousness is a symptom. Even if intracranial hemorrhage is a complication, it is the interference with cerebral nutrition, back of the hemorrhage, which is the proximate cause. In the case of this man a slight general cerebral contusion probably occasioned the transient loss of consciousness, the only symptom of cerebral injury. A limited contusion is always lost in a general cerebral lesion of which it forms a part. A severe general contusion or a laceration occasions a greater rise of temperature, more extended loss of consciousness, and other symptoms of greater urgency.

The prognosis is absolutely good. No symptoms remain except the facial paralysis, which may be expected to linger. The length of time which has elapsed since the injury was received, without the development of secondary symptoms, as in the other case, is a guarantee for the future.

In such cases as these—basic fractures not of gunshot origin and cerebral contusions, cases without intracranial hemorrhage or implication of the vault—no question of operation can arise. Treatment is very simple and has only to follow symptomatic indications. If general shock is pronounced, as in the case of the boy, free hypodermic administration of heart stimulants will be demanded. In the absence of high temperatures or delirium there will be no occasion to resort to the ice-cap. Quiet, moderate liquid nourishment, and daily evacuation of the bowels are usually all that is required. If the patient is restless morphia is the preferable sedative.

Such cases, gentlemen, are not clinically sensational, but their observation and study are very useful and instructive even to the general practitioner.

CLINICAL MEMORANDUM.

ACUTE YELLOW ATROPHY OF THE LIVER.

By CHARLES H. BROWNING, M.D.,
of Oberlin, Ohio.

W. G., a negro, aged nine years, was first seen by me October 1, 1898. His mother gave the following history: The boy had always been well until the previous summer. While in the country he had had what was called an attack of dysentery lasting about ten days, with watery mucous discharges, but no blood. He seemed to recover from this, but from about the first of September complained of severe headaches. He attended school between the 5th and 17th of September, and then was kept at home because of headaches, loss of appetite, and a sense of oppression.

About the 20th of September a mild icterus appeared. He first saw a doctor on this account on Saturday the

25th. During the following week his jaundice seemed to decrease, the fecal discharges were dark in color, and he seemed to be improving. On the following Friday night he awakened with a sharp, cutting pain in the hepatic region, was nauseated, and vomited. He had at the same time some pain on the left side. The muscles of his hands and arms were cramped, more on the right side. He had muscular twitchings while asleep. During the following day there were frequent fluid evacuations of the bowels.

I saw him first during the afternoon. I found him playing about the house, quite comfortable but weakened by the thorough catharsis, and slightly nauseated. His general appearance was good; tongue moist, and quite clean. The icterus was of a moderate degree. He had a temperature of 99.4° F., and a pulse of 118. His liver was palpable 2½ fingers' breadth below the costal margin, and extended fully half way between the ensiform cartilage and the umbilicus. It was sensitive and hard. The spleen was not palpable. Three hours later he complained of sharp, sticking pains in the right hypochondrium, which were so severe as to make him hold his breath; and his fingers and forearms, especially on the right side, were contracted. I saw him half an hour later just as the paroxysm was over, and found him asleep with a temperature of 98° F., and pulse of 96. He had no chill or sweating at any time. Through the night he rested well, slept almost continually unless aroused for medicine, but talked a great deal in a low, muttering way in his sleep. Once during the night he vomited food.

On Sunday morning at ten o'clock I found him with a temperature of 100.4° F., and a pulse of 120, rhythmical and regular, quite full and bounding. He was quite drowsy, but had had no anodyne for some hours. He was easily aroused, and took medicine and nourishment. The icterus was more marked than on the previous day. I examined the blood and found no increase in leucocytes. During my visit he became restless, and complained of the same sharp pain in his right side, and the right hand and arm were contracted. I gave him morphin hypodermically. At two o'clock his restlessness had developed into a wild delirium. He lay on his left side or face, with his head drawn somewhat backward, but not forcibly so. He simply seemed to breathe better in that position. When disturbed he would throw himself in such a way that it was necessary to restrain him by force. It was impossible to make any examination of the abdomen until complete morphin narcosis had been induced. His respirations at this time were 28, his pulse 132, his temperature 103.4° F. The abdomen was considerably distended, and it was impossible to palpate or percuss any liver dulness. The abdominal percussion was almost entirely dull tympanitic in character, not the usual tympanitic note of intestinal distention by gas. Very little gas was passed through a rectal tube. The physical signs seemed almost to indicate that there was a general peritonitis. As the effects of the morphin wore off toward night it was evident that there was a deepening stupor. His pupils dilated and his breathing became stertorous, but at no time slower than 28 per minute, and as the distention increased it rose to 32. It was not possible to arouse him at seven o'clock. At eleven o'clock at night he had a general convulsion lasting perhaps ten minutes. When I saw him a few minutes later his condition was moribund, and he died at midnight in a slight convulsion. After death there was no relaxation of the muscular spasm. Rigor mortis was immediate and lasted sixteen hours.

At the autopsy the abdomen contained a small quantity of bloody or bile-stained serum. The liver was greatly diminished in size, its surface was smooth, it was quite firm in consistency, and on section was very much bile-stained and of a mottled appearance of saffron and yellow. The gall-bladder was greatly distended with a clear fluid very like the white of egg, slightly stained with bile. The common bile-duct was completely closed and from its mouth exuded a drop of pus. The spleen seemed enlarged, and was slightly softened and of a dark-red color. The kidneys were enlarged, and loaded with bile pigments.

The peritoneal surfaces were perfectly normal as far as we could determine except that they were hyperemic. The great omentum showed occasional areas of subperitoneal hemorrhage, and the mesentery of the small intestine was one mass of small blood-clots, some darker in color than others, but covering almost the entire surface of the mesentery. I believe the dulness of the tympanitic percussion-note was at least in part due to these mesenteric hemorrhages. I can give no cause for the intestinal distention except the destruction of the mesenteric arteries, cutting off a large part of the blood supply from the gut.

There was a slight serous exudation in the pleural sacs. The lungs were somewhat congested, but for the most part, crepitant. The heart was found in systole, very pale, and bloodless, but apparently of normal size. The only urine that could be obtained was that at autopsy. It was acid in reaction, of a specific gravity of 1009, and contained a small amount of albumin but no sugar. Bile pigments were present in large quantity. There were a few granular casts, and large numbers of leucin crystals. Sections of the liver showed large areas of tissue necrosis, but the length of time between death and the autopsy made it impossible to obtain satisfactory specimens.

As to diagnosis, I have hesitated to say acute yellow atrophy because of the extreme rarity of the affection, but after reviewing nearly half of the 200 reported cases I am led to believe that this was an acute atrophy following a simple catarrhal jaundice. There was very little vomiting during the course of the illness, and no general convulsions until just before death. It is to be regretted that the tissues were not satisfactory for microscopical work.

MEDICAL PROGRESS.

Biological Conditions in the Families of Epileptics.—BECHET (*Arch. de Neurol.*, March, 1899) from a study

of many epileptic families, draws the following conclusions:

1. The duration of life, the longevity, is considerably less in the ascendants of epileptics, than it is in normal families.

2. The rate of birth, the natality, is higher in epileptic families than is the average in normal ones. Epileptics usually belong to large families. The powers of reproduction of epileptics fall rapidily to a lower level than normal, so that epilepsy tends toward sterility.

3. The life energy, or vitality, is much less in the families of epileptics, than in normal families. It is during the early years that the vitality is the lowest, in epileptic families, just as in normal families, but this is even more marked in epileptic families than in others.

4. The morbidity, that is the frequency of different diseases in epileptic families, presents some curious characteristics. Pulmonary troubles, especially phthisis, is very common in the ascendants of epileptics. Cerebral affections, meningitis in particular, occur with frequency in their descendants. Neurosis and insanity are rare, according to the researches of this author. These results confirm the opinion of Lasegue that epilepsy is not hereditary.

THERAPEUTIC NOTES.

Ipecac in Feeble Digestion. — Mathieu (*La Presse Med.*, April 5, 1899) thinks that ipecac is one of the best remedies to excite the stomach when the motor action is feeble. He prescribes it in minute doses. Following are two of his favorite prescriptions:

℞ Tinct. ipecac. } aa . . . 3 iij.
" columbæ }
" gentianæ }

M. Sig. Take 5 to 10 drops in a little water after eating, and repeat the dose in a half-hour, and again in an hour.

℞ Tinct. ipecac. . . . . 3 j
Saccharin . . . . . gr. j
Menthol . . . . . gr. ijss
Alcohol 80 per cent. . . . . 3 vjss
Syr. simplicis . . . . . oz. ijss.

M. Sig. Two to 4 teaspoonfuls in divided doses after eating.

The Rectal Temperature of a Child.—By examination of 100 children of different ages, Hamburger (*Centralbl. für Inner. Med.*, April 1, 1899) has found that a thermometer, which is passed 5 cm. (2 in.) or more into the rectum of a child, will record higher than ordinary temperatures. A constant temperature was reached when the bulb of the thermometer was a distance of 10 cm. (4 in.), from the anus. At this depth the highest temperature of the body is recorded in less than two minutes, and is at least 0.5° C. (0.9° F.) higher than the axillary temperature.

Gonorrheal Epididymitis Quickly Relieved by Salicylate.—Picot (*Gaz. heb. de Med. et de Chir.*, April 16, 1899) has used salicylate of soda in the treatment of gonorrheal rheumatism with great success. The patient should first be given a thorough purge with sulphate of magnesia, an ounce or more. The next day, the intestine having been thoroughly emptied, and rest in bed with elevated testicles being enforced, the salicylate is given in four doses of fifteen grains each. This is repeated each day as long as is necessary. If the medicine is stopped too soon the symptoms will reappear. In ordinary cases the swelling and pain and induration quickly disappear. It may be necessary to repeat the Epsom salts, as it is of the first importance to keep the bowels open during treatment.

A New Remedy for Tapeworm. — Lauren (*Therap. Monatschefte*, April, 1899) found that the anthelmintic property of aspidium felix mas is possessed by the roots of some other ferns, and especially by aspidium spinulosum, a variety which is far commoner than the felix mas, and therefore cheaper. Having made an etherial extract of the roots of this variety, he cured himself of a tapeworm with which he happened at that time to be afflicted, and afterward administered the medicine to other patients with complete success. In all cases but one a single dose brought away the head. There were no unpleasant symptoms in any instance. The dose was 4 grams (1 dram), and the usual precautions of two-days' previous starvation, and catharsis, were observed. Later Lauren found that the remedy has been considerably used in Finland, in place of felix mas, although not under its own name. It appears, therefore, to have been sufficiently tested to warrant its general use, in localities where felix mas is scarce or expensive.

Massage of the Liver for Biliary Colic.—Moebius (*La Presse Med.*, April 15, 1899) has found a very simple means to overcome or diminish the intensity of attacks of hepatic colic. A deep inspiration is taken, lasting five seconds, and then the breath is held for twenty or thirty seconds in full inspiration, before it is allowed slowly to escape. After a pause of ten or fifteen seconds, the deep inspiration is repeated. This exercise, which is a veritable massage of the liver, may be carried out in a prone or upright position, but the effect is most marked if the patient leans back in an arm-chair resting his forearms on the arms of the chair. The lack of deep respiratory movement is said by this author to favor cholelithiasis, which is much more common in women than men, the difference being due he affirms, to the interference with respiration by the corset. These respiratory exercises ought to be regularly gone through with as prophylactic measures by those persons who are subject to biliary colic.

Cure of Traumatic Tetanus by the Injection of Carbolic Acid.—Pieraccini (*Rev. de Therap.*, March 15, 1899) relates a case of the cure of traumatic tetanus by the injection of carbolic acid, in daily doses of 1.5 minims. The result is the more remarkable, as, according to the report, the case was a severe one, and treatment was not begun until seven days after the onset of symptoms.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 3, 1899.

THE AMERICAN MEDICAL ASSOCIATION.

The principal annual event, so far as the medical profession of this country is concerned, will occur at Columbus, Ohio, next week, June 6th to 9th. Columbus is not far from the center of population of the country, and all signs give promise of a large and interesting meeting. Hostile critics may carp at the quality of the scientific procedures of these annual convocations, but those who have the management of them in hand, as well as the host of general practitioners who come up to the shrine yearly, realize that the functions of such an assembly are many, and that they fulfil their mission admirably. Other medical organizations may adhere more closely to their scientific work, and conduct it perhaps from their standpoint on a higher plane, but the outing that attends these general meetings and the acquaintance and good-fellowship there engendered, together with the stimulus for higher things, is ample recompense for the sacrifice involved.

The division of the Association into sections for annual meetings, with a general meeting once in two or three years, would certainly impair the usefulness of the organization and rob it of the many valuable features of which we have spoken.

The geographical center of our nation, including Alaska and our new possessions, is moving rapidly toward the Western coast. Future meetings at such a center may involve long journeys for the majority of the members, but the outing will be greater, and for those years in which it meets on the Pacific Coast travel and recreation must be the features.

The meeting at Columbus presents a program replete with scientific interest and instruction, and the Medical News will present next week a prompt and interesting report.

"KOPLIK'S SPOTS" IN MEASLES.

We present this week, from Dr. Koplik himself, an article illustrated in colors on this important sign of the early stage of measles. The presence of these spots before any other definite sign of measles is discoverable, and their specific relation to that disease and no other, has been confirmed from so many quarters that there can no longer be any doubt of its positive value. Its recognition will shorten, as a rule, by at least twenty-four hours the period of uncertainty and delay which usually attend the beginning of a case of measles. When once its presence is recognized the diagnosis can be made with assurance. This will prove not only a source of personal satisfaction to the physician in permitting him to make the final diagnosis earlier, but will enable him to begin much more promptly definite quarantine precautions to prevent the spread of the disease.

It is with no little satisfaction that we announce this practical discovery as the result exclusively of American clinical observation. There is to date, we believe, absolutely no counter claim to priority of discovery. It is remarkable that these easily recognized lesions of the buccal mucous membrane should have escaped during all these years the acute observation of so many experienced clinicians. This fact but emphasizes the necessity there is in medicine of seeing things with one's own eyes, and not catching merely the salient features of a case and then filling in on traditional lines its special aspects and minute details.

We are pleased to note moreover how readily good clinical work meets with recognition abroad. Considerably more than a year ago Slawyk, Pro-

fessor Heubner's assistant at Berlin, published an article in the *Deutsche Medicinische Wochenschrift* confirming Koplik's discovery and acknowledging its great practical value. Last year Professor Heubner, himself, who is Henock's successor in the Chair of Children's Diseases at Berlin, made Koplik's spots a special feature of his clinics on the infectious diseases at the Charité, and insisted on their significance. Acknowledgment as ready and immediate has been accorded in other prominent children's clinics in Europe. Koplik's spots may, therefore, be considered an integral part of the classical symptomatology of measles in the sense that it must enter into the body of medical teaching on that disease.

Unfortunately here in America there seems to have been a certain feeling of indefiniteness as to the exact condition described by Koplik, and its exact location on the oral mucous membrane so that his communications on the subject have not received the attention they deserved. We are glad to be able to show in this issue that a number of American physicians have seen the condition described and recognized its value. We sincerely hope that our present review of the subject will set this very important and practical matter properly before the profession in this country.

THE FIELD OF CLINICAL OBSERVATION AND ANOTHER SIGN IN MEASLES.

It is the custom to think and to say that the field of clinical observation has been so thoroughly worked over that it is almost hopeless to look for any new discoveries in it. Notwithstanding this, however, there is pointed out every now and then some hitherto unobserved symptom, some new relation of disease, some significant combination of disease appearances, or some new etiologic trait that serves to make a disease entity clearer. Marie of Paris, though but comparatively a young man, has improved, in most commendable fashion, some of the magnificent opportunities presented by the large institutions in and around the French capital to enrich medical literature with some hitherto undescribed types of disease, the material for which has been gathered with marvelous synthetic intuition. Marie's disease, acromegaly, pulmonary osteopathy, the bulbous fingers and toes of thoracic conditions, and some very interesting groupings in nervous and trophic disorders have been the result of this one man's clinical activity during less than fifteen years.

This example indicates that there is still a very hopeful field in clinical observation. The article of Dr. Koplik in this week's issue is an even more striking confirmation of this, for if there is a subject whose clinical symptomatology seemed reasonably complete and to which it appeared idle to hope for any important additions it is that of the acute exanthema, the ordinary diseases of childhood.

It is interesting to note in this connection that another observer, something over a year ago, pointed out another sign in measles that had not previously been noted and which he hoped would prove to be pathognomonic of the disease at an early stage. This is the friction fremitus which, as Bolognini pointed out, may be felt over the abdomen of children sick with measles before any rash or other characteristic sign of the disease has appeared. He attributed it to a very early eruption of the measles-rash upon the peritoneal surfaces, parietal and intestinal, the consequent inflammatory roughness and dryness causing the friction and fremitus. Other observers have confirmed the presence of this sign in measles but have found it in other diseases also, notably in various intestinal affections. It is not pathognomonic of measles, therefore, and does not occur in every case. The exact significance of the friction fremitus has not yet been decided, but undoubtedly the observation adds to our knowledge of the effects of the exanthemata and severe intestinal diseases, by calling attention to the fact, that the peritoneal surfaces are very often affected in these pathological conditions. This brings us more and more to the realization of the constitutional nature of these diseases and their liability to affect any and every part of the system.

No further evidence than the pregnant suggestiveness of these observations is needed to demonstrate that there is still a valuable field open to careful clinical observation and that its rewards are by no means impossible of attainment. So much valuable clinical material is passing through the hands of American physicians that we cannot but express the hope that American acuity of observation will give us each year some important addition to our clinical knowledge of disease, not the theoretical conclusions of the laboratory but the invaluable results of observation in the sick room and the hospital ward.

MEDICAL STUDY ABROAD.

THIS is the season of the year when, with graduation exercises just past or his service in a hospital just concluded, many a young medical man is apt to think seriously of the question of spending some time in medical study abroad. There are those who say that the European medical experience should come after some years spent in practice, at a time when the young physician is better able to judge of the character of the work to which he wishes to devote himself. This plan undoubtedly, in theory at least, has its decided advantages. Unfortunately its application in practice is almost impossible. A few years spent in practice are apt to bind the young physician fast to his place in life; he does not feel that he can afford to leave his clientele just at a time when he is beginning to be appreciated. And so the roseate dream of meeting and hearing Europe's greatest medical men is allowed to fade into oblivion, or attains fulfilment only in a few hurried months of travel and supposed medical observation during a vacation abroad.

Of the advantages of a closer contact with the great makers of medicine in other countries it seems scarcely necessary to speak. Here in America we owe not a little to the impetus that has been acquired by such contact in the past. Not that American physicians absolutely independent of foreign medical influence have not accomplished work of the highest order, but the personal contact with great teachers abroad has been for many in the past and is at present a source of most active inspiration and of suggestive and enthusiastic devotion to scientific medicine.

As to whether it shall be worth the while to spend some time in foreign study each one must judge for himself. For the ordinary practitioner perhaps not so much is to be gained. For one who hopes some time to be a teacher of others (and to whom does the divine afflatus of wishing to impart knowledge not come at some time in life?) a European trip is almost indispensable. The broadening effect of travel at a susceptible time of life can scarcely fail to have its effect upon the individual's entire after life.

There are certain practical problems connected with a trip abroad; the where, the when, the how to go, the what to look for, and from whom, are sometimes a mountainous molehill in the prospective medical tourist's path. To help him over this we have arranged to publish during June a series of letters (the first one appears in this issue) from students in various parts of the country who have just completed a prolonged stay, two years or more, abroad. They will give as the results of their experience abroad such practical points as they consider would have been helpful for them to have had on setting out. The letters will include experiences in Vienna, in Berlin, in Paris, and a glance at the minor German universities by one who has visited many of them. At least one communication will give some details of a woman physician's experience abroad and her agreeable surprise to find that, contrary to advice in the matter, even in Vienna there is an excellent field for medical work by women.

ECHOES AND NEWS.

The Trustful Medical Man.—One Harry Van C. Homans, of the broker's firm of Eliott & Homans, New York City, has filed a petition in bankruptcy. The list of his creditors is headed by the names of twenty-nine doctors, to all of whom he owes money.

Cholera Outbreak in India.—Cholera is raging in Karachi, the principal seaport town of Sinde; 232 new cases were officially reported on May 24th, and 208 deaths for that date. The official returns show a total of 1197 cases and of 1099 deaths since the epidemic began.

Appointments in the United States Marine Hospital Service.—Walter E. Merrill of Maine, appointed acting assistant-surgeon, assigned to duty at Portland, Maine, May 11, 1899. W. S. Henderson of Michigan, appointed acting assistant-surgeon, assigned to duty at Port Huron, Michigan, May 11, 1899.

A Russian University for Women.—A project is under way in Moscow to found a university for women, to have three departments, medicine, science, and mathematics, in which the teaching shall be on a level with that in the men's universities. A million rubles has already been set aside for the purpose by the will of W. J. Astrokow, recently deceased.

Officers of the American Gynecological Society.—At the recent meeting of this society the following officers were elected for the ensuing year: President, George J. Englemann of Boston; vice-presidents, Edward L. Duer of Philadelphia and Seth C. Gordon of Portland; secretary, J. Riddle Goffe of New York; treasurer, J. Montgomery Baidy of Philadelphia.

Suicide of a Centenarian.—Francois le Merle, aged ninety-nine years, was oppressed with the idea that he

could not die, and so instead of rejoicing in the advanced age, which made him an object of envy to most people who knew him, he went to a railroad crossing close by his home, near Perigueux, France, and threw himself in front of a midnight train. He was cut in pieces.

Bubonic Plague Spreading.—Four cases of the plague were reported at Alexandria, in Egypt on May 24th. M. Guillain, the Minister of the Colonies, announced on May 24th that Grand Bassam, a French town in Upper Guinea, on the African Gold Coast, had been evacuated owing to the ravages of yellow fever. It is elsewhere stated that the sickness at Grand Bassam is really the bubonic plague.

Examination for the Marine Hospital Service.—A board of officers will be convened at New York City, Tuesday, June 27, 1899, for the purpose of examining candidates for admission to the grade of assistant surgeons in the United States Marine Hospital Service. Applications for this examination must be received on or before June 24th. For further particulars apply to the Supervising Surgeon-General, U. S. Marine Hospital Service, Washington, D. C.

The Smell of the Earth.—Nuttall has determined that the smell of freshly turned earth is due to the growth of a bacterium, the cladothrix oderifera, which multiples in decomposing vegetable matter, and more rapidly in the presence of heat and moisture. Hence the odor is especially marked after a shower, or when moist earth is disturbed. In dry soil the development of the bacterium is arrested, but it is immediately resumed with vigor, as soon as moisture is restored.

To Prevent the Spread of Disease by Physicians. — The boards of healths of Lausanne and of Zurich in Switzerland, have offered to physicians who have scarlet fever or diphtheria patients, the free use of the long gowns which are employed by the sanitary inspectors. The doctor may slip one of these over his own clothing when he enters the infected premises, and slip it off when he comes out, leaving it there to be disinfected by the authorities when the patient has recovered.

Denies Mrs. Lathrop's Request.—The New York State Board of Charities has refused the application of Mrs. Rose Hawthorne Lathrop for articles of incorporation for the Cancer Hospital for Women, which she has been conducting in New York City for several years. Dr. Stephen Smith, to whom the matter was referred, stated that the Department of Charities hospitals can care for all such patients as Mrs. Lathrop seeks to reach, and can do it better than she, since there are in the hospitals trained nurses and competent visiting and resident physicians in attendance.

Hysteria in a Cat.—A nine-months' old kitten, very fond of play, was one day bitten in the back by a dog. Thereafter, it dragged its hind legs, and did not move its tail, just as if the cord had been crushed. Later it fell from the first story of the house. It was instantly cured and used its legs and tail as well as ever. It is evident that the shock of the fall produced a psychic effect sufficiently powerful to overcome the idea of paralysis. That the trouble was only a hysterical paralysis was further shown by the preservation during the whole time of the functions of bladder and intestines.

The Fate of Schlatter's Patient. — The woman from whom Schlatter removed the whole stomach for carcinoma lived not quite fourteen months after the operation, and died of multiple cancerous lymphatic nodules, and the resultant cachexia. There was no trouble during this period in keeping up the nutrition of the patient. The autopsy showed that there was no attempt either on the part of the duodenum, or of the esophagus, to dilate and form a pouch, as was observed by Czerny after removal of the whole stomach in a dog. The food taken passed directly from the esophagus into the intestine, and that intestinal digestion was sufficient to supply her wants, was shown not only by the long continuance of life, but by the fact that for a considerable period after the operation she gained in weight.

The New York Woman's Medical College Abolished.—The thirty-first and last annual commencement exercises of the Woman's Medical College of the New York Infirmary for women and Children were held on the evening of May 25th. There were eighteen graduates of whom twelve have secured hospital positions. The Medical Department of Cornell University which has been established in New York City, and which offers to women advantages in medical education that the Woman's College could not offer, has left the latter, in the opinion of its trustees, without adequate reasons for continuing its existence. The undergraduates of the college are to pursue their studies at Cornell. The closing of the college will not affect the Infirmary for Women and Children, of which it has been an adjunct.

Geophagy.—The habit of eating earth, or geophagy, as it is technically called, is more widespread than is generally supposed. In some parts of Germany a fine clay is spread upon bread, under the name of stone-butter. In upper Italy and in Sardinia earth is sold in the markets. In the extreme northern part of Sweden and in the peninsula Kola an earth composed of infusoria and called mountain flour is baked in bread. In Persia earth is used in the manufacture of certain sweetmeats. In tropical regions the use of earth as an article of food is well-known; but it is also employed as a medicine in Nubia, and among different tribes its use has a religious meaning as well. Many explanations are offered for such a widespread custom. It is not impossible that these various earths have more or less flavor, and that they supplant to a certain degree the use of salt.

Commencement at Rush Medical College.—The commencement exercises of Rush Medical College were held May 25th. The degree of Doctor of Medicine was conferred upon 166 students. In addition to this, special honors were awarded various members of the graduating class. Dr. Arthur Dean Bevan, Professor of Surgical Anatomy in the college, has been transferred

from the Department of Anatomy to that of Surgery, with the rank of Associate Professor. Dr. William T. Belfield, Professor of Bacteriology in the college, has been transferred from that department to that of Surgery, with the rank of Associate Professor. Dr. Christian Fenger has been appointed Professor of Clinical Surgery, uniting with Dr. Nicholas Senn in the discharge of his duties in this department. Dr. George Webster of Montreal, who has recently married a daughter of the late Dr. Wm. T. Lusk of New York, has been appointed Professor of Gynecology and Obstetrics.

A High Compliment to an American Surgeon.—Apropos of Professor Dennis' recent election to a Fellowship of the Royal College of Surgeons of England, the London *Lancet* of May 13, 1899, says "The election is not more honorable to Professor Dennis than it is creditable to the college. Few men combine the ideal qualities and the merits of an elected Fellow more than he does. His personal devotion to surgery both as a teacher and a practitioner and the embodiment in him of all that completes our conception of a general American gentleman point him out as worthy to receive the compliment paid to him by his college. It is to this genial quality of his nature that he owes not only his large circle of friends in Great Britain and other European countries but also the fact that he has been able to associate with himself as editor so many distinguished compatriots in the compilation of his splendid system of surgery written throughout by American surgeons." Verily our English cousins are beginning to appreciate us at our true valuation.

The Tuberculosis Congress.—The International Tuberculosis Congress was held in Berlin from May 24th to May 27th. It was opened by the Empress Augusta Victoria, under whose patronage the congress was assembled. There were 2000 members present. Count Posadoinsky Wehner, Minister of the Imperial Treasury, opened the session with an address of welcome to the delegates, in which he declared that this gathering and the peace conference at The Hague would be the most glorious events in the history of the present time. Emperor William, in answer to a message of respect, sent a telegram expressing his good wishes. Surgeon J. C. Boyd, who represented the Medical Corps of the United States Navy, was made chairman of the United States delegates, and Dr. von Schweinitz, the American delegate, was chosen honorary president of the second section of the congress. It was stated that medical science has already gained sufficient skill in combating tuberculosis to effect cures in 20 per cent. of the cases. Professor Virchow made an important address on the causes of infection. Professor Brieget, in a lecture on Dr. Koch's tuberculin, stated that it undoubtedly has a strong healing power if the treatment is persisted in, even in cases which have advanced to secondary infection. In any event, by its means tuberculosis can be recognized in good time and in doubtful cases. The chief benefit of the congress will consist in the renewed public interest aroused in the subject of tuberculosis.

CORRESPONDENCE.

THE MEDICAL STUDENT ABROAD.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—There are three things worthy of consideration in contemplating a post-graduate trip to Europe, namely: The study of medicine, the acquisition of modern languages, and the broadening effect of travel. Any one who wishes to be considered well educated can enthuse over all three, though unfortunately in their acquirement within a definite limited time they more or less infringe upon each other. To obtain properly the broadening effect of travel one should see at least the greater part of Europe, but in a limited time (anything under two years) this would necessitate foregoing so much of the other two that it is not to be seriously thought of, yet it is to be kept in mind as an important side issue throwing some weight as to where one should go.

In order to acquire the languages—and one should not spend two years in Europe without learning at least two, German and French—the best plan would probably be to avoid the cities, which are always crowded with English-speaking people, and stick to the small towns and the lesser universities. But this plan shuts out entirely the third, namely, the effect of travel, and prevents contact with most of the great makers of medicine, which is an education in itself. On the whole, then, it seems to me that the majority will acquire the greatest benefit from studies pursued at the large universities. As to which are the best depends largely on the branch or branches in which one is interested. If general internal medicine is the goal sought then by all means go to Vienna. There the courses on this subject are particularly well arranged, and arranged especially for Americans. There one has opportunities for bedside instruction, ideal in its completeness. The student examines the case and makes his diagnosis. The assistant of one of Vienna's famous professors comes along, asks the diagnosis made, and quizzes on the reasons for it. Then he goes over the case completely, showing your defects in examination, or in your reasoning toward your conclusion. After he has finished you have a second opportunity to examine the case, and within the next week or two can listen to the professor himself demonstrate the case to the student class. Now, if you wish, you may examine the case personally a third time. A more ideal way than this I cannot imagine. The advantages in clinical surgery struck me also as greatest in Vienna; exercise work on the cadaver being the rule, though frequently, too, opportunities for assisting at operations are given.

Special work on the nose, the throat, and the ear seems to be about equally good in Berlin and in Vienna; in both places one has under good guidance perfect freedom for personal examination and treatment, even to the doing of operations. The same is likewise true for eye-work, children's diseases, and gynecology. In clinical and laboratory work on nervous diseases Berlin is much in advance of Vienna. The teachers of nervous diseases in Berlin, many of whom give their personal attention to your laboratory and clinical work, cannot be excelled.

In general pathology there is much to be said in favor of Vienna, though even in this branch some division of the time between Vienna and Berlin, if only to learn the different methods, seems to be advantageous.

There is one subject left, namely, bacteriology. Whether you are interested in this particular subject or not, some knowledge of it is necessary to every physician. Gain this knowledge at the Pasteur Institute. No one ever met Roux and Metschnikoff to regret it. Besides, this brings one to Paris, and though opportunities for personal clinical or laboratory work are not as accessible as at the German and Austrian universities, there are so many different medical methods to be learned, and medical men to be met and heard, not to speak of the broadening effect of the study of Parisian life, that Paris deserves at least three to six months out of two years.

I have left out of consideration the smaller universities because, although one may frequently find in them opportunities for chemical and scientific work on certain special lines, greater than in the larger universities, the general chances are less, and it is usually only by accident or previous arrangement that such opportunities are available. It is worth the while during the vacations to visit the smaller universities to meet and hear some of their famous teachers and look out for the occasional opportunities, but to start from America with the idea of staying one or two entire years at a small university is a mistake.

To the general student my advice would be: Spend six months in Vienna, six months in Berlin, and having had a look at Prague, Leipsic, and some of the other universities, determine for yourself where it will profit you most to spend the third six months. Most students will return to Vienna. Spend the last six months of the two years in Paris, if possible making a short tour through Italy before going there, not omitting to pick up as many scraps of the Italian language as possible.

JOSEPH WALSH, M.D.

PHILADELPHIA, May 27, 1899.

MALARIA IN MOBILIZATION CAMPS DURING THE LATE WAR.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Perusal of an article in a recent issue of the MEDICAL NEWS (Thayer, on "Recent Investigations upon Malaria," MEDICAL NEWS for May 20, 1899) recalls three cases of malaria which came under my observation while on duty as hospital steward in the Thirty-first Michigan Regimental Hospital, stationed at Knoxville, Tenn. While on duty for a short time in the fever ward of the Second Division Hospital at Chickamauga Park I did not observe a single case of malaria, although typhoid raged rampant.

The only insect pests which the soldiers at Chickamauga had to endure were the common house-fly and the much-dreaded "jigger;" mosquitoes were a rarity; in fact, I do not remember ever having been bitten by a mosquito there.

On August 15th the entire Second Division of the First Army Corps was ordered to Knoxville, Tenn. After arriving at Knoxville, the typhoid continued, notwithstanding the fact that the sanitary conditions of the camp were ideal and the water-supply perfect. From August 15th to September 1st upwards of twenty cases of typhoid were admitted to the Regimental Hospital. I believe these cases were incubating during the latter days of our stay at Chickamauga. Not a single case of malaria was observed. During the first week in September I admitted to the Regimental Hospital three cases which I considered suspicious, and it was during this week that the mosquitoes descended upon the camp in swarms. Upon admission all three patients complained of having been severely bitten, and examination showed that the neck, forearms, calves, and ankles were covered with mosquito bites in various stages of development. The patients developed characteristic tertian rigors. Owing to the lack of facilities furnished the field hospitals, I was unable to make a blood examination immediately, but a few days later, through the kindness of a local practitioner of Knoxville who furnished me with slides and cover-glasses and allowed me the use of his microscope, I was able to demonstrate the tertian organism in all three cases, the quinin which was being exhibited having, in the meantime been discontinued for the preceding forty-eight hours.

I mention these three cases because they were the first cases of malaria noted by me during my five-months' experience in the army, and because their appearance at the same time with the advent of the mosquitoes impressed me as being quite significant. During the month of September the number of new cases of typhoid rapidly diminished, but several new cases of malaria were admitted to the hospital, in all of which I was able to demonstrate various forms of the plasmodium malariæ.

Very truly yours,

WALTER MILLER WARREN, M.D.

CHATEAUGAY, N. Y., May 25, 1899.

SECOND ATTACKS OF MEASLES.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—During September and October, 1898, in a boarding-school here, 18 boys and 41 girls were suffering from measles, the last patient being discharged from treatment October 20th. In January, 1899, the disease was again brought into the school, there being 24 cases among the boys and 11 among the girls. Eight of the boys and 5 of the girls had had an attack in September. Two cases of the second attacks were quite severe, the others being milder than the first attacks. Besides these, a lady in charge of the boys, had in the January outbreak, a characteristic eruption and mild bronchial catarrh. She affirms that she had had two previous attacks. In none of the second attacks were there lung complications other than mild bronchitis, while one of the January cases was complicated with rather severe bronchopneumonia.

Very truly yours,

J. C. MCGAHEY, M.D.

FORT YATES, N. D., May 24, 1899.

SECOND ATTACKS OF CONTAGIOUS DISEASES.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Permit me to add the following to your reports of a second attack of contagious diseases. For some years, when scarlet fever has occurred in this city, the family has been carefully questioned as to previous attacks of that disease. I fully realize that the data thus obtained are not entirely reliable as memory cannot always be trusted, and it is by no means certain that the diagnosis of the first attack was correct. Of 515 children who had previously had scarlet fever and lived, at the time of the inquiry, in a family where there was one or more cases of that disease, 75, or 14 per cent. had a second attack. Of 827 adults who had had scarlet fever and were similarly exposed, 12 only, or 1.4 per cent. were attacked. These percentages may be compared with the percentage of those attacked among individuals who were exposed and had never had a previous attack. Of 10,082 children who were thus exposed, 5504, or 54 per cent. were attacked, and of 4085 adults, 250, or 6 per cent. were attacked.

In 1894 I had a patient fifty-eight years old who died of smallpox. He stated that he was vaccinated when a boy, but there was no cicatrix on his arm. His father and brother stated that he had smallpox when four years old and was treated by the late Dr. Turner, one of the best physicians in Newport. There were no indications on his body of a previous attack of smallpox, but I consider it probable that he did have a mild attack as his family stated.

Yours truly,

CHARLES V. CHAPIN.

HEALTH DEPARTMENT, OFFICE SUPERINTENDENT OF HEALTH, PROVIDENCE, R.I., May 26, 1899.

OPENINGS IN THE NASAL SEPTUM AS A RESULT OF TYPHOID FEVER.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—During an epidemic of typhoid fever here last year I met with two rather peculiar cases. Two girls, sisters, aged twenty-one and sixteen years had typhoid at the same time, though in different rooms. Each case was slow to recover. During convalescence I noticed an opening in the nasal septum of the younger girl, about two lines in diameter. The edges had an appearance of diphtheria, a whitish-gray color, which could not be removed by mopping with cotton. The opening gradually grew until it was nearly half an inch in diameter, but now, after eight months it is about a quarter of an inch in diameter. The case of the older sister was similar in every respect.

By keeping their mouths closed and breathing rapidly and forcibly through the nose, a peculiar whistling noise is made. Indeed they can almost play a tune with their noses.

Dora K., aged twenty-two years, living within one hundred feet of the above, had typhoid at the same time, and also the opening in the nose. It has not closed up. The edges of the opening had the appearance of diphtheritic membrane, but there was no discharge at any time, the balance of the nose was not inflamed, neither was there any throat trouble at any time. Three months before this the sister of the first two patients had a well-defined case of scarlet fever, but none of the members of the family had any such trouble.

Very truly,

C. C. HUBBARD, M.D.

WORTHVILLE, N. C., May 26, 1899.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

SEWAGE CONTAMINATION OF THE SCHUYLKILL—A CASE OF CONGENITAL MACROPODIA—ANEURISM OF THE AORTA—SMALLPOX IN NICETOWN—VITAL STATISTICS.

AS a result of a systematic course of investigation into the souces of pollution of the city's water-supply, carried on for the past three or four months, the Bureau of Survey now announces that it has discovered at least one definite proof of the reception of sewage by the intake pipes of a city reservoir. The rather startling statement is made that a system of city sewers, carrying house drainage of a most obnoxious and injurious character, empty into the Schuylkill River immediately above the large intake pipe of the Queen Lane reservoir, and that a portion, at least, of this sewage-laden material must of necessity find its way into the storage basin and into the supply mains of the consumer. When it is recalled that during the typhoid epidemic of the past winter the district supplied by the Queen Lane reservoir was particularly scourged by this disease, the significance of the Bureau of Survey's statement is appreciated in its true light. Of course, the evil will be corrected at once, say the city authorities—but they fail to state their attitude toward the contractors who built the infecting sewer, and toward the city inspectors who passed the work.

A remarkable case of congenital macropodia in a boy of twelve years, was presented before the Philadelphia County Medical Society at its last meeting, by Dr. William J. Mann. The left foot was enormously enlarged, and resembled the foot of a large-sized man. It measured fourteen inches in circumference at a point one inch back of the metatarso-phalangeal articulation, and was twelve inches in length; the three outer toes of the affected foot were nearly six inches in length and six inches in circumference. The entire left leg resembled that of an adult, but otherwise the boy was normally developed, and presented a good family history. A radiograph showed that the three outer metatarsal bones were enlarged about three times their normal size, and that the three outer phalanges were more than twice the normal size. In fact, the entire leg, both as to soft tissue and osseous parts, was markedly enlarged in circumference, though it was not proportionately increased in length. Dr. Mann attempted to correct the deformity by amputating the second and third toes at the metacarpal junction and the first toe together with the entire metacarpal bone. The result of the operation is as yet undetermined,

owing to the short time which has elapsed since it was performed.

Drs. W. M. L. Coplin and E. Q. Thornton reported at the last meeting of the Pathological Society of Philadelphia a case of large aneurism of the aorta rupturing into the pulmonary artery. Post-mortem examination of the case showed that the pericardial cavity contained 700 c.c. of intensely red, clotted fluid, the pericardium itself showing a marked villous, fibrinous deposit abundantly distributed over both visceral and parietal layers. At the upper and outer aspect of the pericardial cavity there was a slit-like opening fully occupied and apparently closed by a post-mortem clot; the opening measured 2 cm. in length, possessed ragged edges, lay immediately adjacent to and parallel with the pulmonary artery, and communicated directly with a globular tumor continuous with the aorta. This aneurismal tumor occupied the superior and middle mediastinum, and pressed backward upon the œsophagus and bronchi and forward upon the sternum, which was slightly eroded. The aneurismal sac was globular in appearance, and had an external diameter of 20.5 cm. It was firm over the whole anterior surface, and as far as could be determined, over the posterior surface, as well; and lay in immediate relation with the upper lobes of both lungs, the bronchi and great veins, the œsophagus, and the sternum. There was considerable subpericardial fat, which at points seemed to run into the muscle. The myocardium was softer than normal, and showed on section, some evidence of mottling and of striation. The cavities of the heart were moderately distended, the right side more than the left. The orifices and valves of the right side were normal; the mitral valves were atheromatous and quite thickened; the aortic valves were slightly thickened, atheromatous, and showed fibrinous thickening extending into the sinuses of Valsalva; the aortic orifice transmitted four fingers. The coronary arteries were normal. At a point 1 cm. from the aortic orifice there was a globular mass completely surrounded by a laminated white thrombus. The cavity occupied by this thrombus measured 16.5 cm. in diameter, and had a wall 4 mm. thick. Anteriorly and to the right the thrombus was 8 cm. thick, while at the left and over the pulmonary blood-vessels it was less than 1 cm. thick. Over the pulmonary artery it was barely .25 cm. thick, and communicated with the pulmonary artery at a point 4 cm. from the pulmonary orifice, by an irregularly jagged, button-like projection for about 1 cm. The opening into the pulmonary artery was 1.5 cm. in length. The canal through the thrombus was like a flattened cylinder, ovoid on section, and barely transmitting three fingers. The aorta was somewhat atheromatous above the valves, and where it left the aneurism became narrowed into a circular orifice which just transmitted the index-finger. This orifice was surrounded with dense, thickened, fibrous bands. The heart pericardium and fragments of thrombi weighed 1880 grams.

The excitement caused by the outbreak of smallpox in Nicetown, a nearby suburb of the city, is not allayed by the seeming irregularity with which fresh cases of this disease are reported from day to day. Up to the present time 35 cases have developed, the majority of which are receiving treatment at the Municipal Hospital.

The total number of deaths in this city during the week ending May 27th, was 384, a decrease of six from those of the preceding week, and a decrease of 25 from those of the corresponding week last year. Of new cases of infectious diseases, there were 29 cases of smallpox; 69 cases of enteric fever, with 14 deaths; 66 cases of diphtheria, with 12 deaths; 48 cases of scarlet fever, with a single death; and 2 cases of cerebrospinal meningitis and 3 deaths. The total number of enteric fever cases reported since the first of the year is 6,475, of which number 915 have proven fatal.

CONSERVATIVE OPERATIONS UPON TUBERCULAR TESTICLES—ARREST IN DEVELOPMENT OF THE RADIUS—PHTHISIS AND ALCOHOLISM—NON-MYXEDEMATOUS INFANTILISM—SIALORRHEA AFTER IODID OF POTASH.

AT the Surgical Society, April 19th, ROUTIER spoke of conservative operations in the treatment of tuberculosis of the testicle. In aged patients bilateral castration may be acceptable, but in young men it is often refused. He therefore treated a number of such cases by opening the abscesses, as they formed, with a thermocautery, destroying the affected tissue as far as possible. It is only in advanced lesions that castration is necessary. In his experience castration is never followed by the disappearance of tubercular lesions in the seminal vesicles or in the prostate.

BERGER asserted that he had seen both the prostate and seminal vesicles resume their normal size after the removal of tubercular testicles. Furthermore, he had never seen the disease develop in the other testicle after a unilateral castration.

POIRIER had a patient aged twelve years with tuberculosis of both testicles and one seminal vesicle whom he treated by the thermo-cautery with apparently perfect success.

MICHAUX had seen pulmonary tuberculosis follow castration. He therefore abandoned this for injections of camphorated naphthol into the affected tissues.

TUFFIER said that nothing is more variable than the evolution of tuberculosis in the testicle, a fact which serves to explain the different views expressed by different surgeons in regard to its course and treatment.

At the session of April 26th, BAZY spoke at some length on the same subject. Castration seemed to him to be the ideal procedure, but unfortunately it does not offer a sure guarantee against the spread of the trouble or its recurrence. That being the case, he preferred deep cauterizations, curetting, and similar palliative measures, which answered the purpose of a castration, and had the distinct moral advantage of preserving the testicles of the patient. He cited an instance in which he had cauterized the left epididymis of a patient having grave constitutional symptoms. These were at once improved by the

local treatment. Two years later the patient returned showing symptoms of a similar character, due to lesions in the right testicle and prostate. The right epipidymis was cauterized, and improvement again followed the conservative operation. One year later the left side was quite healed and the right nearly so, while the abscess in the prostate had apparently undergone cicatrization as it was small and hard.

At the session of May 3d, TUFFIER spoke of the benign course which tubercular disease of the testicle sometimes pursues, mentioning that he had had a patient with this trouble under observation for fifteen years, and that during this long period he had remained in substantially the same condition. Clinically it is useful to separate those cases in which the lesions are diffuse, and simulate neoplasms from others in which the lesions are limited. Castration is the only hope in the former class; while in the latter, one may safely rely on general treatment in the most favorable cases, and upon partial operations in those which are more advanced. An apparent recurrence may be due to a simple inflammation about silk threads, as had recently happened in his experience.

GERARD-MARCHANT showed a boy, April 26th, who had sustained a fracture of the lower end of the radius at the age of eight years. The ulna continued to grow at the normal rate, but the radius kept so far behind it that the normal hand was displaced so much that it became impossible for the patient to seize anything with that hand. Accordingly a resection of 2 cm. (about one inch) of the lower portion of the ulna was performed. The functional result was satisfactory. The arrest in development of the radius was thought to be due to the fact that the line of fracture passed through the epiphyseal cartilage.

FELIZET doubted the explanation given. Such an arrest of development was very rare, and if the cause assigned was the correct one, it ought to be quite common. He mentioned a similar instance in which after scarlet fever the development of the tibia ceased, while the fibula continued to grow until a resection of a part of the fibula was necessary to restore the proper relations between the two bones.

At the Medical Society of the Hospitals, April 21st, JACQUET said that he had investigated the antecedent history of seventeen phthisical patients, and found that in sixteen instances they had at some time been users of large quantities of alcohol. They all drank brandy or rum, and the most of them absinthe as well. In most of these patients the period of ulceration and cavity formation came on rapidly, one or two years after the beginning of the disease, thus showing that it is not true that phthisis has a fibroid tendency in alcoholic drinkers. In many of these patients there was a hereditary tendency toward tuberculosis or alcoholism, but making due allowance for this as well as for the fact that alcoholism is common among the population from which these patients came, it nevertheless remains true that phthisis is frequently contracted "over the bar."

At the session of April 28th, DELPEUCH showed autopsy specimens from a girl aged twenty-five years, whose bodily appearance was that of a child of twelve or fourteen. There was scant hair on the pubes and in the axillæ, the breast glands were undeveloped, and the uterus and ovaries were in an infantile condition. The thyroid gland was normal in size and character. The relations in measurements of the trunk and whole body, according to the tables of Riccardi, corresponded to those of a girl of twelve or fourteen years of age. There was old mitral stenosis with the usual secondary changes in the pulmonary artery and right side of the heart, with a lesser hypertrophy of the left side. The skeleton was fully developed, the last epiphysis, that of the inner end of the clavicle, being solidified. The aorta was narrow and presented the lesions of chronic endarteritis. It was difficult to say what was the cause of these lesions. The heart trouble was antecedent to an attack of smallpox and of rheumatism which the patient had at the age of fifteen or sixteen years. Probably there was a stenosis due to hereditary tubercular taint, and the inflammatory processes invaded the organs secondarily. The case illustrated the point that there is a difference between myxedematous infantilism and the form of infantilism, as in this case, where the thyroid gland is normal.

May 5th TRIBOULET presented a woman who for an attack of the grip took daily for a week 3 grains of sulphate of quinin, and then daily for a week 8 grains of iodid of potassium. The day after the administration of the iodid had ceased she began to be troubled with an increased flow of saliva, a symptom which increased for a month, with the added peculiarity that the flow stopped during sleep.

LE GENDRE said that he had observed two similar cases, and had come to the conclusion that the sialorrhea was of nervous origin.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-fourth Annual Meeting, Held at Philadelphia, Pa., May 23, 24, and 25, 1899.

(Continued from page 672.)

FIRST DAY—MAY 23D.

DR. CHARLES P. NOBLE of Philadelphia, in a paper on "Early Abdominal Sections for Fibroid Tumors, with a Tabulated List of All Operations Prior to 1865," said: In America the first successful myomectomy was performed by John Bellinger in 1846. In 1853 Burnham performed a successful myomectomy. The operation was originally undertaken with the belief that the condition was an ovarian tumor. When the abdomen was opened the tumor bulged forth through the wound and he was obliged to remove it. Kimball was the first American to successfully perform this operation, after having previously made a correct diagnosis.

DR. WATHEN of Louisville opened the discussion by saying that he had talked this question over with Dr. Kimball and that Dr. Kimball thought that he was entitled to the credit of the operation.

DR. PALMER of Cincinnati said that the subject

to him was a most interesting one, as he had discussed it at length before the Society in 1880. At that time he had collected 165 cases of abdominal section, with a mortality of fifty-one per cent., most of these operations being performed after an error in diagnosis had been made. Fifteen to twenty years ago Dr. Thomas Wood of Cincinnati deliberately opened the abdomen in these cases and, after having tied the tumor off with heavy silk ligature, removed the tumor. He was successful in five out of eight cases.

DR. A. P. DUDLEY of New York said that he had talked to Dr. Kimball and he told him that after Burnham's case of suprapubic hysterectomy the patient fell out of bed. Dr. Burnham being away Dr. Kimball was sent for and he was obliged to replace about six feet of intestines before sewing up the wound.

DR. REMEY of Cincinnati said that Dr. Wood's instruments for this operation consisted of only such as he could carry in his pocket-case. He used to cut the uterus wherever he could best get at it, first tying it off with a strong silk ligature, but if that was impossible he would transfix it. He rarely had any trouble—some hemorrhage. Dr. Wood was a man of strong presence, much force of character, a fine mind, a magnificent constitution, and much personal magnetism. Unfortunately he died of sepsis contracted from a patient.

DR. NOBLE closed the discussion by saying that he had only given the history of the operation previous to 1863 for the reason that the history of the operation after that time was familiar to everybody.

DR. J. WHITRIDGE WILLIAMS of Baltimore read a paper on "A Case of Spondylolisthesis, with Demonstration of the Pelvis," in which he said that the patient was a colored woman, aged twenty-two years, four feet, ten inches in height. She was pregnant for the first time, and at full term. The duration of pregnancy had been uneventful. Her pelvis in the usual diameters measured 24, 27, 29, and 18 cm., respectively. Her abdomen was pendulous, and above the right hip was a concavity, and on looking at her back a marked scoliosis was evident in the lumbar region. On vaginal examination the hymen was found to be absent, the pelvic outlet fairly large, and a large bilateral tear of the cervix uteri was present. The dislocation downward of the lumbar vertebræ could be easily felt, but on careful examination he failed to feel the bifurcation of the aorta. The patient denied a previous pregnancy which seemed the most likely cause of the cervical tear.

Her previous history was good. Had enjoyed excellent health until her thirteenth year when she had had a fall upon ice and injured her right hip. Had some rheumatism subsequent to this injury and finally noticed that her right hip was higher than her left. She has always worked hard. She exhibited the characteristic "duck" gait on walking. On being questioned more fully she admitted having had a child four and one-half years ago after an easy labor. Cæsarian section was proposed to her, but after consulting with friends she absolutely refused to allow the operation. She finally went into labor and symphysiotomy by the open method was the operation decided upon. The child was born alive after this operation, but there was much tearing of the maternal soft parts. The patient was markedly shocked after the operation and the next day there was much abdominal distention. On the fifth day the wounded soft parts looked well but on the seventh they were much broken down and on that day she died, death being preceded by marked air hunger. The autopsy was held five days after death had taken place and there was marked decomposition. The uterus was torn from the cervix to the broad ligament. No trace of peritonitis or septic embolus could be discovered. Dr. Williams showed preparations of the bones from this case and they presented the usual features of marked spondylolisthesis. He then reviewed at length the history of this disease and the factors entering into its causation.

DR. DAVIS of Philadelphia opened the discussion by saying that he had had a case somewhat similar at the Philadelphia Hospital in which delivery had been accomplished by forceps. The previous history pointed to a congenital origin of the condition. Mild degrees of this deformity are not uncommon, it being not nearly as rare as is generally supposed. In these cases labor is not always difficult, and where symphysiotomy is performed the head should always be delivered first, as when this is done the danger of death is greatly lessened. In one case death occurred after symphysiotomy as the result of cellular necrosis with slow absorption.

AFTERNOON SESSION.

DR. J. WHITRIDGE WILLIAMS on behalf of the committee appointed at the last meeting to investigate the efficacy of antistreptococcic serum in the treatment of puerperal sepsis read an elaborate report, giving a résumé of the literature on the subject, supplemented by the personal experience of the individual members of the committee. Finally the results of the latter were combined with those found in literature for the purpose of deducing therefrom reliable conclusions for guidance in the treatment of the disease. The history of antistreptococcic serum from a practical standpoint began February 23, 1895. On that date Marmorek presented a communication to the Société de Biologie of Paris, in which he stated he had been able to so increase the virulence of streptococci that they would always produce death in rabbits and that he was preparing an efficient antistreptococcic serum. By passing the streptococci repeatedly through the bodies of animals he was able to raise their virulence to such an extent that the one-one-hundredth-billionth of a cubic centimeter of the bouillon and blood-serum culture will kill a rabbit within twenty-four hours. When a single one of his virulent streptococci was introduced into a rabbit its death was certain. A few weeks later Marmorek presented a second communication in which he stated that he had used his serum in forty-six cases of erysipelas with most beneficial results. Later he treated sixteen cases of puerperal fever by the same method. In all of these cases he examined the uterine discharges bacteriologically and refrained from all treatment while using the serum. Seven of these patients were infected

with pure streptococci and all of them recovered; in three the streptococcus was combined with the colon bacillus and all of them died; in five cases the streptococcus was associated with the staphylococcus and two of these died; while in the last case, in which the infectious agent was the colon bacillus only, the serum had no effect. Marmorek concluded that his serum was a most efficient remedy in cases of pure streptococcus infection, but useless when the infection was mixed. In April, 1896, Charpentier reported forty cases of puerperal infection in which this antistreptococcic serum was used by fourteen different observers. Of these forty patients only twenty-four recovered. Of those cases in which the streptococcic infection was pure, *viz.*, sixteen, seven died. Of eight cases of mixed infection four died. Bacteriologic examination was not made in the other cases.

The serum has been used quite largely in France and England, but very little in America or Germany. Up to the present time 354 cases have been reported, of which 189 patients infected with pure streptococcus recovered, and 40 died, a mortality of 21.1 per cent.

Coming to the second part of the report in which the personal experience of the committee appeared, Dr. Williams reported 23 cases of puerperal sepsis in which bacteriologic examinations were carefully conducted. The temperature in these cases varied from 101° F. to 106° F. Of these 18 were examples of pure streptococcus infection, and 5 of combined streptococcic, staphylococcic, the colon and the gas bacillus. None of them had peritonitis; 10 were very sick, 6 moderately sick, and 5 slightly ill. Mild treatment was employed in all, consisting of one intra-uterine douche, and the adminstration of large doses of strychnin and whisky, pushing each to the full physiologic effects. Of these 23 patients 22 recovered.

DR. PRYOR treated 15 cases with 1 death, by a method to be described by him later in this discussion.

DR. FRY treated 7 cases with 1 death with intra-uterine douches till the character of the infection was established, and then with antistreptococcic serum.

The results of their studies and investigations were summed up as follows:

1. Marmorek's claim that his antistreptococcic serum will cure streptococcic puerperal infection does not appear to be sustained by the results thus far reported.

2. The great variety of streptococci necessitates a special serum for each species of this bacillus (accepting the theory that an efficient serum can be obtained from each).

3. The mortality of streptococcus endometritis if not interfered with is about five per cent., and such patients tend to recover if not too energetically treated locally.

4. Curettage and total hysterectomy are unhesitatingly condemned.

5. If the infection tends to involve the peritoneum Pryor's method of packing with iodoform gauze may be of service.

6. The use of Marmorek's serum has no deleterious effect in these cases.

DR. WILLIAM R. PRYOR, as a member of the committee, gave his personal experience in the management of cases of puerperal sepsis. All cases are excluded from consideration which have failed upon examination to reveal the presence of streptococci. The treatment consists in thorough cleaning of the uterus by curette for the double purpose of removing infected tissue and producing a raw surface for absorbing iodin from the iodoform gauze with which the uterus is then packed. An incision is then made into Douglass' pouch, the contained fluids evacuated, all lymph planes separated, and the pelvis thoroughly packed with iodoform gauze in such a way as to isolate the uterus completely from contact with its peritoneal surroundings except in its anterior aspect. By this extensive application of iodoform gauze to the peritoneal surfaces, as well as the interior of the uterus, the iodin is promptly absorbed by the lymphatics, thus rendering the lymph streams innocuous to the infection. The promptness with which the iodin is absorbed is apparent from the fact that it appears in the urine of patients thus treated three hours after the application of the gauze.

The elimination of the iodin from the system is hastened in grave cases by the intravenous infusion of saline solution, and in all cases by high rectal infusions of salt solutions. By this treatment fourteen patients have been saved out of fifteen treated.

"The Surgical Treatment of Acute Puerperal Sepsis with Special Reference to Hysterectomy," was the title of the next paper, read by DR. H. N. VINEBERG of New York. He began by asking what clinically constitutes *acute* puerperal sepsis. Some hold that the term acute should be applied only to those cases that set in with severe symptoms during the first three days of the puerperium, and which usually terminate fatally any time between the fifth and tenth day. Cases protracted beyond that period they would designate as chronic. A time definition, according to the speaker, would be an infection that takes place shortly before, during, or immediately after labor, that manifests itself by symptoms during the first week of the puerperium, and in which the symptoms persist continuously, with variable severity, until the disease ends in death, in a cure, or passes into a chronic state. But the practical question is to determine whether all fatal cases of acute puerperal sepsis run their course within a given period (five to ten days). The writer collected at random from the literature of the past few years reports of thirty-eight cases in which death occurred from the eleventh to the fifty-fifth day of the puerperium, showing the average of twenty-three days as being the period of a fatal termination. Among these were ten cases of septic peritonitis (of all puerperal lesions the most rapidly fatal) in which death occurred from the eleventh to the twenty-eighth day of the puerperium, or showing an average of more than fifteen days.

The essayist does not agree with those who hold that once systemic infection has set in surgical intervention can do no good. They maintain that the patient will die whether operated upon or not. This is in direct contradiction to daily experience with sepsis arising in other parts of the body, and that arising in the parturient canals obeys the same laws as that elsewhere. But the human economy has its limitations in its power of resistance to bacterial invasion and this very circumstance

forms one of the strongest arguments in favor of timely surgical intervention. Remove a uterus, the walls of which are a breeding-place for bacteria, and the patient may get well, though she shows all the signs of systemic infection; fail to do this and it is more than likely that the reinforcements of the enemy from the reserve army in the uterus will in time destroy everything before it. It is his custom when first called to a case of acute puerperal infection to make a very thorough inspection of the whole lower parturient canal, in order to determine the presence or absence of any wounded surface. If any is found and it shows an unhealthy appearance, it is treated on the general surgical principles of free drainage and frequent irrigation with some antiseptic solution. If it be found that the site of infection resides in the uterus, that organ is subjected to a curettage under narcosis. The curettage is followed by frequent intra-uterine irrigations if the septic manifestations do not promptly subside. This is best carried out by leaving two rubber catheters within the uterus.

The advice frequently given that in curetting a septic uterus care should be taken not to curette deeper than the granulation-zone, first described by Bumm, is absurd in the extreme, for how is it possible to curette the endometrium with the sense of touch, or even with the aid of sight, and avoid a structure in it that is visible only with a high-power microscope? Bumm found the granulation-zone fully developed only in the milder forms of uterine infection in the products obtained by curetting the uterus. The patients upon whom these observations were made recovered, and presumably they were bettered by the curetting, or at all events, they were not injured thereby. In the severe and fatal cases of uterine sepsis the granulation-zone did not exist at all, or was only poorly developed. The patients were not curetted, yet they died.

The majority of cases of uterine sepsis, even of the more serious type (not the so-called cases of sapremia), will yield to curettage and intra-uterine irrigations faithfully carried out. Occasionally, however, the treatment will fail to arrest the progress of the infection, as will be manifest by the pulse and other well-known signs. In the event of such a contingency, an exploratory laparotomy is indicated, one's further actions to be guided by the pathological lesions found. In the majority of these cases total hysterectomy will be necessary. The indications for such a radical procedure cannot very well be described; they must be based on close clinical observation at the bedside. In a general way they may be stated as follows: if despite the foregoing treatment, the pulse goes above 130 and grows weak and irregular, and there are signs of a commencing peritonitis, or a deepening of the septic manifestations, and nothing is found outside the uterus to account for the symptoms, the uterus should be removed.

In making his indications, the writer seeks no aid from a bacteriological examination of the contents of the uterus for the reason that such an examination is extremely unreliable and unsatisfactory, even in the hands of expert bacteriologists. Further, the finding of any given pathogenic micro-organism would be no aid in estimating the severity and probable outcome of the case.

Regarding the technic, he favors the abdominal route because these deeply septicized patients withstand any loss of blood very poorly, and more perfect hemostasis can be carried out through a good-sized abdominal incision than through the vaginal canal. In cases of puerperal infection in which a fairly large collection of pus forms in the pelvic and lower abdominal cavities, the course to be pursued will depend upon their situation. If they are so situated that they can readily be evacuated by an incision in the vagina, or by one above either of Poupart's ligaments, so that the peritoneal cavity is not entered, no time should be lost in carrying it out. But if they are so placed that they cannot be reached by either of these incisions, judicious delay (the patient in the meantime being kept under close observation) is advisable, with the hope that in time their situation will become more favorable. When such a course is not justifiable on account of the general condition of the patient, he makes a median abdominal incision in order to explore the relationship of the abscess. The median incision is then closed, and one is made directly over the mass and the pus evacuated without entering the general peritoneal cavity. The principal object to be arrived at in these cases is evacuation of the purulent collection and the establishment of free drainage without risk of soiling the peritoneum, for it cannot be too forcibly borne in mind that the pus in acute puerperal sepsis is highly virulent, and that the slightest soiling of the peritoneum with it is almost certain to be followed by disastrous results.

DR. J. MONTGOMERY BALDY of Philadelphia read a paper, entitled "Report of a Case of Kraurosis Vulvæ," in which he discussed at great length the symptomatology, and macroscopic and microscopic pathology of this interesting condition. After going over the literature at some length the theories of its etiology were spoken of.

The consensus of the discussion was that this is a similar pathological condition to trachoma of the eyelid and requires similar treatment. Local applications of the yellow oxid of mercury of the strength of 4 grains to the ounce of vaselin had been most successful, the majority of the patients being cured in six months.

DR. ROBERT L. DICKINSON of Brooklyn then read a paper, entitled "Is a Sloughing Process at the Child's Navel Consistent with Asepsis in Childbed?" After the amputation of the cord the same surgical principles should be applied as those that govern other amputations. The following principles are directly opposed to the prevailing practice but would seem to bear on the matter: (1) The mass ligature should be avoided. Hemorrhage follows its use, due to the shrinking of the gelatin in the cord. The ligature belongs on bared vessels. (2) A hernial opening should not be closed by a granulating scar. Primary union is readily substituted. (3) If the location of the future line of demarcation be known removal should be practised at or beyond that point. In the case of the funis one knows where the line of separation is to be. (4) That form of operation should be chosen which will do away with sloughing. (5) To frankly sever the cord

at the skin margins with ligation of the vessels on suture, one or both, brings about safe, clean, and prompt healing. When this be done the navel of the second day looks like the navel of the fifteenth or twentieth day of the old method.

DR. I. S. STONE of Washington, D. C., then read a paper, entitled "The Use of the Compression Forceps in Salpingo-oophorectomy, with Remarks upon the Angiotribe." This instrument, although somewhat clumsy at first sight, is a valuable one, leaving a clean-cut stump. There is no hemorrhage, and ligatures are unnecessary. In every instance the result following its use had been a good one, and the instrument evidently had come to stay.

DR. HANKS of New York opened the discussion by saying that he had performed fifteen operations with this instrument, and in each case the result had been most satisfactory. In only one case had there been a slight secondary hemorrhage, but there was good reason for that as the parts were subjected to considerable traumatism by performing ventral suspension immediately after the operation.

DR. DUNCAN EMMET of New York said that he had used it once with good results, but he could not see that the angiotribe had any advantage over hemostatic forceps, except perhaps it did not have to be left on as long. If the actual cautery be used also the hemostatic forceps are better than the angiotribe.

DR. J. RIDDLE GOFFE of New York said he considered the angiotribe to be a distinct advance on the forceps operation. At first it looked as if it were a clumsy instrument, but after using it in two cases he found it to be not tiresome, and that it answered its purpose admirably. Both of these were serious vaginal operations. In the first case the uterus could not be drawn down, so the instrument was passed up, clamped, allowed to remain in situ for one minute, then the incision was made, and two minutes later the angiotribe was removed and absolutely no hemorrhage followed. The second case was one of double ovarian abscess, in which the uterus could not be drawn down. The angiotribe was used and the operation performed without difficulty. Both patients made excellent recovery.

DR. EDEBOHLS of New York then said that he had given the angiotribe a fair trial, and did not like it. The ligature method is preferable as it is dangerous to use the angiotribe. Where you cannot see just how much tissue you are including in your grasp when you clamp it, the ligatures are easier to apply and the operation can be done faster. The chances are that sloughing will follow the use of the instrument as the result of the compression.

DR. I. J. WATKINS of Chicago then read a paper on "Vaginal Incision and Drainage for Simple Non-pedunculated Cysts of the Broad Ligaments." The essential part of this operation consists in opening the cysts at their most dependent parts through a vaginal incision. After draining the cyst it becomes obliterated by agglutination. No organs are removed, no sutures are required, and the peritoneal cavity is not invaded. Enucleation and the transperitoneal method are both dangerous and difficult. He has performed this operation five times, and in no case has there been a recurrence. In each instance the convalescence was uneventful.

SECOND DAY—MAY 24TH.

MORNING SESSION.

The first papers were by DR. HOWARD A. KELLY of Baltimore, on "The Avoidance of Infection Following the Operation for Complete Tear of the Rectovaginal Septum." "The Localization of Obscure Pain in the Side." A wide field for discussion is opened up by this very interesting subject, for though the classical method of treating complete tears is in general satisfactory it is not always so, for there is a definite percentage of complete failures and a large number of partial failures. Under the latter may be grouped those cases in which a small fistula persists after the operation. Another class of cases is those in which the bowel is not retentive to a greater or less degree. This may be a very slight deficiency, as a weakness of the sphincter allowing gas to pass through, while on the other hand it may be so serious that involuntary bowel movements constantly occur. My efforts have been to so alter this operation that this difficulty is done away with. In some cases of complete tear the patients have had complete control, which may be explained by saying that this control was due to a powerful action of the internal sphincter. In one case this had been so for the past twelve years. The technic of the operation is as follows: The incision is made across the septum beginning at the outer side of the internal sphincter and well above the junction of the vaginal and rectal mucosæ. Then a denudation is made above as in the Emmet operation. A finger is then put into the bowel as a guide to its exact location, and a flap dissected loose and brought down like an apron, of course great care being taken not to wound the bowel. By doing this the internal sphincter is exposed and laid bare. After dissecting this sphincter loose the sides of the septum are approximated with buried figure-of-eight sutures. Three or four of these sutures are all that are required, and when properly applied, they do away with all danger of a central dead space which would be very likely to break down. The parts being in snug apposition the external sphincter is united by either interrupted or a continuous catgut suture. The vaginal surface and the skin perineum are then closed in the usual manner. Then the flap is brought together by a few interrupted sutures. It is now no longer a case of rectal tear, as there is no wound in the rectum, the wounded surface being pushed outside of the anus. The greater the pressure of fecal matter the further outside it goes. So what would otherwise be a place for infection is now removed. The operation has two principal advantages over the Emmet operation in that (1) the central dead space is done away with, and (2) the usual source of infection in these cases is removed.

During the discussion of Dr. Kelly's paper DR. THOMAS ADDIS EMMET of New York was called upon by the president to express an opinion. He said that the closure of a lacerated sphincter is one of the simplest operations in surgery and the description of it has been much over-

done. There is no reason for flaps; the case should be treated as one would treat a case of vesico-vaginal fistula. He has closed these tears for the past twenty years by an interrupted suture. It is to be remembered that there is a considerable retraction of the muscles and that many men make their mistake by only catching the outer fibers of the muscle in their sutures. The vaginal wall also retracts and by this retraction is greatly thinned. All that is necessary is to denude the edge of the muscle on the vaginal wall and the septum can then be made of any desired thickness. The wound should then be closed with interrupted sutures.

When turning up the vaginal wall care should be taken to bring the fold down to the common vaginal fold. We have two arcs of a circle, one on the vaginal side and one on the rectal side and so the sutures should be applied like the spokes of a fan. At the level of the tear the first suture should be put and the next one placed behind the edge of the muscle. This first suture will bring the parts together while the one behind the muscle rolls the muscles up. It is most important that the bowels be moved daily with salines after the first twelve hours, and when this is not done the operation is very apt to fail.

Dr. Kelly then read the second of his papers ("The Localization of Obscure Pain in the Side") and said this is nothing more than a demonstration of some further uses of the renal catheter. This catheter has been extensively used during the past twelve years for securing specimens of urine from either kidney, for dilatation of ureteral stricture, and as a material aid in the diagnosis of kidney-stone, and pyelitis. Many patients have an obscure pain in the side, and careful physical examination and questioning often fail to accurately locate it. In many cases this diagnosis can be facilitated and often accurately made by passing a renal catheter into the pelvis of the kidney, and then injecting some bland fluid. The result of this is renal colic in whichever kidney so treated. His first case was one of persistent pain in the right side in the region of that kidney. Renal colic was artificially produced, and the patient said that her ordinary attacks of pain were in the same place. So an incision was made, and on the kidney being opened the pelvis was found to be greatly dilated. The pelvis was reduced to its normal size by stitches, the patient made an uninterrupted recovery, and has had no return of the pain. The second case was one of great difficulty, there being quite a large mass on the right side in the region between the kidney and the gall-bladder. The renal catheter was passed and the pain produced was not like the pain she generally had, so the diagnosis of disease in the gall-bladder was made and subsequently confirmed by operation. The third patient suffered from pain in the right side, and a large mass was found on examination. On inducing renal colic the patient said that the pain of the colic was somewhat in front of the usual seat of her pain. So an incision was made over the gall-bladder, which was enlarged and adherent to the kidney. It was opened and 500 small gall-stones removed. All of these patients made an uninterrupted recovery.

The President of the Society, DR. JOSEPH TABER JOHNSON of Washington, then delivered his address, and said in part: With the twenty-fourth anniversary of our Society comes our annual reunion for scientific, social, and literary purposes. One of the most important points in the presidential address of the past has been the prophecy of great achievements in the future and the account of advances in the past. The doctrine of expansion has been forced on gynecologists, but the stages of evolution are slow. Influences which succeed in many other directions will never produce a successful abdominal surgeon, who, unlike the poet, is not born but is made by hard work, bitter disappointment, and severe long and special training. It is not the following of cast-iron rules of practice that has made remarkable achievements, but they are the results of matured and trained judgment. It must be admitted that the good old rules are very safe ones for the beginner to follow. Much is now said and written about conservative gynecology that it is hardly necessary for me to say much more, but it may be truly said that though the gynecologists of the next century will not practise it all the time and on all people, yet they will practise it some of the time.

DR. HENRY C. COE of New York then read a paper, entitled "Thrombosis Following Celiotomy in Aseptic Cases," which will appear in a subsequent issue of the MEDICAL NEWS.

DR. B. BERNARD BROWNE of Baltimore read a paper on "Inversion of the Uterus, with a Review of the Various Operative Procedures for Its Treatment, and a Description of the Author's Operation for Chronic Inversion," and said: Inversion of the uterus is a very formidable accident; if occurring during parturition and its reduction be not almost immediately effected death often results from the violent hemorrhage and shock which it produces. Should the patient survive the acute stage pain and hemorrhage continue at intervals until the child is weaned, when profuse menorrhagia and metrorrhagia set in, followed at intervals by a characteristic white discharge. If the lesion be not corrected she drags out a miserable existence for months, or perhaps years, finally succumbing to anemia and exhaustion incident to her condition. This is the most extraordinary of all the physical lesions of the uterus as it is produced by a displacement which the organ executes upon itself, thus reversing the order of nature. It was of more frequent occurrence among the ancients than at the present time, probably as the result of the women being delivered either standing, kneeling, or when seated on a hollow stool. In any of these positions sudden and violent expulsion was liable to occur and so produced that form of traction upon the cord, placenta, and fundus of the uterus, which is one of the most potent factors in causing inversion. In the Bible, in the first chapter of Exodus we read that Pharaoh, King of Egypt, tried to prevent the rapid increase of the Hebrews by ordering the midwives to kill all male children as soon as they were born. The midwives did not do it, and excused themselves by saying that the women were delivered before the midwives could get to them, thus showing how fast was the labor

and how rapid the expulsion. Numerous scientific writers of antiquity give accounts of the etiology, symptoms, and treatment of this condition. An especially good account is given by Hippocrates, and also by Celsus. However, it was not until 1847 that a new era arose in the history of inversion and the possibility of cure became an established fact. At this time Valentine de Vitry reduced, under ether, a chronic inversion of sixteen-months' duration, and from that time to the present a large number of cases have been cured.

At the present time this is an exceedingly rare condition occurring only about once in 2000 deliveries. Dr. Moore Madden states that out of 190,833 deliveries at the Rotunda Hospital there had been only one case of complete inversion. Braun states that out of 150,000 births in his hospitals he has not seen a single case of inversion. The predisposing causes are relaxation of some part or the whole of the walls of the uterus, a very considerable enlargement of its cavity, or adhesion of the placenta to the fundus. The exciting cause may be a short cord or one wrapped about the neck, distention of the uterus by a large amount of amniotic fluid, excessive coughing or sneezing, softness of the uterus, traumatism to the abdomen previous to labor, hydatiform growths in the uterus, fatty degeneration of the uterine walls at the placental site, intrauterine polypi, sarcoma of the fundus, and excessive straining during labor. Even after the uterus has been restored to its normal position after having been inverted recurrence may occur, as has been many times reported. Very rarely spontaneous reposition of an inverted uterus has taken place. The diagnosis is usually easily made; if error occur, it is most likely to be mistaken for a fibroid tumor or a polyp. The appearance of a pyriform tumor in the vagina and the absence of the fundus of the uterus on bimanual examination should make the diagnosis certain. The ancient and various forms of taxis in treatment, and later tampons and pessaries, were tried. The modern treatment is either by rapid or prolonged taxis, which failing, operation should be resorted to. Küster's method consists in opening Douglas' cul-de-sac, incising the posterior wall of the uterus and then reinversion by fixing the funnel with the index finger in Douglas' cul-de-sac and pushing up the fundus with the thumb of the same hand. The wound of the uterus and vagina are closed with deep and superficial sutures. The author's operation is performed by drawing the inverted fundus outside of the vulva with strong volsella forceps. An incision is then made through the posterior portion of the uterus, care being taken to avoid the Fallopian tubes and larger blood-vessels. Then through this incision Sims' large dilator is passed up into the cervix and expanded to its fullest extent. Then Nos. 2 and 3 of Hank's hard-rubber dilators are passed through the cervix after dilatation. The uterine incision is then sewed up with carbolized silk and with but slight manipulation the fundus is easily replaced through the now passable constriction. The advantages of this operation are that it is more certain and not more dangerous than prolonged or rapid taxis. There is no danger of bruising the tissue or rupturing the vagina. It is a much safer operation than laparotomy and one can be certain of always reducing the inversion at one operation.

THIRD DAY—MAY 25TH.

MORNING SESSION.

DR. HENRY T. BYFORD of Chicago read a paper on "The Remote Results of Shortening the Round Ligaments and Hysteropexy by Vaginal Section." He reported thirty-one cases of vaginal section for shortening the round ligaments and suture of the uterus over the bladder. In his earlier cases he did not draw the ligaments tight enough, and had one failure and two imperfect results. In his later cases he drew the ligaments tighter and attached the fundus higher up over the bladder, and had only good results.

He opened the abdomen in three cases some months after the operation and found that the adhesions had held, but that they could be easily separated by the finger. One labor at term, twenty-five months after the operation, was reported, with a normal confinement of a large, healthy child, and a normal position of the uterus two and one-half months afterward.

The steps of the operation are as follows: T-shaped incision in the anterior vaginal wall. Separation of bladder from uterus. Breaking up of adhesions. Drawing down of fundus of bladder and suturing of the fundus uteri above it, with formalin catgut at two points about an inch apart. Drawing down the round ligaments and uterine horns into the vagina, and suturing them as taut as possible to the uterus just above the uterine insertion. As he finishes the suturing of the ligament he throws the same catgut thread around the neck of the loop thus formed and ties it securely.

The method was not advocated as a substitute for Alexander's operation, but only for those cases in which there are adhesions to be separated, or the peritoneal cavity has to be opened for other reasons.

DR. A. LAPTHORN SMITH of Montreal then read a paper, entitled "Vaginal Celiotomy." The following were his conclusions: (1) Vaginal celiotomy is indicated in retroversion with fixation, in minor diseases of the ovaries and tubes, and in small fibroid tumors of the uterus. As a rule, it may be said that the vaginal method of freeing the retroverted adherent uterus is a more difficult procedure than the abdominal method, and vaginal fixation is not so reliable in curing the retroversion and prolapse as in ventrofixation. (2) If the uterus be freely movable, and there are no adhesions to be broken up, one is not justified in opening the peritoneal cavity, either by the abdomen or the vagina, in order to shorten the round ligaments. In such cases Alexander's operation is easy, quick, safe, and more reliable. (3) For the removal of pus-tubes the operation by the vagina is more difficult than by the abdomen in all cases excepting those in which the uterus is removed at the same time, when the uterus is split in halves and each half is removed with its corresponding ovary and tube. When clamps are used the vaginal operation is easier than the abdominal in which ligatures are employed. The vaginal operation is a little safer on account of the drainage which it affords,

but on the other hand, it offers more risk of injuring the ureters.

The author is opposed to the removal of the uterus even when both ovaries and tubes have been removed, owing to the bad moral and physical results, and he is opposed to the use of clamps as compared with ligatures because, although easier and quicker, the clamps prolong the convalescence owing to the bruising of the nerves of the broad ligaments. (4) For the removal of chronically inflamed ovaries and tubes, vaginal celiotomy has the following decided advantages: (*a*) It is less dangerous because the intestines are not exposed to the air or to bruising by the hands, or infection through diseased tissues passing over them so much as when the latter are removed by the abdomen. (*b*) Vaginal celiotomy is less painful, the incision in the vagina causing almost no pain, while the abdominal incision and stitching are exceedingly painful. After vaginal celiotomy morphin is rarely required; in abdominal celiotomy it is cruel to deprive the patient of it, although we know that her chances of recovery are lessened and her convalescence is prolonged by its use. (*c*) There is no telltale scar after vaginal celiotomy, which is often a matter of great moment to young single women who contemplate matrimony. The presence of the scar has to be explained and the patient is suspected of having been unfitted for marriage by the removal of both ovaries, when in reality one or both ovaries remain. (*d*) The danger of hernia. Although the author has had no case of hernia during the last three years owing to his method of suturing and leaving in the silkworm gut either permanently, or at least a month, and he considers this accident entirely preventable, yet, for those who meet with it, its possibility should have great weight in balancing the merits of the two operations. There is never hernia as a sequel to vaginal celiotomy. (5) Much good conservative work on the ovaries and tubes, and even on the uterus, can be performed by vaginal celiotomy with almost no risk or pain to the patient. The uterus and appendages can be brought out at the vulva through an opening in the anterior vaginal wall and cysts can be excised or burned out; one-half of one ovary can be amputated and the remaining bivalvular flaps neatly brought together with fine silk or catgut sutures. The closed tubes can be opened or a piece of the pavilion removed and a probe passed into the uterus, and the mucous and peritoneal layers of the remainder of the tube brought together with interrupted catgut sutures. Small fibroids, not larger than the normal uterus itself, can be cut out and the hole in the wall of the uterus closed with two or three rows of fine sutures. But it is very dangerous to open up closed tubes as long as there is any active inflammation or infection going on, because, by so doing, we break down the wall of defense made by Nature around the infected tubes to save the general peritoneal cavity from invasion. (6) Tubal pregnancy before rupture, and not later than the sixth or eighth week, can be readily removed by vaginal celiotomy. But vaginal celiotomy is contraindicated when the pregnancy has advanced to twelve weeks or has ruptured into the abdomen.

DR. J. WESLEY BOVEE of Washington read a paper, entitled "Abdominal Operations for Conditions Complicating Typhoid Fever." It is but a few years since the condition of patients suffering from typhoid fever was considered so severe as to contraindicate any grave surgical procedure. Then came abdominal section with closure of intestinal perforations incident to the disease, and with results better than those that followed the old policy of non-interference. But even among the most experienced it is quite conceivable that mistaken diagnoses are not rare, as in one of his cases in which he operated for pus-tubes, which entirely masked the symptoms of typhoid fever with which the patient had just been infected. He made a good recovery, and thirty days after the operation was free from fever, and after a short convalesence was entirely well.

DR. S. C. GORDON of Portland, Maine, then read a paper on "Conservative Gynecology," and said: Conservatism may be defined as being preservative or having power or tendency to preserve in a safe or entire state, protecting from loss, waste, or injury. To the patient conservative means the saving of her health when she has it, or the restoration of it when it is lost. To the surgeon the meaning is often different, and men of small experience, often in blind haste, signally fail by being conservative of the organs but not of the patient's health. Although the Tait operation has done much good in many cases, it would seem to be better if the uterus was removed with the appendages, for left in the pelvis it is simply a useless bag, without function and kept in a painful state of chronic passive congestion by the blood from the uterine arteries. The same may be said of the Hegar operation for fibroids; while in some cases the result is favorable, in many more the last state of that woman is worse than the first. Many women from whom one ovarian tumor and the ovary from which it grew were removed have required a second operation for a similar cause upon the remaining ovary, and it is a question as to whether or not it would not have been better to have removed the then apparently healthy ovary at the first operation. The ideal education of the gynecologist will be reached when one can make a sharp, clear diagnosis in this class of cases and so valuable time will not be wasted in useless experimentation.

REVIEWS.

A TEXT-BOOK OF ANATOMY. By American Authors. Edited by FREDERIC H. GERRISH, M.D., Professor of Anatomy in the Medical School of Maine at Bowdoin College. In one magnificent imperial octavo volume of 915 pages with 950 engravings in black and colors. Cloth, $6.50, *net;* flexible water-proof binding for the dissecting table, $7.00, *net*; full leather, $7.50, *net*. Philadelphia and New York: Lea Brothers & Co., 1899.

WE have here a text-book of anatomy that is worthy of America and its American authors. It is a thoroughly practical exposition of all the necessary facts and without

a word too much. The great difficulty with text-books of anatomy so far has been that in endeavoring to be especially complete too many details have been incorporated. This is a fault that has evidently been very sedulously avoided in this case and with striking success. The omissions are judicious, the result a very practical text book of anatomy for student and practitioner.

The illustrations are original and selected and constitute the striking feature of the book. All of them are thoroughly illustrative and the insertion of the names of parts upon the plates themselves rather than their indication by reference figures or letters, or by indicatory lines, makes a glance at the illustration suffice to settle an uncertain point and completes the mental picture very strikingly. The diagrams, of which the book contains a large number from the editor's hand, will certainly prove of great help to the student. In such subjects as embryology and the anatomy of the nervous system the diagrams, often in colors, demonstrate just those points that the anatomical teacher knows by experience students find it hardest to grasp. Their material presentation in diagrammatic form seems calculated to impress the vital points of their explanation upon the student mind. The origin and insertion of all muscles is diagramatically represented by red tracings upon the skeletal structures in a way that makes tiresome, lengthy descriptions, with constant cross-reference by the reader from text to illustration, unnecessary.

Relational anatomy and the surgical anatomy of the ligation of arteries are given a deservedly prominent place, and a series of colored plates brings the subjects out in every practical detail. The important surgical question of the tendon sheaths, their position and relations, receives here, for the first time in English at least, the detailed treatment that its practical significance demands for it. Colored plates show the sheaths distended and demonstrate very strikingly how they favor the spread of pus, especially in the hand and foot.

The illustrations for the nervous system are, as might be expected from the recent attention given the subject on all sides, very complete, while the lymphatic and lymphadenoid systems are treated with an illustrative detail in colored plates that is very commendable. The surgical importance of the lymphatics has only come to be recognized with the realization of its importance as regards infection and the question of recurrences in cancer. Too often its treatment was relegated to a few poorly illustrated pages that left very little impress on the student's mind and demanded his consultation of special treatises as soon as the exigencies of practice made him realize the importance of knowing just what the lymph connections of a part were, and where the origin of chronic lymphadenitis had to be looked for.

Some new and very useful features of the book seem to deserve special mention, though space will not permit us to do more. At the end of the book is a series of plates reproducing plane sections of the body from the cervical region downward, that give all the important medical and surgical relations of the internal organs at a glance. Following these is a series of photographs of various parts of a trained muscular athlete with the muscles that are made to stand out in various poses clearly indicated on accompanying diagrams. Last of all is a series of Röntgen-ray diagrams of the various bones and joints of the body, and of soft structures that cast shadows. This is the first complete set of normal skiagrams we have ever seen in a text-book. Their value for comparative purposes can scarcely be overestimated, as it is frequently not easy to make out the significance of certain appearances in skiagrams, or to know whether they are pathological or not.

The volume is beautifully gotten up, and in its morocco-like, flexible, waterproof binding, so different from the hideous waterproof covers that were in use in our schooldays, is as ornamental as it is useful. There is certainly a place for the book at our medical schools in this country, and we confidently look for widespread popularity for it.

A MANUAL OF ORGANIC MATERIA MEDICA; Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms. By JOHN M. MAISCH, Phar.D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. New (seventh) edition, revised by H. C. C. MAISCH, Ph.G., Ph.D., Professor of Materia Medica and Botany in the Medico-Chirurgical College of Philadelphia, Department of Pharmacy. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

THE mere fact of the appearance of a seventh edition of this work is sufficient evidence of the place it holds in the colleges of pharmacy. Some changes have been made in this edition to make its contents conform to the new British Pharmacopœia and to add as synonyms the British name when it differs from that of the United States. The work is profusely illustrated with the gross and microscopic pictures of the plants of the pharmacopœia. In this edition, there is no doubt that its usefulness will be maintained and increased.

THE PRINCIPLES OF BACTERIOLOGY. By DR. FERDINAND HUEPPE, Professor of Hygiene in the University of Prague. Authorized Translation from the German. By DR. E. O. JORDAN, Assistant Professor of Bacteriology in the University of Chicago. Chicago: The Open Court Publishing Company, 1899.

PROFESSOR HUEPPE'S earlier works on the subject of bacteriology are so well known and have given so much valuable assistance to all works in this line, that the present contribution will be received and read with much pleasure. The book before us is in no sense a text-book and can be placed in the hands only of the advanced student with any expectation of profit. The subject is dealt with in a masterly, philosophic manner and, as the style is in essay form, with due regard given to all the theories pertaining to the matter in hand, the book stands apart from all others of a similar kind as a landmark, and many of its chapters are wonderful examples of the profound, logical mind of the author.

The first two chapters deal with the structure and vital phenomena of bacteria, and their chemistry is fully detailed. Even here many points of a highly practical

nature may be deduced. The following chapter gives a brief description of the most important pathogenic bacteria and makes most interesting reading, but cannot be profitably consulted by the student for all the minor details of growth, structure, and staining reactions.

The author believes that the bacillus of typhoid fever and the bacillus coli communis are two distinct species and does not uphold the theory that the colon bacillus is an œcoparasite which, under favorable conditions may become transformed into the typhoid bacillus and as such penetrate the tissues and produce the characteristic lesions caused by the latter organism. The author also inclines to the belief that there is but one pleomorphic malarial parasite and not three, or as Marchiafava would have us believe, four, distinct varieties.

In the following chapter on the cause of infectious disease there is much that is new and a careful study of the entire chapter will amply repay the reader. The author gives an interesting historical sketch of the various conceptions of infectious disease and does not hesitate to criticise the many conflicting views of various writers on the subject. The three theories propounded by Virchow, his opponents, and Pettenkofer are detailed, and then the author goes to show that all of these antagonistic theories are false and attempts through a series of well-grounded facts, with many logical deductions, to prove his stand. He first describes resistance and external conditions, the liberation of energy, atomic combinations and resistances, predisposition to disease, both acquired and inherited, and disease-stimuli. He shows that disease germs are not specific; that they are capable of producing other effects, of causing fermentations and forming pigments and states that "it is not the transferable 'essence' that determines the character of the 'specificity' of disease, but the similarity and the permanency of the condition of life." In discussing the various ways in which bacteria may affect man, the author explains that "they may cause changes by growing and multiplying in vital organs and through thus altering the metabolism of important tissues may influence unfavorably the metabolism of the whole body; or they may rob the body of important nutrient material and introduce the products of their own metabolism into the body of their host; or they may, in the act of satisfying their own need of energy, split off from the proteids of the human body certain substances which act upon man as poisons; or they may themselves generate poisons in their own bodies and, like poisonous plants, be in themselves poisonous." That the "specific" germ causes only one disease is shown to be false by the statement that similar symptoms may be evoked and that the tissues may show similar anatomical changes by the action of totally different germs. As for example, the production of nodules by the germs of syphilis, leprosy, glanders, and tuberculosis, the production of suppuration by the streptococcus, the tubercle bacillus, the anthrax bacillus, and the germs of typhoid fever and pneumonia; and the production of inflammation of the pia mater by the germs of typhoid fever, pneumonia, and tuberculosis.

That the same "specific" germ may cause very different affections is shown by the bacteria of erysipelas causing also suppuration or inflammation of the lungs; the pneumonia germs causing also blood-poisoning, inflammation of the cerebral membranes, or of the middle ear; the tubercle bacilli exciting tubercle formation, inflammation of the cerebral membranes, suppuration, etc.

Space does not allow us to show further the logical reasoning that causes the author to protest so strongly against Koch's conception of "specific" disease-germs. Suffice it to say that he believes in the natural and acquired predisposition or resistance to disease, and the adaptation to the similarity and permanency of the conditions of life. The author also does not believe in the "specific" curative action of drugs, but believes that the remedies act as stimuli to the human cells, and gives several interesting facts bearing on this point.

It is with the greatest satisfaction that we have read this book, and we can endorse many of the statements made. We urge all clinicians and pathologists carefully to study its pages. The translator is to be congratulated in giving us an exact and faithful reproduction of the original work. The book is amply illustrated and the paper and bookmaking of the very best.

THERAPEUTIC HINTS.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIV. NEW YORK, SATURDAY, JUNE 10, 1899. NO. 23.

FIFTIETH ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION, HELD AT COLUMBUS, OHIO, JUNE 6, 7, 8, AND 9, 1899.

THE PRESIDENT'S ADDRESS.[1]

BY JOSEPH M. MATHEWS, M.D., LL.D.
OF LOUISVILLE, KY.,

Our National Body; Its Purposes and Destiny.—I imagine that when the father of this Association, the Nestor of American medicine, called around him a few devoted friends, accomplished physicians and surgeons, and effected an organization to be known as the American Medical Association, the first thought which filled their minds was the unification of the profession which they loved so dearly. It was their desire, no doubt, to bring together each year the men who were laboring earnestly and honestly for the elevation of the profession, that they in conclave could impart to each other the advance that each succeeding year had brought forth in their chosen calling, and this done in order that the sick and afflicted could be profited thereby.

Shall We Have a Local Habitation?—It is to be seriously questioned whether this Association, so numerically great as it is destined to be, or in truth is now, profits in any manner by its migration each year to distant parts of the Union. It cannot be well denied that a mistake has been made in the past in going to cities too small to entertain it. It certainly adds no dignity to this distinguished body to be thus traveling about, not to speak of the inconvenience occasioned to the majority of its members by so doing. Nor is it right or proper to impose upon a local profession the expense and trouble that it takes to entertain it. If the members will give the subject careful thought and consideration, I believe that they will come to the conclusion that the Association should have a local habitation. The natural question would then be, where could such habitation be found? In the selection of the same, many things would have to be considered. A city within easy reach which offered the most attractive advantages. Of all, the City of Washington is the best suited. The capital of the nation, it has the advantages that no other place can offer. With its great free libraries, it is the seat of learning; its magnificent Government buildings, its natural beauty, its select society, its two houses of Congress, the rendezvous of foreign representatives and diplomats, the home of the Medical Departments of the Government Army, Navy, and Marine Hospital Corps. Then, too, the idea is not far fetched that the Government, liberal always, would at some time lend the Association a helping hand in the way of securing a suitable building in which to hold its meetings and to become the owner thereof. Again it would be in touch with the legislative department of the Government, and it can readily be seen of what value this would be in securing much-needed reforms in a medical way. The *Journal* would here find the most suitable of all abodes; an atmosphere of refinement, education, and wealth. Its editor would all the time be on the alert, and much profit would come to the *Journal* from such surroundings and associations. I beg of you to give this matter your most serious consideration.

Clinics, Dinners, etc.—It has been a noticeable fact for a long time that the clinics which are held each year during the meeting of the Association, by the local profession of the city in which it happened to meet, very materially decrease the attendance at both the general sessions and of the various Sections. This should not be, and it is the duty of the proper officials of this Association to deprecate the holding of such clinics.

The Journal.—It is my painful duty to announce to you the death of Dr. John B. Hamilton, editor of the *Journal* of the Association. This Association never had a truer friend than he. Possessed of a clear-cut individuality, he was always outspoken, and what he did he at least believed to be for the best. We will miss his wise counsel in our deliberations. He made a most excellent editor of the *Journal*, and by his efforts it was brought up to the high standard which it occupies to-day. The Board of Trustees of the *Journal*, after careful consideration and deliberation, has selected Dr. George H. Simmons to succeed Dr. Hamilton as editor. You are to be congratulated upon this wise selection. Dr. Simmons is not an experiment, for he has won his laurels in medical journalism, and already stands among his editorial friends as the peer of any. Having come up from the ranks in journalism, he is ac-

[1] Abstract.

quainted with every detail, and that he will make a good editor goes without saying.

The Management of the Journal.—I trust that it will not be considered out of place if I make a suggestion or two in regard to the management of the *Journal*. It has been frequently urged that much appears in it that should be expurgated. In other words, that a censorship should be established, and many articles withheld from publication. I desire to disagree from this sentiment entirely and unequivocally. The *Journal* is simply the mouthpiece of the Association, and if one single paper read before this body is to be refused publication, then you have violated your pledge and obligation. Any member has the inalienable right to disagree with the sentiment of any paper, and the editor is in no wise responsible for said sentiment. If a paper is good enough to be read before any section in this Association, it is good enough to be published in the *Journal*. If any action is taken, it should be by the Chairman of the Section before which the paper is to be read, saying to the reader that his paper does not come up to the standard. But who will assume this responsibility? and who is to judge the judges? May it not be that a paper, although couched in bad English, might contain matter of real merit? By all means let the editor improve the *Journal* in any way that he deems proper, but let every paper read before this Association or its sections be published in the *Journal*.

There are many hundreds of worthy physicians in the United States who would readily join the mother society if properly approached. Many, very many of them are ignorant of the manner of becoming members. It may be urged that the salary necessary to secure an agent would be too large to justify the employment of such. In refutation I would urge that by such individual solicitation many more would be added to the membership than would be necessary to pay said salary, and they would become permanent members. It can be said, especially to young men, that the mere wearing of the button of the Association adds dignity and confidence.

The Secretaryship.—For several years there has been a heated debate, if not wrangle, at each annual meeting, in general session, over the secretaryship. This is both unseemly and undignified, and is to be much deplored. It seems to me that there is an easy solution to this matter. Let the editor of your *Journal* be the secretary of the Association. The Board of Trustees has wisely insisted that he devote his whole time to the *Journal*. It does, therefore, appear that the secretaryship should be one of his duties. By so acting he is brought into a closer relation with the business management of the Association, and with the active membership of the same. He would himself be responsible for a correct report of all proceedings, and be enabled to keep them without fault. The question whether or not any addition should be made to his salary for this additional work can be determined by the Board of Trustees. Our present secretary has served us long and well, and for his services in the past the Association should, and no doubt does, feel deeply obligated to him. I am sure that he would be the first one to acquiesce in any move that would enhance the business interests or the prosperity of the Association. I, therefore, very respectfully offer the suggestion.

The Public Health.—I shall content myself with employing the balance of my time in asking your consideration of a few things which are not only a menace to the public health, but also to the safety of society. Having served as a health officer for many years, my mind naturally turns into this channel, especially so when I see an opportunity to enlist the interest and cooperation of this large and influential body of physicians.

Tuberculosis.—It behooves this national body of American physicians to take some action, or at least to approve the movement to stamp out, as far as scientific effort can do so, that dread disease that kills one-seventh of the world's population—tuberculosis. A few days ago, May 24-27th, there was held a tuberculosis congress in Berlin, international in character. The Liverpool Medical Institution, one of the most important medical societies in England has recently appointed a committee of its members "to consider what further steps can be taken for the prevention of tuberculosis, and for the treatment of the disease in the human subject." This committee proposes to consider (1) the nature of pulmonary tuberculosis, its communicability and preventability; (2) the provision of sanatoria; (3) the more effectual methods of controlling spread of infection, and (4) the desirability of adopting some form of notification. The eradication of bovine tuberculosis received a powerful stimulus throughout the Empire when recently Her Majesty the Queen gave orders to have killed such of her herd of Jerseys as were shown by the tuberculin test to be infected.

At the recent meeting of the French Association for the Advancement of Science, the Section of Hygiene, at the suggestion of Professor Nicholas, passed a resolution pointing out that the convection of tuberculosis by inhalation is only one of the modes of infection, and that a larger part of the diffusion of the disease is played by contagion through the alimentary canal, as proved experimentally and clinically, urging the necessity of taking adequate measures to insure the sterilization and harmlessness

of articles of food. All Europe is wide awake to the importance of this subject.

From carefully prepared statistics it is found that of the deaths from all causes between the ages of fifteen and sixty years, one-third of the number are victims of tuberculosis, and that it kills four and one-half times as many people as do smallpox, scarlet fever, typhoid fever, and diphtheria combined. It is estimated that at any given time in Germany alone 1,300,000 persons are affected with tuberculosis, and Osler says that 1,200,000 in America have the disease at all times. One in every fifty persons has the disease. Over 13,000 die of tuberculosis in the State of New York every year. In every other American city the proportion of deaths is equally as great. So important has this subject become that at a recent convention held in England to consider the question, "How to Prevent the Spread of Consumption," the Crown was represented by His Royal Highness, the Prince of Wales, who presided over the meeting. Great encouragement was given the mové by Royalty and all others. The medical profession all over the world is deeply interested in the subject, the aid of governments is solicited, and every effort is being made to suppress this formidable disease. Since the germ which causes it is known, and its habitat, the condition under which it thrives, and that the disease is contagious, it does appear but rational to assume that it not only can be prevented by precautionary measures, but that it can be cured by proper environment and treatment. It is equally true that, even in the best of homes, the treatment usually accorded the patient is *nil* in effect and accomplishes nothing. Something more than this must be done if we expect to materially decrease the death-rate. What is that something? Detweiler believes that over twenty-four cent. of cases of tuberculosis are curable; Meisen, twenty-seven per cent.; Braymer, twenty-one and one-half per cent. And this under ordinary climatic and hygienic treatment. A much higher percentage of recoveries could be recorded if a real systematic and scientific treatment could be afforded these patients. Such a course can be instituted only in well-ordered and equipped hospitals designed especially for such inmates. In regard to the extent of the disease, I can do no better than to use the words of Professor Hirsch. He says, "It is emphatically a disease of all times, all countries, and all races. No climate, no latitude, no occupation, no combination of favoring circumstances forms an infallible safeguard against the onset of tuberculosis, however such conditions may mitigate its ravages or retard its progress. Like typhoid fever, phthisis dogs the steps of man wherever he may be found, and claims its victims among every age, class, and race." In answer to the question, What is to be done to prevent its progress? I would suggest a remedy in using the words of a resolution adopted at the International Congress of Hygiene in Brussels, in 1897: "The hospitalization of tuberculosis is urgent and will not long be withheld." In several large cities in the United States an earnest effort has already been made to carry this thought into practical utilization, especially so in Chicago and New York. It can readily be seen, however, that but a comparatively few out of this great number of afflicted can be accommodated in this manner. A country or State that is ever on the alert to prevent the landing of a foreign foe, or a hostile army, surely should ever be ready to aid in the suppression of a foe to the human race ten times more destructive to human life than the invasion of the country by an army of great size armed with the most improved rifles. Let us, then, in the name of humanity, invoke aid from the Government of this very humane people, in order to help put down and thoroughly conquer this foe.

During the last session of the New York Legislature a report of the Senate Committee appointed to investigate the advisability of establishing a State hospital for the cure of consumptives was made. Many reasons for the same were presented in the report. Among other things, the report read: "Tuberculosis is one of the most fatal diseases that the human race has to combat at the present day; its yearly victims inflict a serious and unnecessary drain upon the resources of the State—unnecessary because it is now demonstrated beyond question that by the adoption of proper preventive measures a large proportion of those who suffer from this disease may be saved. This is proven not only by the revelations of science, but by the results which have been obtained in the practical application of the means to prevent the spread of the disease. A large proportion of the cases brought under treatment have been cured, and so many have so improved as to be restored to the producing class. It is also shown that the efforts of the boards of health of this and other States, as well as in other countries, have so far succeeded in reducing the percentage of deaths from tuberculosis by the measures adopted that there is good ground for assuming that with wise laws properly enforced this disease may be almost wholly obliterated." Is it too much, then, to suggest that this Association, representing the most advanced thought of the medical profession of America, take action in this important matter? I would most respectfully urge you to appoint a committee to prepare a careful report on this subject and present it to the next Congress sitting, beseeching that this

Government erect, prepare, or donate hospitals or reservations in and at which the poor or others shall receive treatment for the cure of consumption. Also that it be impressed upon State boards of health in the various States the advisability of the respective States erecting similar institutions. The blind, the deaf, the insane, the feeble-minded, and other classes are so provided for, why not these? They are not able to care for themselves, and they are a menace to the public health. It must be confessed that in so far as the prevention of the disease is concerned that must come from the education of the people to the facts. The best way to accomplish this I leave to you.

The Antivaccinationists.—It may appear superfluous to ask that you consider, in the proper way, a rebuke to a certain class that is doing much to endanger the lives of our citizens, and whose meddling ways are giving the health boards of the various States much annoyance. I allude to the antivaccinationists, encouraged as they are by an antivaccination society. It seems strange and beyond belief that citizens of respectability and supposed intelligence should band themselves together to prevent a means of saving human life. But "'tis true, and pity 'tis, 'tis true." If these misguided people would only inform themselves of facts, patent to every reader of history, they might at least stop long enough in their mad career to think.

We may rest in peace and disregard the efforts of these half mad people, but we must not close our eyes to the fact that, by their loud cry, aided by political influence, given often for self-aggrandizement, they are endangering lives in every community. So far has this thing gone, that the vaccination law in England has but recently been amended so that only those who may desire shall be vaccinated. This is a menace to the public health and smacks of the Dark Ages. I again respectfully ask that you give to the medical profession in America an endorsement of their views in a resolution sustaining *compulsory* vaccination. The safety of the people from this most direful malady demands it.

A Crusade against Syphilis.—An International Medical Conference will be held at Brussels, Belgium, in the month of September next, known as "The International Conference for the Prevention of Syphilis." A statement of this fact has been sent the Honorable Secretary of State of the United States, through the Belgian minister at Washington, with the request that he appoint a delegation to attend this important conference. The Honorable Secretary in turn requested me, as your presiding officer, to name said delegation. This I have already done, as the call was for immediate action. In the preamble which accompanies this notice the following language is used: "The increasing propagation of syphilis and venereal diseases has become a serious danger to society, and it is important while there is still time to take efficient measures to stop the progress of this scourge. The spread of the evil is an incontestable fact; on this point all physicians who are in a position to know or observe its progress are agreed. The number of victims increases daily, and a serious consideration is that this malady is penetrating into a strata of society where it was formerly rarely seen. Scarcely any attempt hitherto has been made to check this social evil, or rather while some attempts have been made, without concerted action, without preconceived plans, and without an international understanding to success."

What can be said of Belgium in this regard can be said of the United States. Perhaps the ratio of cases is not so large, but this matters little. It is estimated that there are in this country between six and seven million people who are afflicted in one way or another with syphilis. A distinguished French authority says that one man in every four has the disease in France. When we consider that by this the very foundation of society is shaken, our families imperiled, the constitutions of our youths undermined, our women wrecked, it is high time, as this official says, that we turn our attention to the subject. The warning should be in words that the most illiterate man or woman can understand, and it should emanate from sources and places that would reach the greatest number. Our false modesty has been too pronounced, and has prevented us from giving to the common people valuable information; so we are in a measure, as a a profession, to blame for the great spread of this blighting curse.

The time has arrived when we as physicians, singly or when in convention assembled, should throw aside all restraint when dealing with this vital question. Fathers, mothers, sisters, brothers, and all others should be informed, and this information should be in the plainest language. The minister and the priest should aid the doctor in this praiseworthy undertaking. The doctrine should be inculcated into the young of both sexes that freedom from this awful condition should exist before the marriage relation is thought of. Upon this declaration rests the hope of the State, as well as of families, for neither good soldiers, good citizens, nor good husbands with tainted blood can be had. Please permit me to suggest that a committee be appointed from this body to report at the next annual meeting on this subject: "What Is the Best Means of Preventing the Spread of Syphilis?"

A Plea for Harmony.—In conclusion, let me beg of you that this meeting be one of perfect harmony and peace. Let nothing of an acrimonious nature be indulged in, but rather let your deliberations be characterized by patience, love for each other, and a desire to ennoble the profession to which you belong. For are we not brothers indeed, fighting for a common cause—the obliteration of the common enemy, disease? May your future life, each and all of you, be one of peace and perfect happiness, and may God grant to all a long life filled with good deeds. If fate should decree that any one of you should pass away before we meet again may you find eternal rest in "God's next country."

A CENTURY OF MEDICINE IN AMERICA.[1]

BY J. C. WILSON, M.D.,
OF PHILADELPHIA.

THE most wonderful century of the world's history draws to a close. Not in all time has there been such a period. The diffusion of knowlege, man's power over nature, and organized human energy have yielded results that mark the latest as the most brilliant epoch of our civilization.

Has medicine, that branch of human endeavor in which we are especially interested, kept progress with the times? Has the century done for it what it has done for other things? The question is not hard to answer. For medicine the changes of this year-hundred have been the awakening from the sleep of ages. The work of the early anatomists, the great discovery of Harvey, Auenbrugger's laborious revelation, Jenner's patient investigation, were stirrings in the slumber.

The dawn of the century was auspicious. Vaccination was widely practised, and its value everywhere recognized. Corvisart rescued the Inventum Novum from oblivion. Laennec invented the stethoscope and discovered auscultation. The methods were practically complete, but it took forty years and the influence of Skoda to make physical diagnosis a familiar art. The era of speculative medicine was fast drawing to a close. Fads and isms arose, as they will arise from time to time among the half-educated and the degenerate, but their influence has been with few exceptions shortlived and its reaction upon scientific medicine favorable. The microscope ceased to be a scientific toy and became an instrument of precision. New sciences ranged themselves as the handmaids of medicine. In 1858 Virchow issued the "Cellular Pathology as Based upon Physiological and Pathological Histology." It was but a step onward to experimental physiology, physiologic chemistry and experimental therapeutics. In truth the "close and severe" methods had come, and had come to stay. It was evident that these methods, and these only could be successfully used in the search for truth. The fairy-tales of science had become the everyday handbook of the doctor. We had fully entered upon the era of experimental medicine. Ether and chloroform anesthesia for operative purposes robbed surgery of half its terrors and rendered possible operations previously impracticable. The germ theory of disease came into prominence as a working hypothesis. Lister made the astounding discovery of surgical cleanliness, and early in the last quarter of the century the New Surgery replaced the old.

The obvious impossibility of the individual mastery of the medical sciences and of the art of medicine gave rise to the specialties. In truth the laboratories were the beginning of specialism, which became an imperative need, partly on account of the necessity of more limited fields of investigation; partly because of the requirements of a precise and extended technical skill. If the specialties have been multiplied somewhat beyond the needs of the profession or the people, and if isolation of thought and shortcomings of practice have come of their too narrow cultivation, these are errors which tend to correct themselves, and, despite its faults, specialism is a power in the medicine of our times both in promoting knowledge and in direct healing, the importance of which cannot be overestimated.

Clinical medicine, great as has been its advancement, began to lag in the progress. It fell behind surgery and for a time kept abreast of the minor specialties. The explanation was not far to seek. It was to be found in the complexity of the problems and in the greater number of unknown values, especially in causation. For a time this great branch of medicine waited for that new science which was to place it foremost among the specialties, to render possible the study of origins, to reveal the nature of infection, to set preventive medicine upon a sure foundation, to point the way to rational systems of therapeutics. The germ theory of disease ceased to be a working hypothesis and became a demonstration. The science of bacteriology came into existence. Youngest of the biologic sciences, it has accomplished more for medicine in three decades than all the rest had been able to accomplish in three centuries. Bacteriology has done away with speculation in medicine forever, and has for all time established experimental research as the final court of appeal.

It is of interest to note the position of the United

[1] The Oration on Medicine delivered at the Fiftieth Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

States in regard to modern medicine. It is no long time since our people were pushing westward over the wilderness and a famous poet and story-writer has accused us of being some centuries behind Europe in learning and manners. Railroads and the telegraph are great civilizers, and the Postal Union a wonderful teacher. There is no wilderness now except that beyond the seas and "a few centuries" is a figure of speech. In medicine the world's knowledge is ours. The latest work of investigators in every field of research and in every country is quickly before us and we give something in return. Laveran discovered for us the malarial parasite, and Marchiafava, Golgi, and others of the Italian school elaborated his observations; but an American, the late Professor J. K. Mitchell, had anticipated the discovery, being "the first to approach in a scientific spirit the nature of infective disease and particularly in malarial fever"; and Laveran's observations were early confirmed on this side of the Atlantic by Councilman, Osler, Thayer, and others. Roux and Behring gave to the world the treatment of diphtheria by antitoxin-serum, but the uncertainties concerning its efficacy were settled by Welsh's analysis of the statistics and the two collective investigations of the American Pediatric Society. Ernest Brand devised the method of treating enteric fever by systematic cold bathing and showed that by it the mortality is cut in half, but it remained for American practitioners to demonstrate that the plan is not only feasible in hospitals but also in private practice. Macewen and Horsley showed that cerebral tumors could not only be definitely localized, but also that they could be successfully removed, but cranial surgery was carried to its full development and a perfect technic laid down by Keen. Here and there we have given more than we have received. We recall the contributions to neurology and especially the successful treatment of neurasthenia and hysteria by Mitchell, the second in the line of an illustrious medical family, and speak of intubation in grateful memory of the gentle O'Dwyer, and in surgery we are reminded that the New World has given something to the Old by the work of Senn, Murphy, Richardson, McBurney, my colleague Deaver, and by that in earlier times of the clear-minded Grosses, father and son, the brothers Atlee, and the heroic McDowell. The instances of accord, response, coendeavor between the workers in medicine on the opposite shores of the Atlantic could be indefinitely multiplied.

It is clear then not only that medicine has kept pace with the progress of the times, nay more, that it has made advances even more wonderful than many other departments of thought, but also that in America the position of the profession compares favorably with that of any other country. Medicine with us is to-day one with the medicine of the world. Yet it is little more than 100 years since the country was without a medical profession in the sense in which the term is now used and was then used in the Old World.

It must be admitted that the rapid strides with which the medicine of the younger country has overtaken, and is now keeping pace with the medicine of the world, were largely due to the facilities of intercommunication that constitute one of the peculiarities of modern life. Knowledge travels far and fast. It has the wings of the light. It must be also conceded that such progress has been aided and accentuated in a remarkable manner by the master-spirits who, from time to time appearing upon the scene, seem to be charged with an especial mission, and whose presence marks eras in the course of human events. Easily, and by far the greatest of these, *primus inter pares*, is Rush. Others among his contemporaries I have already referred to. Nor do I intend to enumerate a complete list. Permit me to name one here and there, sometimes a group, as fine examples of medical men who, to say the least, are not commonplace. It is easy for one who has read our medical history to recall John Morgan, Redman, Hosack, Drake (who wrote the "Diseases of the Mississippi Valley"), that coterie of Louis' pupils, including Shattuck, Oliver Wendell Holmes, and Gerhard, who brought back from France physical diagnosis, the distinctions among the fevers, and reasonable methods of clinical work; Jackson and Morton, and the controversies concerning ether; the group of men who, representing others, it is true, really effected the organization of the American Medical Association, whose officers were Knight, Bell, Delafield, Arnold, Stillé, Jones, of New Orleans, is to be mentioned among those whose writings have powerfully influenced the trend of medical thought in the United States, and Flint, and Otis, and Woodward, to whose industry and ability we owe the "Medical and Surgical History of the War of the Rebellion;" and Billings and Fletcher, who have given to the medical world the "Index Catalogue of the Library of the Surgeon-General's Office of the United States Army," and that unique and most useful of current medical publications, the *Index Medicus*. I mention with that emotion with which we speak of a companion newly passed away, John B Hamilton, of whose skill as an organizer this Association has had abundant proof; and Pepper, a life of matchless energy and devotion to the widest human interests, whose rare gifts as a physician, abilities as a teacher, civic pride, and high patriotism will place him, when the dispassionate

history of our times comes to be written, among the great Americans and in the foremost rank of the citizens of that commonwealth which reverently claims Franklin and Rush as her own.

The tendency which distinguishes American medicine is essentially opposed to isolation, to individualism. It exerts itself in the direction of a higher, more complete and more specialized organization of the profession. It is this tendency that has made the general fund of knowledge accessible to all members of the profession who care to share in it; that has given to the independent worker in whatever department an uplifting sense of companionship, of community of interest, of sympathy in a common cause. It is this that has brought into the life of the toiling practitioner in the monotony of his everyday duties and cares a saving consciousness of personal dignity and power.

MEDICAL ASPECTS OF CRIME.[1]

BY DANIEL R. BROWER, M.D.,
OF CHICAGO.

THE limitation and treatment of crime is one of the great questions of the day. The closing hours of the Nineteenth Century are full of wonders; the progress in medicine, in literature, and in arts has been marvelous. Medicine and surgery have made rapid strides. The insane, the feeble-minded, the deaf, dumb and blind have received in these later years treatment that is scientific and successful. The care of the criminal is the one great question that baffles society, and difficulties have arisen from the fact that the medical aspects of crime have not been sufficiently considered. Criminology of to-day is much in the same condition that psychiatry was when Pinel and Tuke appeared and wrought their memorable reforms, substituting patience and scientific treatment for brutality and chains. This transformation in the care of the insane has been brought about by the medical profession, and it is our duty to-day with equal zeal and earnestness to consider this question of criminality, find out its etiology and provide means for its cure. The pioneers in criminal anthropology have established the fact that the habitual criminal is an abnormal man, the abnormality manifesting itself, first, physically, in the criminal physiognomy, in stigmata of degeneration, in anomalies of the muscular, sensory, respiratory, and circulatory systems; and, second, psychically, in moral insensibility, lack of forethought, low grade of intelligence, vanity and egoism, and emotional instability.

In approaching the study of this subject one is surprised by the rapid increase in crime beyond the ordinary increase in population. The census reports of our own country from 1850 up to and including 1890 represent the prisoners that were incarcerated, and it has been estimated that only about one-third of them are thus accounted for. The number of criminals in 1890 in the United States was about one-quarter of a million. The cost of their maintenance, arrest, and trial has been estimated at about $59,000,000. The statistics of the State of Pennsylvania confirm our national statistics. The same is more emphatically true in New York City. The population of that city has increased in the last ten years about 33⅓ per cent., while crime has increased more than 50 per cent.

The two great etiological factors in crime are criminal parentage and environment. The effects of these two agencies are strikingly illustrated in the history of the Jurke family, as related by Dugdale. Another of these remarkable exhibits is the tribe of Ben Ishmael, studied by McCullock. Professor Pellman, of Bonn University, has discovered and identified the descendants to the number of 709 of Frau Ada Jurke, a notorious drunkard, who was born in 1740, and died in 1810. Of these, 7 have been convicted of murder, 76 of other crimes, 144 were professional beggars, 61 lived on charity, and 181 were prostitutes. This family has cost the German Government for maintenance, cost of courts, almshouses, and prisons, one and a quarter millions of dollars.

An important factor in the cause of crime is intemperance. Fully fifty per cent. of the criminals arrested in Chicago are inebriates, and the police reports of New York show about the same proportion. Ferri has shown beyond question that in France crimes increase and decrease with the more or less abundant vintage, and we may safely attribute at least some of the increase of criminality and pauperism in the United States to the increase of intemperance, and it may be estimated that alcoholics are the direct or indirect cause of probably seventy-five per cent. of all crimes committed.

The constant and rapid increase of the urban population is another etiologic factor. The recent growth of cities is one of the phenomena of our social system. When our government was established a century ago, its first census showed only about 3.3 per cent. of the inhabitants of the country living in cities of 8000 and over. The census of 1890 shows such an increase that 27.6 per cent. of our population is urban.

The criminal laws and their unreasonable execution are another factor in the causation of crime. The code of to-day is largely the Roman code. In ancient Rome it did well because the death penalty

[1] Abstract of the Address on State Medicine delivered at the Fiftieth Meeting of the American Medical Association, held at Columbus, Ohio, June 6–9, 1899.

was common. The Coliseum had to be furnished with material for the amusement of the citizens, and "To the lions!" was a common sentence. And then Rome had her Tarpeian Rock from which the defectives could be hurled, and thus disposed of before the State could be troubled by their presence. To-day, with the death penalty rarely enforced, and with no such cutting off of the supply of criminal material, the law contributes to its increase rather than to its diminution. One of the absurdities of the law is the frequent conviction of the same criminal, which is not only expensive, but unprofitable. The case of Jane Cakebread of London, with her 269 convictions, is but an exaggeration of daily occurrences in our courts.

Our jails are schools of crime. The delay of the law gives children, sometimes arrested for trivial offenses, weeks or months of tutelage under old and often incorrigible masters in crime, even before their guilt or innocence is established, and after conviction further instruction in the same arts, so that when they leave, after a brief period of restraint, they are experts and will do much damage to person or property before they are again sent up for further instruction.

Then, again, laws are defective because they are directed against the crime and not the criminal, overlooking the important fact that the crime is an accident, and the criminal may be the product of a long line of etiological factors demanding for his cure, not punishment, but reformation. The habitual criminal, who constitutes the great bulk of the class, is a biological study, and his anatomic, physiologic, and psychologic nature demands most careful investigation in order that physicians may determine the ways and means to settle the various and vast questions to which he gives rise.

The brain weight of the criminal does not differ materially from that of the non-criminal. The potentiality of the brain does not depend so much upon its size and weight as upon its structure. The brain of Gambetta was very small but very elaborately convoluted, so that it doubtless contained more and better neurons than that of the average person, and one of the heaviest brains on record is that of a bricklayer who could neither read nor write. Flesch, out of fifty brains of criminals, did not find one without anomalies. From an examination of twenty-eight brains he found alterations in the meninges to the extent of fifty per cent. in the way of adhesions, various forms of meningitis, hemorrhage, atrophy, and atheroma; these observations have met with abundant confirmation. Benedikt, one of the most thorough and conscientious workers in this field of criminal pathology, found in an examination of nineteen brains of criminals, a confluence of fissures. Another anomaly noted by this observer is that the frontal lobe is sometimes divided into four convolutions instead of three, which he considers an evidence of reversion to the carnivorous type. He has found other anomalies in brain-structure in criminals. The feet of the criminal frequently show a tendency to revert to the flatfoot of the lower races, and this is usually associated with a low instep. The thyroid glands of the inmates of the Elmira and Pontiac reformatories have been examined by Talbot, who gives the author the following figures:

	Examined.	Normal.	Excessive.	Deficient.
Elmira.....	1045	106	909	36
Pontiac.....	465	145	183	137

Bono, in studying the eyesight of criminals, found sixty per cent. of 221 young criminals color-blind. Biliakow, who made similar observations on 100 murderers, found fifty per cent. of them color-blind. Tactile, temperature, and pain sense are rarely normal in criminals. They are usually much diminished, especially pain sense. Anomalies of patellar tendon reflex are common; they are either exaggerated or very frequently absent.

In fifty autopsies Flesch found twenty per cent. which showed affections of the heart so grave as to be the cause of death. On calculating accidental affections of the pericardium and endocardium the rate was fifty per cent. In this respect the criminal resembles the insane. Many of the manifestations of insanity are due to cardiac vascular disturbances, and this might reasonably be expected when it is remembered that the blood-supply of the brain is much more extensive than that of any other organ not concerned in blood-making or blood-purification.

On the psychical side of the criminal's character we find moral insensibility, a lack of forethought, a low grade of intelligence, vanity, egoism, and emotional instability.

The next important aspect of this question is the treatment, which should be based on etiology to be scientific, and as criminal parentage and environment are the two great causal factors, so the treatment should be directed against them. First, the propagation of crime should be stopped. It should be made impossible for there to be any more Jukes, Ben Ishmael, or Jurkes families, and to do this marriage should be regulated. There should be no possibility under the law for these people to marry and propagate their kind.

The operation proposed by Dr. Ochsner, which consists in a resection of the vas deferens, does not mutilate the person. It does not destroy his sexual power, but it does prevent propagation, and it is an

operation attended by very little risk to life. In the speaker's judgment it may be made a most useful agent in preventing an increase in criminals. Castration has been proposed by some, but the operation is vastly more dangerous. It is a great mutilation, destroys sexual power, and for these reasons is by no means as useful an operation as the one proposed by Ochsner.

The children of these degenerates should be taken in charge by the courts and placed at the very earliest possible age, certainly not later than seven years, in a favorable environment, and by this means the great bulk of them might be made useful citizens. Alcoholism is a very important and difficult etiological factor to control. The saloon is such a powerful factor in our political system that it seems to be impossible to have legislators enact laws that will regulate properly this great traffic. The way to accomplish positive results is for physicians to spread information among the people as to the baneful influence of intemperance, and so educate the old and the young as to the powerful influence of this great factor in politics, so that it may be neutralized. Legislation is needed for inebriates; authority to place them in prolonged confinement, during which they may undergo such treatment as may be necessary for their cure. Legislation is certainly needed to diminish the traffic in alcoholics, and to improve the quality of the liquor furnished. But the best way out of it is not by prohibition at this time surely, but it may be by a high-license system. There should be some remedy provided against the constant increase in urban population. Some method should be provided for the restoration of the equilibrium; some way by which the unproductive citizen may be transported to the country and made productive.

The last etiological factor, the laws and the unreasonable manner of their execution, demands such changes that those who are concerned in the sentencing of criminals should know something about their biological condition, and surely the ordinary juror cannot possibly possess this knowledge. All sentences should be indeterminate; the criminal should be sent to a prison or reformatory, not for any specific time, but until he is reformed or cured, precisely as a patient is sent to a hospital. A person who has committed his first offense should not be permitted to associate with hardened criminals. Trials should be speedy and prompt. The pardoning power should be taken out of the hands of governors of States, and placed under the control of a board of pardons, whose members shall be skilled in criminal anthropology. For criminal minor children there should be reform schools, where, through a protracted period, these children should be educated by manual training, and taught some useful occupation that may be to them the means of earning an honorable livelihood, and when the time comes for their discharge, they should be furnished with means by which they may establish themselves in the occupation for which they have been trained. This is not an untried proposition, but is to-day a practice in Russia. There should be reformatories for the older criminals who are capable of reformation, and these also should be taught not only the rudiments of an English education, but useful arts, and their confinement should last until they are able to withstand temptation and earn an honest living, and, when released from the care of the reformatory, they, too, should be provided with a reasonable capital with which to make a start in life. And, lastly, for those who are incapable of reformation, there should be penitentiaries for their lifelong incarceration, and these should be made as near self-sustaining as possible by having the prisoners employed in useful occupations.

SANITARY LESSONS OF THE WAR.[1]

By GEORGE M. STERNBERG, M.D., LL.D.,
SURGEON-GENERAL, UNITED STATES ARMY.

As compared with the Civil War and with other great wars during the present century the mortality from wounds and disease among our troops during the war with Spain has been low. Our wounded have, to a large extent, had the advantage of prompt treatment with antiseptic dressings and a very considerable proportion of those who were not killed outright have recovered without any mutilating operation or septic complication. The mortality from disease has also been comparatively low, but unfortunately during the first months of the war that scourge of new levies of troops, typhoid fever, prevailed in many of our camps and claimed numerous victims. It is well known to sanitarians and military surgeons that, as a general rule, more soldiers succumb to disease than are killed by the bullets of the enemy, and our recent war has not been an exception in this regard. The total number of deaths reported in our enlarged army, including regulars and volunteers, from May 1, 1898, to April 30, 1899, is 6406. Of these 5438 died of disease and 968 were killed in battle or died of wounds, injuries or accident. During the Civil War the number of deaths from disease was 186,216.[2] The number who were killed in battle or died of wounds was 93,969, or about one-

[1] Abstract of a paper read before the Section on State Medicine at the Fiftieth Meeting of the American Medical Association, Columbus, Ohio, June 6–9, 1899.

[2] In addition to this 24,184 deaths are recorded as from unknown causes, and probably most of these deaths were from disease.

half of the deaths from disease. The total deaths from disease in the Union armies from the commencement of the war to the 31st of December, 1862, was 34,327, and in the Confederate armies during the same period, 31,238.

The following table gives the monthly death-rates from disease in our armies from May 1, 1898, to April 30, 1899, and, for comparison, the rates for the same period during the first twelve months of the Civil War:

Comparison of Monthly Death-Rates (per 1000) from Disease.

	1861–1862.			1898–99.		
Months.	Mean Strength.	Number of Deaths.	Ratio per 1,000 of M. S.	Ratio per 1,000 of M. S.	Number of Deaths.	Mean Strength.
May	16,161	18	1.11	.26	42	163,726
June	66,950	55	.82	.44	90	202,526
July	71,125	106	1.49	1 72	451	262,613
August	112,359	242	2.15	5.21	1,400	268,507
September	165,126	365	2.21	5.89	1,541	261,824
October	256,884	725	2.82	3.17	809	255,000
November	301,848	1,145	3.79	1.51	365	242,000
December	343,184	1,471	4.29	.84	201	240,000
January	352,760	1,598	4.52	.85	180	211,000
February	327,734	1,346	4.11	.87	156	180,000
March	328,878	1,575	4.79	.90	123	136,000
April	410,416	1,881	4.58	.71	80	113,000
Annual	229,452	10,522	45.86	25.73	5,438	211,350

In comparing the death-rates from disease during the year of the Spanish-American War, May 1, 1898, to April 30, 1899, and the first year of the Civil War, May 1, 1861, to April 30, 1862, note should be taken in the first place that the mean strength in May, 1861, was only 16,161 as compared with 163,726 men in service in May, 1898. The mustering in of volunteer troops progressed more slowly in 1861 than during the recent war, so that it was not until September and October, 1861, that the mean strength assumed proportions equal to that of the months of the Spanish War. Although the number present in the camps of 1861–62 after October, 1861, was largely in excess of those aggregated during the past year, the average annual strength during both wars did not differ greatly. Nevertheless the deaths from disease in 1861–62 numbered 10,522, while in 1898–99 they amounted only to 5,438. The death-rate per thousand of strength mounted gradually month by month in 1861–62, and indeed it did not reach its acme until February, 1863, when the rate of 6.39 was reached. In 1898, on the other hand, the acme, 5.89, was reached suddenly in September, but owing to the sanitary measures adopted the fall during October and November was as rapid as had been the rise.

The same gradual rise is seen in the mortality statistics of typhoid fever during the Civil War. The highest death-rate, 2.81, was not reached until May, 1862, the thirteenth month of the aggregation of the troops, when 1092 men died of this disease, and the fall of the rates was as gradual as the rise. On the other hand, the rise in 1898 was sudden, the maximum rate, 3.57, being reached in September, when 933 men died of this disease; but the fall during the months of October and November was as notable as the rise. This sudden suppression of the disease cannot be attributed to an exhaustion of the susceptibility of the troops to attack from this fever, as they only suffered at the rate of 12.37 per thousand of strength during the twelve months, whereas the troops of the Civil War suffered at the rate of 19.71 per thousand. It can be attributed only to the active preventive measures that were instituted, and especially to moving the troops to fresh camp sites and to the greater care exercised in the disposal of excreta.

The average mortality from typhoid fever in our regular army since the Civil War has been: For the first decade (1868–1877) 95 per 100,000 of mean strength (.95 per 1000); for the second decade (1878–1887) 108 per 100,000; for the third decade (1888–1897) 55 per 100,000. This latter rate compares favorably with that of many of our principal cities. For example, it is exceeded by the typhoid death-rate in the City of Washington, which is 78.1 per 100,000 (average of 10 years, 1888–1897); by that of the City of Chicago, which is 64.4 per 100,000; by that of Pittsburgh, which is 88 per 100,000. These figures, however, do not show the entire mortality in the cities mentioned as a result of typhoid fever, for without doubt many of the deaths ascribed to "malarial fevers" were in fact due to typhoid infection. Thus in the City of Washington the deaths reported from typhoid and typho-malarial fever (average of 10 years) numbered 78.1 per 100,000 of the population, while 23.4 per 100,000 are recorded as due to malarial fever. In Baltimore the mortality, as recorded, from typhoid fever is 41.5 and from "typho-malarial and other malarial fevers" 18.3 per 100,000. In St. Louis the figures are: Typhoid fever 35.7, typho-malarial and other malarial fevers, 49 per 100,000; in New Orleans typhoid fever 26.1, typho-malarial and other malarial fevers, 107.2 per 100,000.

It will be seen that sanitary conditions at our military posts in time of peace, as judged by the typhoid death-rate, compare favorably with those in our large cities in various parts of the country. As a matter of fact great attention has been given to post sanitation for many years past, and through the persistent

efforts of officers of the Medical Department great improvements have been made, especially during the past ten years. The result is shown in a reduction of the typhoid mortality from 108 per 100,000 in the ten years ending in 1887 to 55 per 100,000 in the decade ending in 1897. Hygiene is made one of the principal subjects of examination for candidates desiring appointment in the Medical Corps of the Army, and at subsequent examinations for promotion to the grade of Captain and Major is given a most prominent place. It is also the most prominent subject in the course of instruction at the Army Medical School, where the student-officers spend five hours daily for a period of five months in practical laboratory work, relating for the most part to the cause and prevention of infectious diseases. It should be remembered, however, that the Army Medical School was not established until the year 1893, and consequently but a small proportion of the medical officers of the army have had the advantage of this course of instruction.

But the comparatively small number of medical officers of the regular army for duty in the large camps occupied by our volunteer troops at the outset of the war proved to be entirely inadequate to control the sanitary situation in these camps, and as a result of the conditions existing the mortality from typhoid fever in our armies during the year ending April 30, 1899, has been more than twenty-two times as great as it was in our regular army during the decade immediately preceding the war period. As compared with the first year of the Civil War, however, there is a decided improvement, the typhoid mortality for the first year of the Civil War having been 1971 per 100,000 of mean strength, and for the Spanish-American War 1237 per 100,000. Moreover, the vigorous sanitary measures enforced enabled our troops to quickly free themselves from the ravages of this infectious disease, and while the line of typhoid mortality continued to ascend during the first year of the Civil War and subsequently, it rapidly fell after the middle of September, last, and for the last six months of the period under consideration has been remarkably low. Indeed, in the history of large armies the record has never heretofore been equalled.

Typhoid fever in our camps has been to a large extent due to the neglect of well-known sanitary measures indicated by me in Circular No. 1, dated, Surgeon-General's Office, Washington, April 25, 1898; also to a very general failure upon the part of medical officers attached to regiments to recognize the disease in its milder forms and during its earlier stages. As a result of this the camps became infected, and the failure to use proper methods of disinfection, and the continued occupation of infected camps, has led to the development of veritable epidemics of typhoid fever in several of the camps occupied by our troops.

The principal lessons to be derived from our recent experience may be stated as follows:

A trained medical corps, hardly adequate for an army of 25,000 men, cannot control the sanitary situation when this army is quickly expanded to 250,000. Physicians and surgeons from civil life, however well qualified professionally, as a rule are not prepared to assume the responsibilities of medical officers charged with administrative duties and the sanitary supervision of camps. The proper performance of such duties cannot be expected from a physician without military training or experience, no matter how distinguished a position he may have held in civil life.

Courage and patriotism on the part of line officers and enlisted men cannot take the place of knowledge and experience. New levies of troops are, as a rule, ignorant of the first principles of camp sanitation, and reckless of the consequences of their neglect of prescribed sanitary regulations. Therefore, training and discipline are essential factors in the preservation of the health of soldiers in garrison or in the field.

The value of the aphorism "in time of peace prepare for war" has received additional support. This preparation should include a corps of trained medical officers larger than is absolutely necessary for the army on a peace basis, and systematic instruction in military medicine and hygiene for the medical officers of the National Guard, as well as for those of the regular army; also instruction of line officers in the elements of hygiene, and especially in camp sanitation. It should also include the establishment of camping-grounds in various parts of the country, having an ample supply of pure water, a proper system of sewers, etc. If our volunteers could have been assembled in such camps during the late war a saving in lives and money would have resulted which would without doubt have demonstrated the economy of such preparation for war in time of peace.

RESPIRATORY FAILURE OCCURRING BEFORE CIRCULATORY FAILURE IN BRAIN INJURY AND DISEASE, AND ITS CLINICAL BEARINGS.

By W. H. HUDSON, M.D.,
OF LA FAYETTE, ALABAMA.

In an article of mine, which has not yet been published, reporting a case of cerebellar cyst, which I located and successfully removed, I refer in a superficial way to the subject of this contribution. I

also discussed the subject more fully before the Alabama State Medical Association, at the meeting in Birmingham in 1898. I am impressed that the subject is of the highest importance and, from the little that is said and written about it, I think that perhaps many in the profession are not fully awake to the importance of this fact, either from the physiological bearing of the condition or its clinical significance. In 1890 I observed the continuance of circulation after breathing had ceased in a child which had a meningitis complicating pneumonia. In the early part of 1893 I observed the phenomenon which was present in a most striking manner in an infant a week old, whose cerebellum had been injured at birth; this infant was kept alive for twelve hours by artificial respiration.

The most striking instance of the importance of recognizing this condition that has come under my personal observation I will refer to later in giving a synopsis of the history of the case of cerebellar cyst. Before taking this up I will add here some of the most important cases which have appeared in the literature, and discuss briefly some of the most important contributions to this subject.

Leyden (*Virchow's Archivs*, Bd. xxxvii, 1866) was the first to record the changes in blood pressure by a series of experiments in which he raised the intracranial pressure by forcing air into the skull by a piston. He noted the slowing of the pulse, the deep stertorous respiration, the final arrest of respiration, and the final great rapidity of pulse. Hilton Fagge ("Principles and Practice of Medicine," pages 526 to 551, 1886) observes that some patients with cerebral tumor or abscess die from failure of respiration. In one case the respiration ceased thirty-five minutes before death; in another, a case of multiple cerebral abscess in the posterior and middle lobes, the breathing ceased ten minutes before death.

Professor Macewen of Glasgow, in his magnificent work, "Pyogenic Infective Diseases of the Brain and Spinal Cord," speaks of several cases of depression of the respiratory function with slowing of cardiac action. In his lectures delivered in San Francisco in 1896 he reported cases in which the pulse-rate was lowered to forty or even to twenty in the minute as the intracranial pressure increased. He also noted the occurrence of modified respiration resembling the Cheyne-Stokes type in cases of abscess of the cerebellar fossa, leading to death from pressure on the respiratory center, the pulse remaining quick and strong. In one case artificial respiration was carried on twenty-four hours, the pulse never flagging. Macewen has met with two cases in which the breathing was reestablished after hours of artificial respiration. In one case cited he opened and evacuated a cerebellar abscess while artificial respiration was being practised. In this case the relief of cerebellar pressure greatly relieved the general condition, and soon afterward the respiration became voluntary. This patient recovered temporarily but died later from cardiac failure, probably due to exhaustion, the restored breathing continuing perfect to the end of life. Macewen observed this phenomenon in a case of apoplexy, and also in a very interesting case in which the respiratory apparatus was destroyed by a crushing force, the heart continuing to beat, producing at each impulse a cracking of the broken ribs.

Mr. Victor Horsley, in a very valuable contribution to this subject, published in the *Quarterly Medical Journal*, July, 1894, calls attention to the fact that patients suffering from cerebral hemorrhages, tumors, depressed fractures of the skull, sudden and violent concussion, especially when applied in the occipital region, die from respiratory and not cardiac failure. Horsley, Spencer, and Leonard Hill confirm these observations. Horsley's clinical studies show that in cases of cerebral tumors, hemorrhages, and inflammatory foci death is apt to occur suddenly from arrest of the respiration. Indeed, respiratory arrest appears to be the common cause of death in all cases of pathological intracranial tension, especially when the disease is extremely chronic. He offers the suggestion that in cases in which patients fall apparently dead after sudden blows on the head, they do not die, as is commonly believed, from cardiac failure, but from the arrest of the respiratory function. In such cases he thinks that it might be possible to preserve life by artificial respiration. Direct experiments prove also that bullet-wounds of the cerebral hemispheres, severe injuries, etc., produce arrest of the breathing and when the respiratory center is not destroyed by the pressure of hemorrhage, or by direct injury, life may be preserved by carrying on the respiration artificially.

Sir Dyce Duckworth, in a notable paper read at the International Medical Congress, Moscow, August, 1897, calls attention to this phenomenon and thinks that the condition has not been fully recognized. In this paper he gives a record of four cases, which occurred under the care of Butlin, himself, Brunton, and Walsham. The salient points in these cases were diseases of the cerebellum, or posterior cerebral lobes, infective in nature with attending signs of increased intracranial tension. In three of his cases the temperature was normal or subnormal, in one instance rising from 96.8° to 102° F. in sixteen hours. It is possible that the inhibition of

the respiratory center may bear some relation to this absence of pyrexia, in a condition in which infection and inflammation play the important rôle. In each of these cases there was respiratory failure before heart failure, and though artificial respiration successfully prolonged life for a short time, in no case was death averted. It is the opinion of Duckworth that the respiratory center is the first to give way and is the most vulnerable of all the great nerve centers, being the first to resent undue intracranial pressure.

Without going further into the consideration of reports of these cases I give here a short history of a case which came under my care:

Julie R., a negro girl, seven years old, was placed under my care for treatment in the summer of 1896. The immediate family history was good; she was a well-nourished, healthy-looking girl, rather large for her age. Her head measured twenty-two inches in circumference, her eyes were prominent and protruding, with a lateral nystagmus; the movement of the eyeballs was restricted in all directions. The abducens of the right eye was more defective than the other ocular muscles. To close the eyelids required an effort, and they could be kept closed for a short time only. The pupils were widely dilated and did not react to light; there was double optic neuritis, with small retinal hemorrhages in one eye. She could barely discern light and only a short time later became totally blind. There was paresis of the right facial nerve. Hearing was good in both ears; taste and smell were normal; pulse was sixty-five beats to the minute; the respiration was lowered.

Her appetite remained good and at times was voracious; there was pain of moderate severity located in the back of the head and right side of the neck. The muscles of the neck were stiffened and the head was slightly retracted. There was severe pain when an attempt was made to straighten the neck. There was no pain on percussion, but firm pressure over the cerebellar fossa elicited pain. The grasp of the left hand was much weaker than that of the right. Both knee-jerks were absent. When lying down coordination in the arms and legs was good. In attempting to walk her gait was staggering and uncertain, and she would usually fall after walking a few feet. In walking there was a tendency to turn first to the left, later, as intracranial pressure increased, to the right. Percussion of the head indicated much ventricular distention. There was vertigo and vomiting, and also undoubted signs of paresis of the trunk. Toward the last, before the operation was performed, there was rapid failure of the mind, and a loss of sphincteric control.

From the foregoing symptoms a diagnosis of cerebellar disease was made, which was located with reasonable certainty in the right cerebellar lobe. I advised an operation, expecting to find a tumor, perhaps of tuberculous nature, as the child had been living in the house with persons affected with pulmonary tuberculosis. Her condition, however, did not suggest tubercular disease and I considered a sarcoma quite as probable.

I operated in June, 1896. It was evident that the intracranial pressure was very much increased and I apprehended the danger that might result therefrom during the operation, so I requested one of my assistants to hold himself in readiness to perform artificial respiration on the first indication of respiratory failure. I furthermore notified him that I would finish operating under artificial respiration if it should be necessary. With the most approved surgical precautions the skull was opened. The bone was not thicker than ordinary blotting-paper. The dura mater bulged into the opening through the bone, was very tense, showing the most marked intracranial pressure. When the dura was incised the brain was forced through the incision, and it at once became apparent that the excision of the protruding mass of brain would be necessary before a satisfactory examination could be made. After the first portion of the brain was cut away, more brain was forced out, which was also excised. On account of the pressure, perhaps, the brain presented an abnormal appearance, which I mistook for a tuberculous foci, and on this account stopped the operation without exploring the brain in any direction. (A month later, a second operation was performed, a large cyst opened and evacuated, with recovery almost complete, with the exception of blindness, which has remained stationary to the present time, May, 1899.)

The incision of the dura mater was closed by sutures as was the scalp wound. There had been very little bleeding during the operation and it was thought that the patient had stood it remarkably well. Just as the bandaging of the head was being finished respiration ceased, though the pulse remained good. I at once proceeded to practise artificial respiration, which had to be carried on fully thirty minutes, as estimated by the assistants present. At the end of this time there was a weak effort at breathing, which gradually grew stronger and in a few moments was established normally. The pulse at no time showed any sign of failure, when respiration failed, during the practise of artificial respiration, or during the establishment of normal respiration. I can but be certain that the life of this patient was preserved by the knowledge of the fact that this phenomenon may be looked for as a condition attending such a process existing in the brain, and that it is possible by artificial respiration to carry on this function until the breathing-center reasserts itself.

The sole purpose of this paper is to call the atten-

tion of physicians and surgeons to the fact herein brought forth; and as a summary of the study I would suggest: That in cases of intracranial pressure death is generally produced by failure of respiration and not of circulation; that in many cases of severe injury to the brain, such as gunshot wounds, blows, etc., the respiratory center may be inhibited and we may be able to save life by keeping up artificial respiration until hemorrhage may be stopped and the wound otherwise attended to; that the pouring of hot sterile salt solution on the exposed brain and on the patient's head, as suggested by Horsley, adds somewhat to the reestablishment of the arrested brain functions; that in operations upon the brain, especially those involving the posterior cerebral lobes and cerebellum, whether or not there are signs of increased intracranial pressure, we should be ready to practise artificial respiration even to the extent of carrying it on through the entire operative procedure.

As artificial respiration is a positive necessity, in the safe management of the cases here suggested, I would consider it of especial importance that we be able to perform it in the most effectual manner, and, therefore, the Fell-O'Dwyer apparatus should be at hand with an expert to use it, as the most effectual method we have at present, for the practise of artificial respiration, bearing in mind that it may be necessary to use external force to expel the air from the lungs.

THE RESISTANCE OF BACTERIA TO COLD.[1]

By MAZYCK P. RAVENEL, M.D.,
OF PHILADELPHIA;
BACTERIOLOGIST TO THE STATE LIVE STOCK SANITARY BOARD OF PENNSYLVANIA; INSTRUCTOR IN BACTERIOLOGY, VETERINARY DEPARTMENT, UNIVERSITY OF PENNSYLVANIA.

It is the object of this communication to put on record the results of some experiments made with liquid air in March and April, 1898, to determine what effect such intense cold would have on bacteria. The recent use of liquefied air in surgery, and the claim that it is a germicide give the subject a direct practical interest, and have led me to make this report in a much more incomplete state than I had expected and hoped. The difficulty in obtaining the air for experimental purposes is my only reason for not having carried my experiments further and it is my purpose to do so when possible. I am greatly indebted to Professor George F. Barker of the University of Pennsylvania for the interest shown by him in the subject, and for his kindness in supplying me with the liquid air used.

The temperature of liquid air is 312° F. below zero, and when one sees the effect it has on inanimate objects, and the rapidity with which it destroys tissues, one finds it hard to believe that vegetable life can withstand it even for a few moments, yet such is the case. My experiments were tried with anthrax spores dried on silk threads, with recently grown cultures of diphtheria on blood-serum, and with agar cultures of the typhoid-fever bacillus, and the bacillus prodigiosus. In the case of the three latter organisms a suspension of the growth was made in sterile water, silk threads impregnated with this suspension, and the threads then immersed in the liquid air without drying. At intervals a thread was removed, transferred to bouillon, and placed in the incubator. In this way anthrax spores were exposed to the action of the liquid air for one, five, ten, fifteen, and thirty minutes, and three hours; the diphtheria bacillus for fifteen and thirty minutes; the typhoid bacillus for twenty, forty, and sixty minutes; the prodigiosus for thirty and sixty minutes. In no case were the bacteria killed, nor could any inhibition even be detected, all cultures growing as rapidly and as vigorously as the controls.

When these experiments were tried it was my belief that bacteria had never before been subjected to such low temperatures, but in this I proved mistaken. I have, however, been able to find but one other such experiment recorded, by Pictet of Geneva, who subjected a number of bacteria, the names of which are not given, to the action of liquid air. He states that they afterward developed in the same way as controls kept at ordinary temperature. He could not detect any appreciable difference between the two. He does not give the length of time the cold was allowed to act. Previous to this Pictet and Yung had subjected various cultures to low temperatures. After an exposure to cold of 70° C. below zero, continued for 108 hours, and 130° C. below zero for twenty hours, they found that anthrax spores retained life and virulence intact, but virulent anthrax blood became innocuous. The bacillus of symptomatic anthrax retained its virulence also under the same treatment. Bovine vaccine lymph was rendered sterile. Brewer's yeast was not killed, but lost to a great extent its power of producing fermentation. Similar results were obtained by Frankland and Templeman, who found that anthax spores were practically unaffected by repeated freezings, the process having been repeated twenty-nine times, and the temperature being reduced on each occasion to 20° C. below zero, while the ice formed was not melted until twenty-four hours had passed. On the other hand sporeless anthrax was almost entirely destroyed by one freezing, and completely destroyed by two freezings. In the first experiment the freezings and

[1] From the Laboratory of the State Live Stock Sanitary Board. Read before the Philadelphia Pathological Society, May 11, 1899.

thawings extended over a period of three months, while in the latter only five days were occupied.

That what may be considered moderate degrees of cold can not be relied on for the destruction of infection has been painfully demonstrated by the epidemic of typhoid fever at Plymouth, Pa., in 1885, when the stools remained frozen for some time; and by the outbreak of yellow fever on the United States Corvette "Plymouth" in 1879, after having been frozen out at Boston, the ship piled up with ice, and the temperature falling to 28° F.

The former of these experiences prepares us for the statement of Prudden concerning the resistance of the bacillus of typhoid fever to cold. Prudden kept this organism in artificial ice at a temperature of 14° to 30° F. for 103 days, without entirely destroying its vitality. At the end of eleven days one million germs per c.c. were found; after seventy-seven days seventy-two thousand, and at the end of 103 days seven thousand per c.c. still remained. This bacillus has unusual powers of resistance to cold, and it is said by Seitz that multiplication begins to take place at 4° C. Certain water bacteria are said to be able to vegetate as low as zero centigrade, but among pathogenic organisms, the bacillus of typhoid fever is unique in its power to grow at low temperatures. Alternate freezing and thawing is rapidly fatal to the typhoid bacillus, according to Prudden. Beginning with 40,000 per c.c. he reduced the number to ninety in twenty-four hours, three thawings having intervened, and in three days the bacteria were entirely destroyed.

As would be expected, the power of resistance to cold varies with the species, and also in the same species to some extent. Prudden found that the staphylococcus aureus from an old and half-dried culture was destroyed after seven days of freezing, while that taken from a fresh agar culture, and present in uncountable numbers at the beginning of the experiment, still showed 50,000 per c.c. after sixty-six days of freezing.

Of twelve species of bacteria kept in a freezing mixture in gelatin culture by Heyroth for seven days, only three failed to grow; and of eighteen species kept for ten days only one failed to grow, the temperature being presumably about 20 ° C. below zero. These four were the organisms of swine fever, swine plague, rabbit septicemia and sporeless anthrax.

In conclusion I think it may be safely said that, so far at least as our present knowledge of it permits of its application, cold cannot be relied on as a disinfectant. In spite of the extravagant claims made for liquid air as a germicide, it is practically innocuous in this respect.

MEDICAL PROGRESS.

Paget's Disease of Thirteen-Years' Duration.—Masland and Babcock (*Proceed. of the Path. Soc. of Phila.*, April 1, 1899) showed a specimen of Paget's disease of the nipple taken from a white woman aged fifty-six years, who had been married but had never borne children. The interesting point about the trouble was that it had existed for thirteen years, and had not developed into carcinoma, although the nipple had been obliterated, and the greater part of the surface of the breast had been involved, being denuded of its superficial epithelium, and covered with a sero-purulent discharge. Microscopical examination showed that the mammary ducts were entirely obliterated, and to this fact the authors attributed the freedom from extension inward of the epithelial cells, as usually happens in Paget's disease after about two years. Aside from speculation as to its true nature, the chief interest in Paget's disease lies in its relation to carcinoma of the breast. It is not, however, a very frequent forerunner of this trouble, as investigation showed its occurrence only five times in 400 cases of mammary carcinoma.

Chloroform Water as a Preventive of Accidents after Chloroform Anesthesia.—Weber (*Bull. Gen. de Therap.*, April, 1899) says that the nausea after chloroformization may be avoided if the patient will take chloroform water for several weeks before undergoing operation, so as to accustom the system to it. His attention was called to this fact by the absence of nausea after operation in the case of two patients, who on account of digestive disturbances had taken chloroform water after each meal for several weeks. As the taste and smell of chloroform is repugnant to some persons, the following mixture is recommended:

℞ Aq. chloroform. . . . . ʒ vj
Spir. menth. pip. } aa . . . *m.* iv.
Spir. anis. }
Filter after twelve hours.

Successful Nerve Transplantation.—Peterson (*Amer. Jour. Med. Sci.*, April, 1899) reports a case in which a secondary resection of a little more than an inch of both the median and ulnar nerves was made and the gaps closed in with portions of the sciatic nerves of a young hound. The result was exceptionally good, as both sensation and motion returned to a large degree. The author also gives a resumé of all the published notes of similar cases. He was able to collect twenty of these, nineteen of the operations having been performed upon the median, ulnar or musculo-spiral, one upon the sciatic. The implanted nerves were in six cases obtained from recently amputated human limbs, in the others from the sciatics of dogs, rabbits, or kittens. In twelve of the twenty cases there was improvement in sensation or motion, or both. In no case was there a perfect restoration of muscular power in every muscle affected. The return of sensation was complete in four cases, and nearly complete in three others, but collateral sensation has to be considered as possibly explaining a part of the return

of normal feeling. Vicarious motions of other muscles must also be watched, as this may be the true explanation of a very early supposed restoration of the nerve action. On the whole, however, the author considers nerve transplantation as a legitimate surgical procedure.

Prevention of Urinary Infection.—DOWD (*Buffalo Med. Jour.*, May, 1899) insists upon the importance of asepsis in the urethra before the passage of instruments into the bladder. No matter how carefully the external parts have been cleansed and the instruments boiled, they will be covered with germs before they have gone an inch from the meatus, unless the urethra has been disinfected. Of the numerous syringes which have been devised for this purpose, Dowd prefers a six-ounce syringe with a long nozzle, and a cup-shaped shield with the concavity looking outward. There can be no soiling of the clothes or hands with this instrument, and the surgeon can readily estimate the resistance of the urethra and the capacity of the bladder. He prefers a solution of formaldehyd as a disinfectant. After the instrument has been used, the bladder is filled with an astringent antiseptic solution, which the patient is allowed to pass immediately afterward. The irritation of instrumentation will thus be avoided. By these simple measures infection will be almost certainly avoided.

Synovectomy or Resection in Tuberculosis of the Knee.—BEGOUIN (*Gaz. heb. de Med. et de Chir.*, April 2, 1899) had an excellent opportunity to compare the relative advantages of synovectomy and resection in tuberculosis of the knee of adults, when limited to the synovial membrane. Two patients, aged twenty and twenty-six years respectively, entered the hospital at about the same time. The man, aged twenty-six years, was treated by resection, and in three weeks his leg was solid in a good position, and he walked without fatigue. The young woman was treated by synovectomy, and obtained a joint which could be moved a little for a time after the operation, but which became constantly stiffer and a little more flexed, so that at the end of three months she could not walk far without fatigue, and the process of flexion of the leg on the thigh was still going on. Whatever may be the desirability of synovectomy in the upper extremity, in the knee-joint an absolute immobility is far better than a rough, painful joint. A slight shortening of the limb which follows resection, is after all no disadvantage, as when the knee is ankylosed, it is a convenience to have the limb 1 inch or 1½ inches shorter than the other, to secure its easy manipulation.

The Thermal Death-Point of Tubercle Bacilli. — SMITH (*Jour. of Experiment. Med.*, March, 1899) found in his experiments that tubercle bacilli suspended in distilled water, were killed by exposure to 60° C. (140° F.) for fifteen or twenty minutes. The larger number were killed by an exposure of five to ten minutes. Suspended in milk, some of them were able to resist this temperature for more than an hour. The explanation of this apparently contradictory statement is given by Smith, who found that many bacilli were caught in the pellicle which forms on the surface of scalding milk, and that they escaped the general temperature of the liquid in this manner. He suggests that this may be avoided, either by submerging entirely the bottles containing the milk, or by filling them completely. Otherwise it will be necessary to continue to use the higher temperature of 68° C. (154° F.) which is now generally employed.

THERAPEUTIC NOTES.

Simple Treatment of Ingrowing Nail.—KINSMAN (*Columbus Med. Jour.*, April 4, 1899) says that he does not remember an instance in which, by the following method, he has failed to cure an ingrowing nail: (1) Remove all pressure from the nail by cutting away a piece of the shoe. (2) Disinfect with hydrogen dioxid until no more "foam" appears. (3) Apply a drop of strong solution of cocain in the base of the ulcer. (4) Apply a drop of Monsell's solution to the ulcer, then cover loosely with gauze. Repeat this process every second day until the edge of the nail is released, by the retraction of the hypertrophied tissue. The patient suffers no pain from the application, and all pain has disappeared by the second day. The cure is effected in a week or two without inconveniencing or interfering with business.

Aseptic Vaccination. — POEPPELMANN (*Deut. med. Wochenschr.*, March 9, 1899) insists upon five requisites for a perfect vaccination. (1) An animal lymph which is free from bacteria; (2) instruments made sterile by boiling; (3) the sterilization of the skin, preferably by a brisk rub with alcohol. This rapidly evaporates and so does not interfere with the success of the vaccination. In fact, the removal of the surface epithelium and the hyperemia induced by the rubbing favors the "taking" of the lymph; (4) the prevention of post-vaccinal infection, which is best accomplished by covering the wound with a celluloid capsule made for the purpose; (5) rapidity of execution.

Irrigation of the Bowel in Fermental Diarrhea.—HUBBARD (*Arch. of Pediatrics*, April, 1899) says that the worst cases of fermental diarrhea present clinically the picture of a severe toxemia. The ideal treatment would be to flush out the alimentary canal from the mouth to the anus. When seen the offending matters have usually passed from the stomach, so that it is the large intestine only which is accessible to irrigation. A large soft rubber catheter and a fountain-syringe are all that is needed, and water or saline solution, or some mild antiseptic, such as a weak solution of sulphonaphthol may be used for irrigation. The temperature of the fluid should be about 85° to 90° F., and the syringe should be held three feet above the body. The irrigation not only lowers the temperature, but quiets the restless babies, some of them even going to sleep during the process. The pulse is improved. No contraindications are mentioned as no bad results were seen to follow the irrigations in any instance.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 10, 1899.

THE COLUMBUS MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

IN the midst of record-breaking temperature there has been held, during the week, a most enthusiastic meeting of the American Medical Association in Ohio's fair capital city.

Nearly 3000 members registered, and the attendance from even distant parts of the country shows that the Association is growing in popularity and becoming more and more, with each succeeding year, what it should be—the actual representative body of the American medical profession. The reception accorded various portions of the president's address well shows the temper of the profession in this country with regard to certain practical questions, which, with most judicious discernment, he suggested for action on the part of the Association.

There was but one opinion regarding the adoption of measures to prevent the spread of syphilis in the United States. A hearty reception was given the proposal that State and Federal aid should be invoked in the active warfare it is expected henceforth to wage against tuberculosis, and the suggestion looking toward the erection of sanatoria for the treatment of the disease was heartily commended.

The proposal to have a single meeting-place for the Association, Washington to be designated as the most desirable situation, was received with applause at the meeting, yet the tone of private conversation afterward, among the members, showed that the suggestion meets with little favor. The proposal to make obligatory the printing in the *Journal* of the Association of all papers read at the annual meeting did not seem to have the sympathy of the audience.

In the Session on Surgery it was very noticeable that even the most conservative of surgeons no longer urges that there is any adequate medical treatment for appendicitis. The division of opinion now appears to be whether operation is indicated when symptoms of general peritonitis are present. The older men seemed to think that in this lies the patient's only hope, and that operation should be performed even in the face of almost certain failure. The younger men, on the other hand, considered general peritonitis a contraindication to operation and some advised, as the result of some successes, medical treatment with rectal feeding. In gall-stone surgery it was evident that immediate operation as soon as the diagnosis is assured is what the near future holds. It will no longer be counselled to wait in hope that Nature will dispose of the offending concrement, but just as in appendicitis true conservatism will dictate its removal and positive avoidance of the dangers connected with the let alone treatment.

The discussion in the Section on Medicine of cerebrospinal meningitis proved most interesting. It is clear that Professor Osler did well in selecting "Cerebrospinal Meningitis in America" as the text for the Cavendish lecture, to be delivered next week in London. Physicians in this country have had a most varied and instructive experience with the disease. It has occurred seemingly sporadically among us under the most varied circumstances, and the results of scientific clinical observation from various parts of the country show that we have in America a great deal to add to the subject in the ordinary text-book.

THE EFFECT OF ALTITUDE ON THE BLOOD.

THIS very interesting subject, the effect of lowered barometric pressure on the blood, has been attract-

ing attention during the past ten years. The discussion at the recent meeting of the American Climatological Association of Dr. Solly's paper on the subject shows that there is still much about it that is doubtful and deserving of further investigation. Blood counts made within twenty-four hours after an ascent to a height of even 2000 feet show seemingly an increase in the number of red blood-corpuscles present. This disappears upon the individual descending to the ordinary level. Animals kept in bell-jars from which the air has been exhausted to a certain degree, exhibit the same phenomenon. The amount of hemoglobin is not at first increased proportionately to the number of red cells but there is a gradual rise in its value, and also an increase in the specific gravity of the blood.

The subject deserves further investigation especially from the clinical side and this seems to be a proper time of the year to suggest it as large numbers of people go during the summer months to the mountains. A careful comparison of the state of their blood as made by their family physician at home and their physician at the summer resort would furnish important scientific data. Examinations of their blood made after their return and compared with its condition before their departure would be especially valuable. It is the subsequent condition as revealed at the expiration of several months that has not been studied as much as other aspects of the question. It is, too, the most practical side of the problem, because it will reveal how lasting any effect of altitude on the hematopoietic system may prove to be.

Meantime it is well to bear in mind certain objections that carry a good deal of weight against admitting that the increase of red blood-cells is real, *i.e.*, that there is an actual addition of a large number of red corpuscles to those already existing in the body. In severe anemia, especially in pernicious anemia, when, because of the destruction of red cells, there is a constant call for the manufacture of them in greater numbers there develops over such important parts of the hematopoietic system as the flat bones, a tenderness to pressure that is the index of the increased function of the red marrow. The spleen is also enlarged and there is tenderness in the splenic region. Such symptoms have not been noted after ascent to an altitude though that ascent is seemingly followed in twenty-four to forty-eight hours by an increase of one half to one million or even by more red cells in every cubic millimeter of the blood.

Moreover, after the descent to the lower level the blood count descends as rapidly as it had previously increased. Despite the fact, however, that millions and millions of red blood-cells are seemingly destroyed, there are no manifestations of that fact and no appearance of the pigment of these cells in any part of the system. There is no icterus and no hemoglobinuria. Where the destroyed cells go to remains a mystery. To say as some observers have said that there are more shadow corpuscles in the blood after descent, does not mean much so long as the hemoglobin remains unaccounted for. Neither does the claim that there are a few more nucleated red blood-cells and mitotic figures to be found in the blood during the supposed rapid multiplication of red cells just after the ascent carry much weight.

It will be seen then that there is in this effect of altitude on the blood a most interesting question on which the clinician may throw a good deal of light. Is the effect only a redistribution of the red cells of the body in such a way that while they were previously crowded into internal organs they are now allowed in the rarefied atmosphere of mountains to reach the periphery? If this be the fact what effect has it on the general well being and on metabolism and above all, how long after descent do these effects continue?

ANTENATAL THERAPEUTICS.

THE subject of treating the fetus in utero for various conditions from which it may be supposed to be suffering has recently awakened renewed interest. Fournier has shown that it is possible to treat satisfactorily, through the mother, the child of a syphilitic father, even though the mother herself shows no signs of specific disease. In the *British Medical Journal*, April 15th, Dr. J. W. Ballantyne of Edinburgh publishes the concluding lecture of a series of six on the subject of antenatal therapy, which also gives some very pronounced opinions on this rather fateful question.

At times claims have been made that almost every drug in the Pharmacopœia will pass through the placenta and affect the fetus, while at others the whole subject has been thrown into its pristine confusion by the announcement, supposedly on experi-

mental grounds, that scarcely any drug will pass directly to the fetus. Dr. Ballantyne practically adopts this latter conclusion, which is also that of the French school, and considers that the fetus is affected only indirectly, the nutritional function of the placenta being influenced by medication sufficiently to produce its modifying effect upon the fetus. Of the drugs that he has found especially valuable in this way, the chief are the antisyphilitic remedies, mercury and the iodids, potassium chlorate, and alcohol. The antisyphilitic remedies he considers of the greatest service. Potassium chlorate he regards, as did Sir James Simpson and does Lawson Tait, as a useful drug in cases where premature labor or abortion has become habitual or is for any reason feared. Alcohol in any excess on the part of either parent always robs the fetus of its power of resistance to disease and makes it morbid during life.

He closes his lecture with a warning with regard to the use of quinin in the pregnant woman, even for malaria, because of its liability to produce abortion. He also refers t the supposed fact that female workers in tobacco factories frequently abort. These are two fetiches that have crept into obstetrical literature and continue to have libations poured out before them by each new writer in this specialty. We do not know that there are any statistics in medical literature that justify the assertion that workers in tobacco abort easier than other women. In tropical countries where malaria abounds and quinin is freely used the idea of quinin ever initiating labor pains is ruthlessly scouted though it is considered by many, because of its tonic effect, to strengthen pains already occurring.

ECHOES AND NEWS

Tuberculosis Tests in Chicago.—In Chicago, on May 29th, twenty-five dairy-cows out of a herd of sixty-one were found, by means of the tuberculin-tests to have tuberculosis. These twenty-five cows were slaughtered and the tests confirmed.

Physicians' Certificates.—Some of the New York City justices have announced that they will no longer accept physicians' certificates of sickness for unwilling jurors, but that in such cases the physicians will be called into court to testify concerning such illness.

State Private Charities.—The forthcoming number of *Charities*, the official organ of the Charity Organization Society of New York City, gives a full statement of the private charities of New York State that receive public aid. The total of the public appropriation for this purpose in 1899 is $3,251,802.84.

New Dispensary in Brooklyn.—The new building of the Bushwick and East Brooklyn Dispensary, erected at the corner of Lewis and Myrtle avenues, Brooklyn, by Henry Batterman, in memory of his daughter, Laura Frances Batterman, will shortly be opened. The structure has cost $20,000 and Mr. Batterman has donated $25,000 for the work.

New York Quakers on Vivisection.—The Friends of New York have replied thus to a communication from the Friends' Antivivisection Association of London: "We feel that while vivisection may be justifiable as a means of gaining knowledge for alleviation of disease, we believe the practice for the purpose of testing or illustration of what is already known to science should be discouraged and restricted."

Mountain Toothache.—A peculiar affection of the teeth, mountain toothache, has recently been observed by an Italian dentist. The sufferers are engineers and laborers, new hands, working at an elevation of 2600 yards or over, and consists of intense pain in several adjoining teeth. This lasts for from four to five days, until the new men become somewhat accustomed to the altitude. The teeth in every case were apparently healthy.

New Officers of the American Orthopedic Association.—At the executive session, held June 2d at the New York Academy of Medicine, the following were elected as officers of the Association for the ensuing year: President, H. M. Sherman of San Francisco; first vice-president, R. Tunstall Taylor of Baltimore; second vice-president, A. R. Shands of Washington, D. C.; treasurer, E. G. Brackett of Boston; secretary, John Ridlon of Chicago.

Smallpox in the United States.—During the week ending June 3, 1899, 140 cases of smallpox, with 10 deaths, were reported to the Surgeon-General of the United States Marine Hospital Service, as having occurred throughout the country since May 15th. According to this report Louisville, Ky., leads the list with 75 cases, with 4 deaths, while Swampscott, Mass., reports 20 cases, with 1 death; Philadelphia, 29 cases, with no deaths, and St. Louis, 16 cases, with no deaths.

Christian Science in Chicago.—On June 1st it was reported from Chicago that within a few days two patients ill with diphtheria had been treated by Christian Scientists and had died. Each was four years of age. It is stated that the Health Department of Chicago has decided to take steps to compel those having charge of contagious diseases to provide medical attendance, in order that the lives, not only of the patients themselves, but also of those about them, may not be jeopardized.

A New Preparation of Thyroid.—Switzerland, the classic home of struma, still continues to contribute to the literature on thyroid therapy. In a recent number of the

Correspondenz-Blatt für schwetizer Aertze Professor Dr. Jaquet concludes a paper on experimentation with thyroid extracts and commends a new preparation called aiden. This is a precipitate from a solution of thyroid in normal salt by means of tannin and is said to contain a greater number of the extractive principles of the gland than have hitherto been obtained. It has not yet been sufficiently tried clinically to prove its efficacy, although the results from experiments on animals are promising.

Yellow-fever Quarantine.—In consequence of a yellow-fever case having been found in New Orleans the Texas State Health Authorities established a quarantine against that city on May 30th. On June 2d health officers of Alabama, Mississippi, and Louisiana reported concerning the health conditions in New Orleans to the effect that they could find no other cases of suspicious illness and could not trace the source of infection in the reported case of yellow fever. The investigators considered it unnecessary and unwise for any State or city to quarantine against New Orleans under conditions existing up to that date (June 2d). This report will probably influence the Texas Health Board to withdraw its quarantine.

Harvard's Medical Teaching.—Plans are well matured for the creation of a College of Comparative Medicine at Harvard University, an institution which will promote research work on original lines and with which the different medical departments of the University—the Harvard Medical School, the Harvard Veterinary School, and the Harvard Dental College—are to be coordinated. Three hundred thousand dollars has been set aside for the erection and the maintenance of a laboratory to be named after the late Henry L. Pierce. Six hundred thousand dollars additional will be required. It is proposed that the new college shall give the same facilities for research as the Pasteur Institute of Paris, the Jenner Institute of London, and the Institute of Hygiene of Berlin.

Christian Scientists Held.—Mr. and Mrs. George H. Kinter, Christian-Science "healers," and Mr. and Mrs. James C. Saunders, who are also Christian Scientists, were arrested at Buffalo, N. Y., on May 23d, on warrants charging them with manslaughter in causing the death of the nine-year-old son of the latter, Ralph L. Saunders, who died from pneumonia, and who, during his illness, had no medical care and no treatment other than that given by the above-mentioned "healers." As the death occurred on Federal ground the trial is being conducted under the United States laws before Commissioner Charles K. Robinson, United States District Attorney Close being the prosecuting officer. Mr. Close promises that the prosecution will be vigorous and thorough.

Coroners' Inquests.—After September 1, 1899, by an amendment to the Code of Criminal Procedure of New York State, which is to take effect on that day, coroners will be empowered to conduct inquests without the aid of a jury, except in a county which contains a city of the first class. After that date, therefore, coroners' juries will be impanelled only in New York, Kings, and Erie Counties. However, in New York County, the practice in the coroner's office has been for years, and no doubt is now, in accordance with the following law passed at Albany: "When, in the City and County of New York, any person shall die from criminal violence, or by a casualty, or suddenly when in apparent health, or when unattended by a physician, or in prison, or in any suspicious or unusual manner, the coroner shall subpœna a physician properly qualified, who shall view the body or make an autopsy, as may be required. The testimony of such physician, and that of any other witnesses that the coroner may find necessary shall constitute an inquest." In such cases juries are not called upon.

New St. Vincent's Hospital.—The new Free Hospital for the Destitute Sick, which has been built as an addition to St. Vincent's Hospital, at Seventh avenue and Eleventh street, New York City, was formally opened and blessed by Archbishop Corrigan, on May 30th. The hospital can accommodate, at one time, 1100 patients. The new building is seven stories high and has a frontage on Eleventh street of 145 feet. It is fireproof throughout and is so arranged as to afford plenty of light and pure air. This end is secured by a spacious roof-garden and by the arrangement of an interior courtyard, in which are a lawn, a large fountain, and a number of trees. The medical ward and the gynecological department were furnished throughout by Dr. and Mrs. F. S. Dennis. An X-ray apparatus was provided by Mr. John D. Crimmins. The building will be entirely devoted to free patients. On the first floor will be a dispensary and a reception-room for ambulance cases. On the second floor there will be children's wards. In the remainder of the building there will be six wards for men and three wards for women.

Obituary.—Dr. Henry E. Crampton died at Glen Ridge, N. J., on May 28th. He was sixty-two years old. At the time of his death he was Treasurer of the New York Academy of Medicine and a member of the New York County Medical Society, the Harlem Medical Society, the New York Medical Union, and the New York Genealogical Society. He was a veteran of the Civil War. He was for many years a Vice-President of the Association for Improving the Condition of the Poor. He devoted much time to philanthropic work.—Dr. Norman Shanks Kerr died in London on May 31st. He was very successful in the treatment of inebriety, and wrote a number of works on that subject. He was President of the Society for the Study of Inebriety.—Mr. John Hein, one of the originators of the Brooklyn German Hospital, which has just been opened, died on June 2d. He had been a sickly child and had never been well during the eighty-one years of his life. It is said that in his early youth, feeling that good health would forever be denied him, he resolved that he would devote his life to the accumulation of money with which to relieve the sick and destitute. He gave $30,000 toward the building fund of the Brooklyn German Hospital and $15,000 to the New York German Hospital.

A Psychopathic Epidemic.—Thomas Carlyle said:

"England has sixteen million inhabitants—mostly fools." He who doubts that as regards mankind in general there is a measure of truth in this statement would have had his doubt dissipated had he been at the Metropolitan Opera House in New York on the afternoon of May 28th. The immense auditorium was filled with people, about four-fifths women, who heard a young man give the lie to the wisdom of the ages. The occasion was a glorification of "Christian Science," and the lecture was given by one Mr. Carol Norton, C.S.D., Member "International Board of Lectureship of the Mother Church of Christian Science, Brookline, Mass.," under the auspices of the fourteen Christian Science Churches of the metropolitan district. Examples of the lecturer's fanatical credulity and insane vagaries are the following: "Christian Science has cured and is healing such diseases as locomotor ataxia, blindness, deafness, softening of the brain, paresis, Bright's disease of the kidneys, cancer, tumor, erysipelas, rheumatism, floating kidneys, paralysis, calcareous deposits in the joints, and shaking palsy." . . . "Physicians of both the allopathic and homeopathic schools are now accepting 'Christian Science' as the highest curative method known to the present age." The lecturer was no doubt unconscious of the humor lurking in the following: "Christian Scientists do not administer drugs, refrain from manipulating the body, and therefore cannot be classed as practitioners." A brief notice of some of the tenets of these odd folk may not be *mal a propos*. The teachers of this city would have us know, to begin with, that Christian Science is true because it is founded on reason and common sense. "All in mind—there is no matter." Yet the Christian Scientist eats solid food to nourish a body which he considers does not exist. And he pays a very substantial price for a weighty book in order that he may become cognizant of the mental vagaries which the leader of his sect exhibits therein. "Mortal mind," he tells us, "is error." Yet it is by means of this mortal mind and in no other possible way that he thinks, lives, moves, and has his being, and appreciates the relation of the world external to his *ego*. "The evidence of the senses," he tells us, "is a lie." Yet he relies upon one sense to take him into the lecturer's presence, upon another to find himself a seat, and upon a third to receive the lecturer's statements, which he considers Gospel truth, but which emanate from the lecturer's mortal mind, and are thus conveyed to his mortal mind, both of which mortal minds are in his opinion incapable of appreciating any truth whatever.

CORRESPONDENCE.

THE AMERICAN MEDICAL STUDENT ABROAD.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Although occasionally one meets in Europe, an American taking the regular university course in medicine, the question of the study of medicine abroad, which is of paramount interest, refers to post-graduate work. Many Americans who intend spending the bulk of their time at Continental clinics and yet possess little knowledge of the required languages think it well to take up work in the pathological or bacteriological laboratories of universities situated in the smaller towns, of which Göttingen, in Germany, will serve as an example. Here social opportunities are greater and through these one may pleasantly further one's knowledge of the native tongue. It may be said, however, that where pathological studies of the nervous system are intended this plan will not do, as the smaller university cities offer few patients, and fewer autopsies of neurological interest.

When able to take the lectures it will be wise to proceed to one of the capitals on account of the greater clinical opportunities. Another reason is that the presence, in the smaller towns, of a considerable colony of foreign students is responsible for the arrangement of courses, which, in a measure, are planned for their needs.

Where only English is at one's command, and but a short stay contemplated, say six months, I think it best to devote one's time to British clinics exclusively. While my personal knowledge refers only to those of Germany and Austria many men met abroad who had spent some time in Great Britain testified to the wealth of clinical material there presented. They added, however, that in the use of the same it was expected that a man must make his own opportunities. Somewhat different from this, the natural aptitude to teach, which belongs to the German, makes no detail too small to bring to the attention of the student and scarcely a scruple stands in the way of using the patient to fulfill every requirement of a clinical demonstration, a factor carried to extreme limits at times.

Of the various university centers Vienna, no doubt, offers the best advantages to do all-around work, because, with a faculty second to none, everything may be accomplished within or near the great complex of buildings known as the General Hospital. Of special importance as regards physical diagnosis is a series of daily demonstrations at the bedside in the internal medicine and neurological wards. Clinical instruction in no other city, not even Berlin, permits an American student, without engaging himself for a specified time, in exclusive service, to daily enter the wards, there to examine an assigned patient, make his diagnosis if possible, and receive a demonstration of the case the second hour by the physician in charge of the ward. When one considers that the assistants are distinguished workers in medical science numbering among themselves such men as the lamented Dr. Müller, whose death from the plague has recently been reported, the high class of the work can easily be estimated.

It cannot be denied, however, that all the special courses (a plan of instruction which the American bent on saving time and imbued with the propriety of paying for what he wants to a great extent avails himself of), are not equally satisfying. For instance, the time was when the foreign student taking a special obstetrical course could attend patients in labor, but no Continental clinic that I know of gives this privilege, upon the above terms,

to-day. Normal cases may be had in some clinics if the student binds himself to remain six months in service. In Berlin, between sessions, in spring and fall, there are two courses which include demonstration on the manikin and attendance outside the hospital upon labor cases, all of which are abnormal. However, the great number who now subscribe reduces the cases appointed to each student to not more than two, while the abnormality may mean a stitch to repair a slightly lacerated perineum quite as well as a version. Moreover, in addition to the considerable stipend, one is obliged to purchase a small paraphernalia, pay one's own cab-hire, and to tip the clinic attendant two marks for each notification. Therefore, these courses, although of some worth, are to-day good ones to keep away from. A number of other vacation courses, however, especially such as are diagnostic in character, afford excellent opportunities and give good returns. The popularity of these classes arises either from the special character of the instruction given, as in the instance just mentioned, which afforded particular opportunities in obstetrics, or from the fact that the first assistant at this time may use the amphitheater of his chief for his special course, and thus being able to lecture to a comparatively large number of students, makes a reduction in price per man for the privilege of personally examining the cases presented. There is, however, much irregularity in this respect; although one can, in Vienna, for a florin a day, continuously obtain the excellent bedside demonstrations in internal medicine and neurology previously noted, one is compelled to pay 2 florins for children's diseases and 2½ florins for diagnostic gynecology and obstetrics. For these reasons, wherever the American student begins his work, let him seek to make a few friends among his countrymen who may best be found in the pathological section at the hour the post-mortems are held.

Men following specialties have this advantage: they will be more apt to have the time to serve as hospitants in the wards for a stipulated time, or as assistants in private clinics, while, for the same reason, they may visit a greater number of universities and thus place themselves under special teachers.

The cost of one's trip naturally depends upon individual demands for comfort or luxury. With care in expenditure $100 per month will carry one through nicely, but if something may be added the opportunity is afforded of spending some of the vacations in travel and so gather the many impressions of various peoples and scenes which add much to the fund of pleasant reminiscences usually carried to home shores.

BERNARD OETTINGER, M.D.

DENVER, COL., June 1, 1899.

KOPLIK'S SPOTS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—You ask me concerning Koplik's sign in the diagnosis of measles. I am in the habit of watching for it in every case, and by its presence I have been able to diagnosticate subsequent cases occurring after exposure to a previous case before the eruption has appeared on the outer surface. In this respect it is pathognomonic and of practical importance, for, as a consequence, proper treatment can be promptly commenced, and the patient isolated at once. I can safely say that I have observed Koplik's sign in the mucous membranes of the mouth in ninety per cent. of the cases which have come under my care. Truly yours,

J. H. FRUITNIGHT.

161 WEST FIFTY-SEVENTH STREET,
NEW YORK, May 31, 1899.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—Since my communication to the American Pediatric Society, published in the *Archives of Pediatrics*, January, 1899, I have looked for Koplik's sign in all cases of measles seen in private practice. I have not kept any notes of these cases, but I have no hesitation in stating that the "speck" described by Koplik is an important aid to the early diagnosis of measles. I am not positive that I saw the spot in some mild cases, but I shall continue to examine all patients in whom I suspect measles for this early manifestation of the disease.

I have failed to find the buccal spots in children with rubella. I am Yours truly,

WALTER LESTER CARR.

68 WEST FIFTY-FIRST STREET,
NEW YORK, May 31, 1899.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—Replying to your letter of May 18th, my experience with Koplik's sign in the diagnosis of measles has been too limited for me to be in a position to express a positive opinion regarding it.

In a recent case, however, it was of positive value.

Ruth H., aged six years, on May 2d, had a slight dry cough, and redness of the conjunctiva. Her temperature was 100° F., in the forenoon. Thoracic signs were negative, and the fauces appeared normal. May 3d, the temperature was higher. Koplik's spots were seen on the inner surface of the cheeks and under lip. May 4th, the rash of measles was evident on the face and forehead, and in the next twenty-four hours was general. Bronchitis was mild. The course of the disease was uneventful. Very sincerely yours,

W. H. KATZENBACH.

17 WEST FORTY-FIFTH STREET.
NEW YORK, May 25, 1899.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—I cannot give you a very satisfactory answer to your question. I believe Koplik's sign is pathognomonic, and it is my custom to watch for it in all cases of measles. But it so happens that I have seen unusually few cases of measles in the last year, so that my personal experience is not extensive. It so happens, too, that there has been, as far as I know, no paper read on the subject in Philadelphia, and consequently no general expression of opinion in discussion, which has come to my ears. As far as I have heard men speak, it is believed in and sought for.

Sincerely,

J. P. CROZER GRIFFITH.

123 SOUTH EIGHTEENTH STREET,
PHILADELPHIA, May 25, 1899.

BLOODLESS TONSILLOTOMY.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your issue for May 27th appears a courteous reply from Dr. Lefferts. In it he asks one or two questions, and they are answered herein. Notwithstanding the fact that I have used the purse-string and recorded the instance to check severe tonsillar bleeding, and that he has not, the Doctor evidently considers that it would be hopelessly difficult. I beg to disclaim any special skill; used as advised, under anesthesia, the bleeding meanwhile checked by finger-pressure, anyone may do it successfully.

In re the case of furious hemorrhage which he describes, Dr. Lefferts asks whether the purse-string would have been applicable.

Why not? With a good light, a good gag, and the patient being in a faint, it would have been simple enough, and without anesthesia. Dr. Lefferts was fortunate in that case. Had the vessels divided been a shade larger probably the violent bleeding would have been resumed as soon as the heart began pumping again—or the surgeon's finger was removed. The purse-string would, however, have made further hemorrhage impossible.

To agree upon this point is less important than to recognize the value of *prevention* of bleeding in this operation. It was to advocate bloodless tonsillotomy, and to describe a case of it by my method, that the letter of May 20th in the NEWS was mainly written, and oddly enough Dr. Lefferts does not touch upon that point at all.

Bloodless tonsillotomy is a *fait accompli*. And while I have never as yet had the luck to meet with such a delightfully histrionic case of tonsillar bleeding as Dr. Lefferts describes, I should suppose that after just one such experience he would be the last man to decry an absolutely certain means of preventing its repetition. In that very case, if he had placed and tightened the purse-string *before* cutting out that tonsil, no blood need have been lost; the patient need not have been seized by the hair; all would have been politeness and decorum. And I do not think that Dr. Lefferts, who (upon theoretical grounds) considers my method so difficult of application to a case already bleeding, will assert the same thing when used as a method of *prevention*.

I must believe that in the future, when the plan becomes better known, it will be regularly adopted, at least in the class of cases where it is at once easiest of application, and where severe hemorrhage is commonest—that is, among adults.

Eucain (preferably) or cocain is first applied, freely and long. Then the four stitches are placed quickly and easily, as described in my letter. We next tie tightly the first half of a surgeon's or friction-knot. The tonsillotomy may now be done practically bloodlessly. After a delay of some minutes to permit of clotting in the divided vessels distal to the ligature, the silk may be loosened. Whether to remove it then entirely or to retain it loosely in place for a day or so as a measure of precaution in such adults, or to retie tightly at once, will depend upon the vascular conditions present when the purse-string is first relaxed after the amputation.

Of course the careful use of the snare would prevent the necessity for the purse-string. But as Dr. Lefferts' personal instance proves, even a specialist at times uses a speedier method and a simpler. And the bulk of the profession unquestionably use, and will continue to employ, the tonsillotome. To do this hereafter without risk of hemorrhage seems to the writer a distinct gain.

Yours truly,

ROBERT H. M. DAWBARN, M.D.
105 WEST SEVENTY-FOURTH STREET,
NEW YORK CITY, May 27, 1899.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

IMPORTANT ACTION TO BE TAKEN BY THE PHILADELPHIA COUNTY MEDICAL SOCIETY RELATIVE TO REFORM IN THE ARMY MEDICAL DEPARTMENT—SUPPRESSION OF NEWS CONCERNING CONTAGIOUS DISEASES—HEALTH STATISTICS.

PHILADELPHIA, June 6, 1899.

THE Philadelphia County Medical Society, through its delegation to the Columbus meeting of the American Medical Association, will bring to the attention of the Association the subject of reform in the medical department of the army. The general character of the army medical department during the Spanish-American War, the question of political influence in appointing volunteer medical officers, the notorious inadequacy of many parts of the army medical organization, and many other pertinent and vital topics will be considered. The following resolutions will be presented at the Columbus meeting for adoption and presentation to the President: "Whereas, the morbidity and mortality statistics of the late war have served to call to the attention of physicians of the United States the weighty and enlarging problem of the care of soldiers and sailors in peace and during campaigns, under widely varying conditions of climate and environment, now in many respects presenting themselves for the first time; therefore be it Resolved and recommended by the American Medical Association: (1) That the Medical Corps of the Army and Navy be enlarged to meet properly all demands that may be made upon them. (2) That the transportation of medical supplies be under the control of the Medical Department. (3) That a corps of sanitary inspectors be created, whose duty it shall be to examine into the sanitary condition of camps and troops in transit, and advise in relation thereto. (4) That the Government establish permanent camp sites, the selection to be subject to the approval of the surgeon-general, for use in the mobilization of large masses of troops. (5) That a professor of military hygiene be appointed at West Point to instruct the cadets in the principles of sanitation. (6) That the medical officers of the National Guard be subject to a rigid examination both for admission to the service and for promotion. (7) That the surgeon-generals of the army and navy in time of peace and war be empowered to call into requisition the services of skilled specialists. (8) That the President of the United States be respectfully urged to recommend to

Congress the appointment of an Army Medical Commission, to be composed of physicians and sanitarians taken from military and civil life, including the surgeon-generals of the army and navy, whose duty it shall be to prepare a report containing a detailed plan of a modern system to govern the medical departments of the army and navy in peace and war. (9) That a national department of public health be established, with a Cabinet Minister at its head."

The American Dermatological Association, at its annual meeting held in this city during last week, elected the following officers for the ensuing year: President, Dr. Henry W. Stelwagon of Philadelphia; vice-president, Dr. George T. Jackson of New York; secretary and treasurer, Dr. F. H. Montgomery of Chicago; member at large of council, Dr. T. C. Gilchrist of Baltimore. Among the notably valuable subjects presented at the last meeting were contributions on the sensory disorders of leprosy, by Dr. P. A. Morrow of New York; on the rôle of pus micro-organisms in diseases of the skin, presented for general discussion; on blastomycetic dermatitis, by Dr. J. N. Hyde of Chicago, and a general discussion on the pathology of skin diseases. The next meeting of the society will be held in Washington, as a part of the Congress of American Physicians and Surgeons.

The attempts made by the health authorities of this city to suppress the news regarding the prevalence of contagious diseases has met with a prompt and vigorous opposition by the State authorities. The latter body has issued resolutions, couched in unmistakable terms, deprecating this "ostrich-like policy," as they appropriately term it, and issued a statement advocating, for the protection of the public, the fullest publicity and the exact truth regarding outbreaks of contagious diseases. In the case of the present outbreak of smallpox in the suburb of Nicetown the city authorities have pursued such a high-handed policy of concealment, thus preventing residents in the neighborhood of infected houses taking necessary precautions for their own protection, that it is indeed high time that a halt is called on their peculiar methods. Copies of the State Board's resolutions have been presented to the Mayor, the Director of Public Safety, and the Chief of the Bureau of Health.

Col. J. Lewis Good has been appointed the new chief of the Bureau of Health, at an annual salary of $4000. Colonel Good has long been associated with the Board, and has been its acting chief since the disbanding of the old organization by a recent act of Legislature.

The total number of deaths in this city during the past week was 426, an increase of 42 over those of last week, and of 20 over the corresponding period of last year. Of this number, 115 were of children under five years of age.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

ILLINOIS STATE MEDICAL SOCIETY—ADIPOSE TISSUE AN ETIOLOGICAL FACTOR IN HERNIA—SURGICAL TREATMENT OF HEMORRHAGE FROM GASTRIC ULCERS—ADRENAL TUMORS OF THE KIDNEY—VESICULAR MOLE—JOURNAL ILLINOIS STATE MEDICAL SOCIETY — OFFICERS — CHICAGO HOSPITAL — CHICAGO SOCIETY OF INTERNAL MEDICINE.

CHICAGO, June 6, 1899.

The Illinois State Medical Society held its Forty-Ninth Annual Meeting at Cairo, May 16th, 17th, and 18th. The attendance was small, but notwithstanding this a large number of papers were read, some of which were of a high scientific order. Dr. Alexander Hugh Ferguson of Chicago, read a paper on adipose tissue, an etiological factor in hernia. The evidence which proves adipose tissue to be an etiological factor in hernia is its physical properties; its tendency to accumulate in spaces and cavities, and then to descend; its locality and frequent accompaniment of hernia; its association with the development of certain forms of rupture, the fatty mass forming first and the true rupture following. Small lipomata form in the openings where hernia is most liable to occur, and by intra-abdominal pressure atrophy of the rings occurs; they thin out and weaken and become enlarged, and then the ball of slippery fat urged out by the *vis à tergo* protrudes more and more and drags the elastic peritoneum with it. If, however, the abdominal wall has no congenital deficiencies in the structures protecting the normal rings a hernia is rare indeed, and no accumulation of fat is liable to take place.

Drs. E. Wyllys Andrews and Daniel N. Eisendrath contributed a joint paper on the surgical treatment of hemorrhage from gastric ulcers, in which they reported two cases, and animal experiments. They reached the following conclusions: (1) The result of the practice of the best modern surgeons warrants the statements previously made on theoretical grounds that only operative interference can save the lives of some of the patients affected with bleeding ulcers of the stomach, namely those not improved by internal medication. (2) Surgical intervention is to be recommended, firstly, in small repeated hemorrhages; secondly, in severe ones, occurring more than once, especially if more than 500 c.c. is lost at each hematemesis. (3) A single copious hemorrhage is not necessarily an indication for operation. (4) In the ulcers at or near the pylorus, pyloroplasty (Heineke-Mikulicz) is ideal. It makes local treatment possible and gives all of the benefits of gastro-enterostomy and is safer. (5) Cauterization and curretting of the ulcer should give place to resection wherever the stomach wall can be reached from without. (6) If adherent posteriorly and at the ends of the stomach, cauterization, curettage, and ligature *en masse* are best substitutes for excision. (7) Ligature *en masse* is shown by the experiments to endanger perforation, except when supported by external sutures.

Dr. Bayard Holmes read a paper on adrenal tumors of the kidney. Grawitz described a group of tumors of the kidney resembling adrenal tissue, which he believed to

grow from fragments of adrenal tissue left in the kidney from the earliest embryonal period. Since that time these tumors have been more or less generally recognized. They appear (1) as masses troublesome only on account of their size, or on account of their tendency to metastasis in the lungs and bones, and (2) as sources of adrenal intoxication, producing a complexus of symptoms diametrically opposite to those of Addison's disease and parallel with the intoxication produced by hypertrophy of the thyroid observed in exophthalmic goiter. The cases presented illustrated both of these manifestations of the disease.

Dr. Carl E. Black of Jacksonville, reported a case of vesicular mole in a patient twenty years of age, accompanied by degeneration and rupture of the uterine wall, and great hemorrhage, necessitating the ligation of the left uterine artery. In this case the mass half filled an ordinary washbowl, and had the appearance of thousands of small white grapes piled up together.

Instead of publishing an annual volume of Transactions, as was heretofore done, the Society will undertake the publication of a monthly medical journal, to be known as the *Journal of the Illinois State Medical Society*. It is thought that this method of publishing the proceedings will materially increase the membership, as fully a thousand copies of the journal will be issued monthly. The new journal will be patterned somewhat after the official organ of the Pennsylvania State Medical Society, whose success in journalizing the proceedings of that body has been remarkable. Its editor will be the secretary of the society, Dr. E. W. Weis, of Ottawa, who is an indefatigable worker, and thoroughly capable of launching and conducting the new venture. The following officers were elected for the ensuing year: President, Dr. Harold N. Moyer, Chicago; first vice-president, Dr. J. T. McAnally, Carbondale; second vice-president, Dr. Weller Van Hook, Chicago; treasurer, Dr. George N. Kreider, Springfield; secretary, Dr. E. W. Weis, Ottawa. Place of next meeting, Springfield; time, third Tuesday in May, 1900.

The trustees of the Chicago Hospital have just had plans completed for what will be one of the finest hospital structures in the city. The cost of the building will be $200,000. It will be located in Fifty-first Street, west of Cottage Grove Avenue, and opposite Washington Park. It is to be in the shape of a wheel, with three three-story wings, forty-six feet in diameter, radiating from the hub. Fireproof construction will be followed, the building having steel frames, red pressed brick interior, with white terra cotta columns, iron balconies at each floor and tile roof. The entrance and rotunda will be of marble. This part alone will cost $45,000.

The Chicago Society of Internal Medicine, at its regular monthly meeting, held May 25th, elected the following officers: President, Dr. John A. Robinson; first vice-president, Dr. N. S. Davis, Jr.; secretary, Dr. Edward F. Wells; treasurer, Dr. M. L. Goodkind, and censor, Dr. Arthur R. Edwards.

OUR LONDON LETTER.

[From Our Special Correspondent.]

SCHOOL PHYSICIANS — ANOTHER MEDICAL HERO— INCREASE OF VACCINATIONS UNDER CONSCIENCE CLAUSE—"TRAGEDIES BOUND IN OAK" — DISAPPEARANCE OF MALARIA IN ENGLAND—MEDICAL RESEARCH SCHOLARSHIPS—LONDON FOG.

LONDON, May 25, 1899.

THE London School of Tropical Medicine has been formally launched upon the charity of the public. At a public dinner, held at the Hotel Cecil, the Secretary of State for Foreign Affairs, Mr. Chamberlain, in an admirable speech, sketched the plan of the scheme and eloquently depicted its many and great advantages. So great were the latter he declared that even the starchy formalism of the great Government Offices, the Indian, the Foreign, the Colonial, had been melted to enthusiasm by it. The scanty metallic deposit which resulted from this melting we have already alluded to, but the long-suffering public has meekly done what was expected of it and made good the deficit. It was announced at the close of the dinner that of the $80,000 required no less than $75,000 had been already subscribed, including the Government's gift of $16,000.

Stirred by the excellent work done and published of late by American and German school-physicians the English profession is beginning to demand a formal and official recognition of its opinion in educational matters. If there be anything which is being more emphasized than another in the new education it is the importance of the physical condition and fitness of the child, and yet the views of the only body of men really competent to give advice on this subject are absolutely ignored in the makeup of the working staff of the school and school board. Curricula are laid out, hours of work fixed, nay even buildings planned and ventilated by teachers and trustees ignorant of the simplest principles of physiology, or of the needs of the growing organism. A physician, as the *Lancet* is now demanding, should be a regular officer or member of every important educational body.

Another name has been added to the public roll of medical heroes (which does not represent a tithe of the actual number) who have risked their lives to save their patients. Dr. R. J. Burns of Sunderland was called to see a man who had attempted suicide by taking a quantity of rat-poison containing phosphorus. The stomach-pump broke down and the brave doctor actually applied his lips to the tube and sucked out the deadly contents of his patient's stomach, thereby saving his worthless life. A more repulsive and dangerous service was never rendered from pure love of humanity, for the patient was a drunken ne'er-do-well, little better than a tramp. It was a beautiful illustration of that noble, old traditional instinct of our profession, of absolute devotion to our patient, as such, regardless of who or what he may be personally. But what of the wife or children or parents of the physician and their rights in the premises? We may not, of course, weigh for a moment the value of our own life as against that of another, but there are others whose rights and interests in us we are morally bound to con-

sider. Dr. Burns' action was magnificent, but it wasn't war, and while we glory in his splendid bravery, we reserve our opinion of his judgment. Fortunately Dr. Burns escaped with a sharp attack of phosphorus poisoning, from which he soon recovered.

Professor Haffkine, who is in England on leave of absence, is to lecture before the Royal Society, upon "Preventive Inoculations," June 8th.

And still that bastard compromise, the new Vaccination Act, seems to be working well in practice. Mr. Collings reported in Parliament a few days ago, that in Ipswich, where the average number of vaccinations for several years past has been 33 per quarter. 198 had been performed in the January quarter of the present year. And these again, as at Oldham, included the families of several hardened "anti" offenders, and even children, for whom an exemption had been taken out only a few weeks before. Truly the "*bete humaine*" can be easier led than driven.

An excellent story at the expense of the profession is going the rounds here. Alexander Dumas, when a young man, was introduced to a pompous old physician who, in a patronizing way, asked him if it were really true that he "made tragedies for a living." "Yes," replied Dumas, "just as you do, only yours are bound in oak."

The recent developments in the natural history of malaria and the desire to obtain material for direct study are calling attention to the remarkable manner in which the disease has disappeared from England. In the great London hospitals it is practically unknown, it is regarded by most general practitioners as a tropical disease, and even in the celebrated Fens of Lincolnshire and Cambridgeshire, where, within the memory of living men, it was as common as in "Injeanny," it is now quite rare. In conversation with several prominent East Coast physicians a short time ago the writer was greatly struck by the unanimity with which they all declared that they had scarcely seen a case of malaria in twenty-years' time. And there is an abundance of low-lying land by both sea and river, indeed, the entire island is like a sponge lying in an ocean bath-tub. *But every acre of it is drained*, and this seems to be the secret of the rapid decline of malaria, for the mosquito cannot continue to breed where swamp-water is not constantly present the year round. Fifty years ago quinin was a regular article of daily diet in Lincolnshire as it is now in the valley of the Wabash, and only a short time since an elderly patient consulted a London otologist for deafness, whose origin he attributed to the large amount of quinin he had taken as a boy in the Fen district. The drain-tile is the chief enemy of malaria, as also of typhoid and pulmonary tuberculosis.

The defeat of the bill compelling shop-keepers to provide seats for their saleswomen by the House of Lords has produced a most unfavorable impression in the profession. No medical man, American least of all, has the slightest doubt of the vital importance of such a provision and the crying need for legislation to secure it, and its defeat, solely upon the ground advanced by Lord Salisbury, in his sudden outburst of ignorant bitterness against it, that "people can usually be trusted to manage their own sitting down and rising up without the assistance of law," a speech which killed the bill after it had passed the Commons and been favorably reported by the Committee in the House of Lords, will be a serious blot upon the reputation of that gentleman in the eyes of the entire medical world.

On every hand the value to the State of medical research is being more and more widely recognized. The Technical Education Board of the London County Council is now cooperating with the Asylums Committee in offering a scholarship of $750 a year, tenable for two years, for the investigation of the preventable causes of insanity. The research is to be carried on in the Pathological Laboratory of the Claybury Asylum.

The Secretary of the British Medical Association announces that the annual sum set apart for grants toward medical research will be allotted June 15th, and the two research scholarships be granted on that date. He, therefore, invites applications from medical men desirous of availing themselves of the assistance of a grant or scholarship in their investigations. The value of the scholarships is $750 and one of them is the Ernest Hart Memorial Scholarship in State Medicine.

A singular case of blood-poisoning has just been reported in London. A woman fell and slightly grazed her wrist and, to protect the injured surface, covered it with stamp-paper, or strips of the gummed paper which borders the sheets of postage-stamps. This adhered firmly and completely sealed the wound, but pain and throbbing quickly set in, septic symptoms developed, and death occurred within sixty hours.

The following medical men were elected Fellows of the Royal Society, at the annual election, last week: Ernest H. Starling, physiologist at Guy's Hospital; Bertram C. Windle, anatomist; Major Bruce of Tsetse-fly fame, and Henry Head.

The National Association for the Prevention of Consumption is making rapid progress, having already a membership of nearly 1500 and some $6000 in its treasury.

It really looks as if the London-fog nuisance was going to be seriously attacked at last. From tables given in a recent lecture by the Honorable Rollo Russell, before the Building Trades' Exhibition, it appears that during the five months of last winter, from November to March, London had less than half the amount of sunshine of inland stations and barely a third of that of the stations on the South coast. As the mortality records show it is this loss of sunshine which is the real damage of fog and not its effects upon the respiratory organs as usually supposed. A fog, suffocating as it seems, really increases the deaths from respiratory diseases but very slightly. An active crusade against this nuisance by compelling the use of smoke-consumers is already on foot.

ON THE EXAMINATION OF WHITE BLOOD-CORPUSCLES —ALKAPTONURIA — APPENDICITIS RESULTING IN SUBPHRENIC ABSCESS—ENCYSTED VESICAL CALCULI —PHAGOCYTOSIS OF EXTRAVASATED RED BLOOD-CELLS — TUBERCULOSIS OF THE STOMACH — ARTHROTOMY FOR PAIN AND FOR ABNORMAL JOINT PRODUCTS—THE CAUSES OF DEATH AFTER ABDOMINAL OPERATIONS.

AT the Royal Medical and Chirurgical Society, April 25th, PHEAR read a paper on the clinical examination of the white blood-corpuscles, calling attention to the advantages which fluid films of blood have over dried preparations. In the latter the forms of the corpuscles are distorted, and some of the corpuscles may be washed away in the course of preparation. In preparing his specimens he adds a drop of a two-per-cent. solution of methyl-blue in alcohol, to a small drop of blood on a glass slide, and mixes the two fluids by blowing air on the drop through a pipette. A cover-glass is laid on the drop, and its edges sealed with vaselin. The preparation may then be examined at leisure with an immersion lens. In making blood-counts, a large area should be examined, the larger the better for the purposes of accuracy. The daily variations in the average number of the different kinds of cells are remarkably small. In a healthy individual, the following figures represent the average limits of percentage variation of the different kinds of cells: (1) polymorphonuclear cells, from 45 to 60 per cent.; (2) rounded hyalin cells, from 35 to 40 per cent. (inclusive of lymphocytes from 10 to 20 per cent., and large hyalin cells about 2 per cent.); (3) large oval cells, with irregular nuclei and protoplasm staining diffusely with methyl-blue (a form of cells not described by those who use the dry method), from 5 to 10 per cent.; (4) cells containing coarse oxyphil granules, from 1 to 1.5 per cent.; and, (5) cells containing basophil granules, from 0.3 to 1 per cent. The blood should, if possible, be procured for examination before the first meal of the day has been taken.

At the meeting of May 9th, GARROD read a paper on alkaptonuria. This name is applied to a condition of the urine which causes it to turn a dark color soon after it has been passed. The addition of an alkali makes the change in color still more striking. Such urine will reduce Fehling's solution with the aid of heat, and ammoniacal silver nitrate in the cold. Hence it might easily be mistaken for a glycosuric urine. Only a few cases of the passage of such urine have been reported, but the reader of the paper had opportunity to make examinations in five such. He had come to the conclusion that the essential feature of alkaptonuria is the presence of homogentisinic acid, and that uroleucic acid when present is of the nature of a by-product of abnormal metabolic processes.

PAVY said that he had had experience with five cases. It was curious that the health of the individuals in question was not affected. In this respect one might draw a parallel between alkaptonuria and cystinuria, as the presence of cystin in the urine gives rise to no symptoms unless crystals form.

At a meeting of the Medical Society of London, April 24th, ROBINSON read a paper on some cases of appendicitis in which the pus found its way upward along the colon into the space between the inferior surface of the liver, the upper part of the kidney, and the hepatic flexure of the colon. Sometimes it was difficult to decide whether the route was an intraperitoneal or an extraperitoneal one, but the former seemed more probable.

BATTLE mentioned three instances in which an appendical affection had traveled up the peritoneal surface of the bowel and caused an abscess between the liver and diaphragm.

CLARKE read a paper, May 8th, on encysted vesical calculi, giving an account of twenty-seven cases. If a stone is fixed to the bladder wall, the usual symptoms of calculus, pain, and hematuria, are absent, but there is apt to be cystitis. Most of the encysted stones were near the base of the bladder, and it was often difficult to detect them either with a cystoscope or other instruments. They usually occurred in individuals between sixty and seventy years of age. If possible to grasp an embedded stone, it should be crushed *in situ*, but frequently it was held so firmly that it could scarcely be seen or felt after a suprapubic incision had been made.

FREYER spoke of the rarity of encysted stones, as he had met with only 20 in 2000 cases of vesical calculus, or just 1 per cent.

At the Pathological Society, May 2d, ANDREWS showed pus from an injured knee-joint, illustrating phagocytosis of extravasated red blood-corpuscles by leucocytes. An arthritis had set in seven days after injury, and the joint had been aspirated several times, but no organism could be demonstrated either by examination or by culture. The pus-cells were large and showed numerous included red blood-cells.

STILL reported five cases of tubercular ulcer of the stomach in children, the only ones he had met with in the examination of 226 children with tuberculosis. In all five cases there was extensive tuberculosis of other parts of the body. In one case perforation had occurred but owing to adhesions about the stomach there had been no acute peritonitis.

At the Harveian Society, May 4th, LOCKWOOD read a paper on arthrotomy for the relief of pain, removal of synovial fringes, loose bodies, and fibrocartilages. Four operations upon the wrist-joint were for pain alone. One wrist was found to be tubercular; two were possibly pyemic, and the head of the ulna in the fourth was found to be chronically inflamed and eroded, and was excised. The other cases were drained. In all the relief from pain was immediate and permanent. The knee-joint of a woman was found to present no lesion except the inflammation and thickening of the synovial fringes. The ligamentum patellæ was divided to give a good exposure, and the fringes were excised. The result was excellent. In three cases the internal semilunar cartilage had been ex-

cised. The locking of the joint was in every case relieved, and the functions of the limb were in no case interfered with.

MARSH thought that a transverse division of the patella was the most satisfactory way in which to expose the knee-joint.

ALLINGHAM, who had operated upon fifty cases properly classified under the title of the paper, preferred a longitudinal division of the patella. He had removed the dislocated semilunar cartilage in 18 cases, and sutured it in 13 others.

At the British Gynecological Society, April 13th, SMYLY read a paper on deaths after abdominal celiotomy, mentioning as causes, shock, hemorrhage, ileus, uremia, inanition, tetanus, embolism, and sepsis. He said that shock is a term applied to a group of symptoms which may be due to a variety of causes, but is generally in direct proportion to the magnitude and duration of the operation, especially when associated with long exposure and manipulation of the intestines, to the amount of blood lost, and the cooling of the body generally. No doubt the larger number of cases reported as deaths from shock have been due to loss of blood during or subsequent to an operation.

Ileus is one of the most disappointing sequelæ of laparotomy. The early diagnosis of this complication is of the utmost importance, but unfortunately this is often impossible. When the symptoms set in suddenly with violent paroxysmal pain in a localized position, when the peristaltic action of the intestine can be seen and felt through the abdominal wall, and the patient lies prostrated between the attacks bathed in cold perspiration; when neither flatus nor feces are expelled after energetic efforts to procure evacuation, when vomiting sets in after the second or third day, and the abdomen becomes distended, an error is scarcely possible, but such a stormy onset is exceptional, and most of these symptoms are simulated by other conditions. The obstruction may even be incomplete, and the bowels may be evacuated at intervals, and yet the patient may be lost. In any case active measures should be at once employed to induce the bowels to act, the stomach should be washed out, and copious enemata administered with a long tube, and, when the stomach can tolerate it, calomel, Glauber's or Epsom salts administered. Should these measures fail, the abdomen should be reopened without further loss of time.

Thrombosis occurs from septic infection, or from prolonged pressure of pelvic tumors upon veins, or sluggish circulation due to the quiet recumbent posture or the change in the intra-abdominal pressure due to the removal of large tumors. . As thrombus is a potential embolism, and as it may be set free even at a late period, patients should be cautioned against violent efforts or straining for some time after an abdominal operation. Smyly lost a patient three weeks after operation from embolism, brought on by buttoning her boots.

Speaking of sepsis, the reader gave great credit to Lawson Tait and Bantock, saying that the doctrine of cleanliness originated with them and has been based upon their teaching. "Years ago," he said, "whilst most of us were practising antiseptic methods, they, in the face of bitter opposition, insisted upon the importance of perfect cleanliness, and pointed out the injurious effects of chemical substances in irritating and poisoning the tissues."

In the discussion which followed, ELDER took exception to the credit given Tait, saying that he considered that the modern knowledge of asepsis is due to the untiring efforts of Lister.

SOCIETY PROCEEDINGS.

AMERICAN ACADEMY OF MEDICINE.

Twenty-fourth Annual Meeting, Held at Columbus, Ohio, June 3-5, 1899.

THE meeting was called to order by the President, DR. EDWARD JACKSON, in the assembly hall of the Chittenden Hotel. Renewed interest was manifested in the organization by the election of thirty-one physicians to fellowship, among whom were F. F. Whittier of Brookline, Mass., J. E. Brower of Columbus, F. D. Bullard of Los Angeles, W. W. Keen of Philadelphia, Gertrude A. Walker of Philadelphia, N. P. Dandridge of Cincinnati, J. S. Marshall of Chicago, and F. W. Spaulding of Clifton Springs.

The scientific business was opened by the reading of a paper by DR. L. DUNCAN BULKLEY of New York, on "How Far Has Specialism Benefited the Ordinary Practice of Medicine?" By elevating medicine as a science, specialism has advanced its honor as a calling. Special study has classified diseases more clearly and simplified nomenclature. Obscure conditions of disease have been discovered and elucidated. Treatment has been simplified and crystallized, and new methods and measures introduced. All the discoveries and advances made by specialists have been freely given to the profession in current literature and text-books and by means of lectures and clinics every effort is made to enlighten the general practitioner in regard to each branch. The specialist has frequently succeeded in the cure of diseases which the general practitioner has been unable to accomplish unaided, and has often relieved him of great embarrassment. Incidentally specialism has tended to improve the financial relations of patients to physicians and educated the public as to the value of professional services.

The next paper, on "Some Obstructions to the Progress of Specialism in Medicine," was read by DR. G. HUDSON MAKUEN of Philadelphia. The obstructions to the development of specialism are almost wholly within the profession itself, in the attitude of its members toward their patients and toward one another. An innate selfishness and a natural desire for gain engender a foolish spirit of competition which should have no place in professional transactions, where duty to patients demand first consideration. Some illustrations were given of the lack of professional courtesy in the interchange of patients, and an attempt was made to show that this lack of courtesy is the greatest obstruction of specialism in medicine.

DR. L. R. CONNOR of Detroit: Any one familiar with

the history of medicine will recollect two facts, one of which is that great epoch-making discoveries in the past have been from men called general practitioners, as evidenced in the work of John Hunter and Lister, the discoverer of chloroform, and those who have opened up the specialties of disease pertaining to women. I am glad the specialist has come, but still more glad that the general practitioner remains with us.

DR. H. O. MARCY of Boston: I was reminded by Dr. Bulkley's paper of a little anecdote of the First Massachusetts. When on its march there was an overturned engine by the roadway. The commander asked if there was any one in the ranks who could help repair it. Out stepped one of the privates, and said: "I helped to build her, and think I know something of the repairs;" and in a short time it was on the track. There is an illustration of the specialist in the ranks. He was quite ready to carry his rifle or serve his country as best he might, and there came his opportunity to do it in a special way. The ideal physician is the exponent of God's great law; he is the engineer, who like the private understands the repair of the engine. He must be an anatomist, which is the ground-work which makes him what he ought to be.

DR. AUGUSTUS P. CLARKE of Cambridge: Every one must feel that the subject of medicine is too broad for any one person to comprehend and, therefore, there must be subdivisions in the practice. One of the drawbacks to specialism is that the young men want to enter too soon without adequate knowledge. Those who have succeeded best have been those who have walked along the lines of general medicine, have had rough experiences, and have discovered something that has impressed them in connection with some one subject to which they are adapted.

DR. A. GOLDSPOHN of Chicago: Specialism in medicine is an absolute necessity; division of labor is absolutely essential. While it is true that some few discoveries have been made before specialists were distinctly classified as such, they have been made along the line of much digging out, much concentration of thought, and so the advancement of medicine as a whole is in that course, with a few accidental discoveries made by general practitioners. Advancement of medicine is undoubtedly due to this division of labor, concentration in certain lines.

DR. DIDAMA of Syracuse: I was much pleased with Dr. Bulkley's paper, in which he claimed that there were advantages in specialism and that there are dangers; the danger of the general practitioner treating a case that he does not know much about, and the danger of the specialist in thinking he knows it all. There are so many specialists that there is not much left for the practitioner. Going back to the fathers of medicine we know that they did discover something by being general practitioners. Up to a few years ago discoveries were made by general practitioners and I think they are doing very well now. The great danger is that the student, when he receives his diploma, decides that he will be a specialist. He does not like to say it is because there is money in it, but that does influence some of them.

"Ethics of Specialism," was the title of a paper by DR. A. L. BENEDICT of Buffalo. He said in part: The existence of specialism is a departure from the old principle, that the assumption of superior skill is unethical. The specialist implicitly claims such superior skill, if he is honest. Specialism should not consist merely in experience accidentally acquired in general practice. Specialists should always be prepared for emergency practice.

DR. G. HUDSON MAKUEN: It seems to me that the subject is broad enough to occupy our whole attention without bringing into it that which does not rightly belong in it. Ignorance and falsehood are the same thing, whether they are in the daily life of the so-called specialist or the general practitioner. Very much that has been said against specialism, I think, is not against specialism at all. Certain classes of men find in the new order of things a place to hang their complaints upon, and I fear, in our profession, specialism is such a hook to a good many men.

DR. GEORGE M. GOULD: Whatever will be said, the thing is going on. It is in the line of science. Our science to-day of medicine is such an infinite thing that no living soul can amass the knowledge required in any one branch; we will have to divide it in order to conquer. Of course many ignorant men will press into specialism. These are the evils which must be met as evils. One way of meeting these evils is the great improvement in medical education; we are educating our men better. The increased length of the medical course, the higher standards of the initial examination prepare our men better in general medicine and make them understand the general principles upon which any specialty rests.

"The Passing of Materialism," was read by DR. GEORGE M. GOULD of Philadelphia. He said: Some twenty-five years ago materialists and atheists had a weapon called science placed in their hands; and many others using this without a knowledge of psychology and metaphysics rushed into materialism. Herbert Spencer is probably more responsible than anyone else for the materialism of modern scientific thought. The world is, at last, learning that he has contributed little or nothing to the evolution of philosophy and genuine science. This condition is happily passing away. The lessons suggested are: (1) The method of science is by logical and legitimate induction from facts correctly observed, without prejudice or dogma. (2) There is a character or soul-unity in a people, or a school of investigation, which does not change despite a revision of the nomenclature. (3) The individual may be impelled to err from various conditions; prejudice, passion, conservatism, with a resulting injury to the individual. (4) The science of medicine suffers along with this individual injury.

DR. CONNOR: I rise to express my gratitude to Dr. Gould for the presentation of this paper at this time. I don't know whether the presence of Christian Science, or of a pure psychic medicine abroad in the land is the result of the sins of the medical profession in failing to recognize that there is a science outside of the science of matter. And yet I am sure that every practitioner, gen-

eral or special, when he recounts his work will have a conviction that the best of the work he ever did never had any relation to matter. Most of us believe that which retains time and activity acts and operates on as definite lines as do the laws of Nature, and these laws we have not studied to master as much as we might.

At the opening of the meeting June 5th, the nominating committee announced the following appointments: President, G. Hudson Makuen of Philadelphia; first vice-president, Charles I. Plummer of Salt Lake City; second vice-president, A. Goldspohn of Chicago; third vice-president, Edward F. Wilson of Columbus; fourth vice-president, A. L. Benedict of Buffalo; secretary and treasurer, Charles McIntire of Easton; assistant secretary, Walter L. Pyle of Philadelphia. The question of the place of meeting was left with the Council.

The President, Dr. Edward Jackson of Denver, then read his address, entitled "The Doctor's Duty as a Teacher." He said in part: Let us pause a moment to think of those whose work with us has ended. Vermyne, with broad strong face and kindly heart; Carpenter, keen, incisive, highly strung; Rohé, looking on medicine and life from many sides; Pepper, carrying great burdens yet always ready to listen and to give earnest effort for the good of profession or public; Sibbet, patiently working with assured confidence for the future — these have taken permanent places in the storehouse of memory. There can be no doubt but that the founding of the Academy was due to Sibbet. If, as Emerson says, an institution is but the lengthened shadow of a great man, he was the man.

The title of doctor-teacher has been most widely used and most willingly accepted in this country to indicate a membership in our profession. I believe this has come about through some perception, however imperfect, of the fact that the doctor's highest, most prominent, and most important relationship to the community is that of teacher. His function as a dresser of wounds, a remover of diseased tissue, a repository for certain knowledge regarding the action of drugs, and the skill to recognize disease are important ones, and more likely to meet an immediate financial recognition. But all we do in this direction is surpassed by the advice and teaching which enables our patients or the community to best develop and sustain and conserve their vital powers. In addition to this it is well worth while to recall the urgent need of the body social for guidance and instruction from its doctors. At the present time hygiene is practically a special branch of medicine in its wider sense. The teaching of this department has been deficient and one-sided. From the standpoint of racial health and vigor of what avail is it to save from cholera infantum and diphtheria merely to swell the number of cripples, consumptives, and the insane? How insufficient to improve the street-paving and the sewage system for men and women who work with the needle sixteen or eighteen hours a day and live on bread and tea at one end of the social scale, or who do not work at all and live on the stimulants of diet and amusement at the other end?

Until men become wise and virtuous the war against quackery must continue. To destroy the foundations of quackery we must teach the truth that the influence of the drug for benefit is at best but partial, temporary and not unmixed with evil, that cures are wrought by great natural forces which medicines cannot create. The well-being of society demands the full performance of the doctor's service in teaching, the guidance of his thought in its attitude and reaction toward the myriad influences of our civilization that may serve as the normal stimulants of life, or become the starting-points of morbid action, making for racial degeneracy and social death.

"Advertising in the Medical Profession," was the title of a paper by DR. C. T. MCCLINTOCK of Detroit. The writer dealt with advertising in the profession only. In no business, certainly in no profession, are the people so incapable of choosing the good from the poor as in the choice of a physician, as is evidenced by the success of the medical pretenders. Many physicians are giving more time and thought to the securing of patients, advertising if you choose, than to the study of their profession. Many young men are rusting in medicine because their time is taken up in advertising, lecturing in medical colleges, attending medical societies, not to learn, but to become known. There are prominent men who mail five thousand reprints of their papers. Others scatter broadcast illustrated papers showing the "before and after taking" of orthopedic surgery. These are reputable men, college men, prominent men in the profession. Probably the most skilful advertisers are the college professors, working on the students for patients in after years. The sanatoriums are probably the worst offenders in such advertising. The people see nowhere a distinct line separating the reputable and disreputable physicians. It is more than doubtful if the young practitioner, well qualified, who locates in our larger cities would ever meet with reasonable success if he stuck literally to the spirit and letter of the code. Higher education will not solve this difficulty. With every increase in the requirements for the practice of medicine there goes an increase in the number of medical students. The best that can be hoped for is that the profession may assist the people in choosing their physician, so that the most deserving shall receive their dues.

The next paper, by DR. E. STUVER of Fort Collins, Wyo., on "What Will Be the Future Policy of the Medical Profession with Regard to Medical Advertising?" was read by DR. G. HUDSON MAKUEN of Philadelphia. All physicians, from the most eminent to the most obscure should be accorded equal advertising privileges. Professional advertising should be limited to the insertion of plain cards in the local papers or a sign pointing out the location and office hours of the physician. All local notices in which the name of the physician is mentioned in connection with the treatment of cases or the performance of operations should be absolutely interdicted. The public should be educated to regard active participation in promoting the organization of the medical profession and assisting to build up and strengthen medical societies as a criterion of greater professional eminence and distinction than mere local notoriety.

THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES.

The Association of American Medical Colleges held its regular annual meeting in the hall of the House of Representatives June 5th. An unusually large number of members was in attendance.

DR. J. M. DODSON, junior dean of Rush Medical College, Chicago, read a paper on "The Elective Course in Medical Schools." This was an elaborate attempt to adapt the system which prevails in universities to the medical curriculum. The men who discussed the paper showed that the plan would prove disastrous by leading at once to the development of superficial specialists.

DR. G. C. SAVAGE of the University of Nashville presented a paper on "The Condition of Medical Education in the South." Despite the desperate struggle that had been necessary during the last thirty years to maintain the medical schools of the South, the battle has been bravely won for most of the schools, and the prospect is bright. They are not ready just yet to put into force, at least all of them are not, the four-year's course. The peculiar circumstances under which they had labored demands recognition and continued indulgence of the Association for at least two years longer, at which time they would all expect to come into line on the four-years' course.

The American Medical Association at its meeting in Denver, in 1898, officially accepted the standard of the Association of American Medical Colleges as the minimum standard of colleges that will be recognized by it as entitling its graduates to membership in its ranks. The decision of the Association of Colleges in any individual case is equivalent, therefore, to admitting or excluding medical men from representation in the Association. Admission to membership in the Association of American Medical Colleges is, therefore, sought by all the medical schools of the country. This year the Cornell University Medical College of New York made application for membership, but was refused on the ground that it was graduating men this year on a three-years' course.

After a heated discussion on the part of the Chairman of the Judicial Council, and Dr. Connor of Cincinnati, the mover of the resolution, the following amendment to the Constitution was adopted:

Every penalty for violation of an article of the Constitution (such violation having been reported to the Association by the Judicial Council after due examination made by said Judicial Council), shall be determined by vote of the Association at the annual meeting at which the violation has been reported, a three-fourths affirmation vote of the colleges represented being required for expulsion.

THE NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS.

This Association held its ninth annual meeting June 5, 1899, under the presidency of DR. WILLIAM WARREN POTTER of Buffalo. Addresses of welcome were delivered by GOVERNOR BUSHNELL and DR. CHARLES A. L. REED of Cincinnati, which were responded to by DR. JOSEPH M. MATHEWS of Louisville.

The president delivered his annual address, in which he emphasized the great importance of higher medical education and of more rigid preliminary requirements.

DR. N. R. COLEMAN of Columbus presented the report of the Committee on Minimum Standard of Requirements. The standard of minimum requirements of several States was given. The committee is of the opinion that educational qualifications for entrance to medical colleges must be essentially uniform in order that technical courses of study builded upon them may also conform to each other. In no other way does it seem possible to establish that educational reciprocity which is believed to be desired by all States. In spite of certain objections the committee has adopted as a minimum standard, the four-years' course in the high school, for the reason that the high school is found equally distributed over all the States and Territories. Furthermore, being maintained by public funds it is enabled to furnish the best possible facilities and equipment free of charge to our youth, whereas a college education can be enjoyed by few other than the more prosperous in the communities.

The confederation elected the following officers: President, Dr. J. N. McCormack of Bowling Green, Ky.; secretary-treasurer, Dr. A. Walter Suiter of Herkimer, N. Y.

THE AMERICAN MEDICAL EDITORS' ASSOCIATION.

The meeting was called to order by the President, DR. THOMAS H. HAWKINS of Denver, Col., in the Hall of the Young Men's Christian Association on June 5th.

After the transaction of routine business DR. J. D. EMMET of New York read a paper on "The Ends and Aims of Medical Journalism," in which he prophesied the approach of that millennial time when all medical publications shall emanate from the profession and shall be owned and published by members of the profession, with such a strict censorship that no patent or proprietary drug or surgical appliance shall receive mention therein.

A brief discussion was also held on the relations of editor and author and the rights of each as regards contributed articles. This proved too delicate a subject for general public discussion and it soon became apparent that the rules governing this relation must be formulated by each one for his own guidance. The banquet was held at the Columbus Club, at which covers were laid for one hundred guests. Dr. I. N. Love of St. Louis was elected president for the ensuing year.

AMERICAN MEDICAL ASSOCIATION.

Fiftieth Annual Meeting, Held at Columbus, Ohio, June 6-9, 1899.

(Special Telegraphic Report to the MEDICAL NEWS.)

GENERAL SESSION.

FIRST DAY—JUNE 6, 1899.

AFTER prayer by REV. WASHINGTON GLADDEN, D.D., GOVERNOR BUSHNELL of Ohio welcomed the Association to the capital of the State very heartily and fraternally, recalling the fact that he had been an apothecary himself before he went into the mower and reaper business in another line. MAYOR SWARTZ of Columbus extended the

freedom of the city to its medical guests. The president, DR. JOSEPH M. MATHEWS of Louisville then delivered the president's address. DR. HOLTON presented the account of the Rush Monument Fund. Only three States, Colorado, New York, and Pennsylvania, have fulfilled the promise made two years ago to raise $2000 each. The District of Columbia has given $250, and just before the present meeting California presented $500. The amount of the fund now is $10,582. DR. GIHON, the last surviving member of the original Rush Monument Committee, sent in his resignation. The treasurer of the Association reported $33,760 received during last year. On December 31, 1898, $28,729 was in the treasurer's hands, besides $3000 in the sinking fund.

DR. FENTON of Philadelphia presented a set of resolutions demanding reform in the United States Army Medical Service that will bring it up to date in modern sanitary scientific aspects, and asking that the Association appoint a committee to wait on the President of the United States to this effect.[1] Similar resolutions were presented by the State Society of Georgia. A resolution offered by the State Medical Society of Pennsylvania that opticians are not qualified practitioners and must not be consulted with was referred to a committee for action later. DR. GEORGE M. GOULD of Philadelphia, Pa., presented a resolution providing that the *Index Medicus*, which is compelled under present circumstances to suspend publication, be taken in charge by the American Medical Association; that a suitable editor and corps of assistants to maintain it at its present high standard be appointed, and that the Association guarantee it financial support, not to exceed $3000 to be expended in any year. On motion the resolution was referred to the Board of Trustees for consideration and report next year.

SECTION ON PRACTICE OF MEDICINE.

FIRST DAY—JUNE 6TH.

The Chairman, DR. FRANK BILLINGS of Chicago, called the meeting to order in the Hall of Representatives. He said that an attempt had been made this year to present synopses in the program of the papers to be read. This was the first time that an effort had been made in any of the Sections to do this, and the fact that out of a total of eighty-three papers fifty-four abstracts had been submitted proved that the attempt had been successful. These published abstracts give members an opportunity to acquaint themselves with the subject matter and prepare themselves for the discussions. He desired that original research should be stimulated, especially in the line of clinical work. Reports of cases with full reports on the clinical findings, and, when possible, supported by thorough post-mortem examinations, would be of greater value than papers upon general subjects more or less theoretic in character.

DR. N. S. DAVIS of Chicago read the first paper, entitled

[1] See our Philadelphia Letter, page 735.

WHAT ARE THE PHYSIOLOGICAL PROCESSES OR FUNCTIONS THAT IMPART TO THE LIVING HUMAN BODY ITS VITAL RESISTANCE OR IMMUNITY TO THE ACTION OF TOXIC AGENTS TO WHICH IT MAY BE EXPOSED; AND HOW CAN THEY BE AIDED BY THERAPEUTIC AGENTS?

He said that it is plain that the natural processes or functions which impart to the dying human body its vital resistance, which constitute the *vis medicatrix naturæ*, are, first, the inherent power of selection and rejection possessed by each cell or organized mass of bioplasm of which the blood and tissues are composed; second, the oxidation by which tissue metabolism is effected; and, third, the excretory and eliminating processes by which the products of metabolism and other disturbing elements are attracted from the blood currents and passed out of the system. The vital resistance of any living body may be said to depend directly upon the activity and efficiency of these several physiological functions and processes. The active investigations of the last half century have pretty fairly demonstrated the important etiological fact that nearly all the acute general diseases or febrile affections are caused by toxic agents called ptomains, leucomains, or toxalbumins resulting either from pathogenic bacteria introduced from without or from the retention of excrementitious products of metabolic change within. Both experimental and clinical experience have shown that the external application of water in the form of baths or sponging not only diminishes the fever heat but also increases in a marked degree the oxidation and decarbonization of the blood and the elimination of the waste and toxic products by the kidneys and other excretory organs. Strychnin and digitalis directly increase the action of the respiratory and vasomotor nerves, thereby sustaining the important functions of respiration and circulation. And yet every well-devised experimental investigation has demonstrated that alcohol, chloroform, and ether in the system directly diminish the sensibility and action of the respiratory and vasomotor nerves in proportion to the quantity used, and also markedly record the oxidation and decarbonization of the blood and lessen both the activity of leucocytes and of normal metabolism, thereby placing the effects in direct antagonism to the effects of the other remedies given in conjunction with them. A large part of the prevailing skepticism regarding the curative effects of drugs has resulted from such coincident use of antagonistic agents and the frequent use of agents for the relief of some prominent symptom, while the ulterior effects are injurious to the natural processes of vital resistance instead of aiding the same.

DR. B. M. LINNELL of Chicago followed with a paper, entitled

A COMPARISON OF THE VARIOUS METHODS OF ESTIMATING HEMOGLOBIN.

The two instruments that are most used in this country are Fleischel's hemometer and Gower's hemocytometer. Sources of error are known (1) in color tests. Two eyes rarely agree in accurate estimation of varying shades of color. Eyes of the same individual vary at different

times, due to fatigue and the influence of varying intensities of light. (2) In adding water to dilute the hemoglobin one is apt to over-dilute the solution, thus making it necessary to repeat the test. (3) One cannot make a number of estimates of the same specimen and strike an average. The speaker drew the following conclusions: We need a system of estimating hemoglobin which will eliminate the necessary inaccuracies of color comparisons. Hammerschlag's method is mechanically accurate and eliminates the necessary errors of color comparisons. The errors made in taking the blood are common to both methods. The tests seem to show that the specific gravity varies with the percentage of hemoglobin. Variations under normal conditions in blood are not great enough to interfere with the value of the specific gravity test.

DR. JUDSON DALAND of Philadelphia agreed that so far as color tests are concerned all tests are objectionable. He referred to methods by which he could reduce a certain percentage of error in the use of Fleischel's instrument.

DR. GEORGE DOCK of Ann Arbor, Michigan, thought that the specific gravity methods are easy to carry out, but one should bear in mind that the specific gravities do not always correspond to the hemoglobin present. Gower's method is faulty.

DR. LAMBERT OTT of Philadelphia then read a paper, entitled

THE SPREAD OF DISEASES IN SCHOOLS AND ITS PREVENTION.

The diseases usually spread in schools, naming them in the order of frequency, are diphtheria, scarlet fever, measles, whooping-cough, varicella, and variola or varioloid. There are three common sources of danger, first, being in school during the inception and development of the disease; second, returning to school too early in the convalescence, or permitting children in the infected household to attend school; third, in daily attendance in school during a light and overlooked attack of contagious disease. The common means of contagion or contamination are by personal contact, inspiring exhalations, kissing, by the common use of the drinking cup, by exchanging working material, such as pencils, cleaning-rags, etc., by passing around from mouth to mouth a whistle or a mouth-organ. A grave question arises as to when children should be allowed to return to school during the convalescence of contagious diseases. The speaker's rule is as follows: (*a*) after diphtheria, four weeks from its inception, and after one week in the open air; (*b*) scarlet fever, four weeks from its inception, and after one week in the open air; (*c*) measles, two weeks from its inception, and after one week in the open air; (*d*) whooping-cough, not until every vestige of the cough has disappeared; (*e*) smallpox, two months from its inception, and after one month in the open air.

DR. ARNOLD of Boston referred to an attempt to correct the evil in schools in Boston. In 1894 there was started a system of school inspection. The city was divided into fifty districts and a medical examiner appointed for each district. During the first fourteen months 667,790 pupils were examined, of which number 6053 were not sick, and 10,737 were found to be ailing, of which number 2041 were ill enough to be sent home. Of these, 453 had some contagion and would have been a source of danger if allowed to remain at school.

DR. RAYBURN of Washington, D. C., advised not sending children to school before the age of seven years, on account of their greater susceptibility to contagion before that period.

DR. AXTELL of Denver spoke against the indiscriminate use of lead-pencils in schools. He had once suggested to a lead-pencil manufacturer that it would be a wise plan to incorporate in the black material quinin or some bad-tasting substance to prevent children carrying the pencils to their mouths.

DR. JOHN MUSSER of Philadelphia made a motion, which was carried, that a committee of three be appointed to bring this subject before the General Session for consideration. Dr. Ott was appointed chairman of this committee, with Drs. Axtell and Rayburn.

DR. T. N. MILLER of Rockford, Ill., read a paper, entitled

CEREBROSPINAL MENINGITIS.

Regarding the treatment of this disease he knew of no better remedy than ergot, combined with calabar bean, pushed to its full physiological effect. Bromids are less efficient. Bleeding is bad. While he did not consider opium the "sheet anchor of our hope," yet he could see that it is of great aid in all stages of the disease. Especially in the first three days of the disease he considered the iodids of paramount importance, both from their well-known effects in preventing suppuration and effusion into the ventricles, and also in softening of the brain tissue. He also used counter-irritation. Applications of ice he had never used for fear of the depressing effects upon the general circulation and blood stagnation.

DR. GEORGE L. EYSTER of Rock Island, Ill., followed with a paper, entitled

SOME UNUSUAL FEATURES OF EPIDEMIC CEREBROSPINAL MENINGITIS.

A clinical report of two cases of cerebrospinal meningitis of the markedly intermittent type, accompanied by mucopurulent discharge from the nasal cavities, in which were found large numbers of the diplococcus intracellularis meningitidis was made, with a description of the post-mortem findings.

SECTION ON SURGERY AND ANATOMY.

FIRST DAY—JUNE 5TH.

The Chairman, DR. W. J. MAYO of Rochester, Minn., opened the meeting by reading a paper, entitled

CICATRICIAL STRICTURE OF THE ESOPHAGUS AND ITS SURGICAL TREATMENT,

and said that the treatment of this condition has always been a surgical problem. The number of cases met with are so few that it is a rare condition, yet sufficiently frequent to stimulate our best efforts for its relief

Esophageal obstruction may be classified into, first, those located within the esophagus, as inflammatory strictures, etc.; second, pressure obstruction located without the esophagus, as in tumors involving the thyroid gland, etc. Cicatricial stenosis is the result of the healing of an ulcer which may be produced in many ways. The paper treated of the first of these two classes of cases. The diagnosis is usually easy, the clinical picture being generally a perfect one, and the diagnosis easily confirmed by the passage of bougies. The prognosis in those cases seen early is good. The treatment, briefly stated, is gradual dilatation every other day by bougies before the contraction begins if possible. All foreign bodies should be at once removed, and if the cause of the stricture be either syphilis or tuberculosis appropriate constitutional remedies should be employed. If the stricture be dilatable its treatment depends on its location; if in the vicinity of the cricoid cartilage external esophagotomy is the operation of choice.

DR. JOSEPH RANSOHOFF of Cincinnati then read a paper on

CONSIDERATIONS ON THE DIAGNOSIS AND TREATMENT OF GALL-STONES,

and said that little is known of the etiology, but perhaps excess of cholesterin in the bile is the cause, the nucleus around which they form being either of helmic or bacterial origin. The diagnosis is usually not very difficult, and the operation of choice should be cholocystotomy with the establishment of a biliary fistula. Out of forty-six cases only three deaths resulted.

DR. A. J. MCCOSH of New York read a paper, entitled

OBSERVATIONS ON THE TREATMENT OF GALL-STONES.

The surgeon generally sees these cases early in their course. The decision as to the best method of treatment is often most difficult. Distention of the gall-bladder will often occur when the cystic and common ducts are entirely free. Jaundice is not always dependent on the obstruction of these ducts. A stone in the common duct will not always cause distention of the gall-bladder, but instead it will shrivel up. In nine cases of operation for stone in the common duct in not one was there dilatation of the gall-bladder. In one case a stone the size of a goose-egg was found occupying the entire common duct. The stone was four and one-half inches in length and six inches in circumference. The gall-bladder and passages are very easily infected. This is proven by the fact that in nearly every case of typhoid fever there is an infection of the gall passages with the typhoid bacillus. It is often difficult to know when to stop palliative measures and to resort to surgical interference, which should not be put off too long. The longer the operation is postponed the greater becomes the mortality, and thus avoidable delay is fatal to the patient's chances. Cholocystitis often calls for operative interference, especially if there is no change for the better after a fair trial for a week or ten days of palliative measures. Repeated gall-stone colics is an indication for operative interference. Jaundice which persists may not be due to an impaction of a stone, and just when to operate is hard to determine. Timely operation should be performed in every case after a correct diagnosis has been made.

DR. W. E. W. DAVIS of Birmingham, Ala., then read a paper on

SURGERY OF THE COMMON BILE DUCT.

The surgery of the biliary ducts is still in its infancy. After reviewing the etiology, symptomatology, and treatment, he said in conclusion that cholocystotomy with drainage is the ideal operation. Sutures, as a rule, are not necessary, and in many cases are a distinct disadvantage.

DR. H. O. WALKER of Detroit opened the discussion on these papers and said that there is no necessity of draining in these cases. The purse-string suture answers every purpose and unless there is distinct indication for drainage it should not be employed.

DR. BEVIN of Chicago said he believed the majority of gall-stones are mycotic in origin, and they have been artificially produced in the French laboratories. The best incision for ordinary cases is one through the rectus muscle, enlarging it if necessary at either or both ends to an S shape.

DR. R. T. MORRIS of New York said that he generally closes up the gall-bladder by a purse-string suture.

DR. MURPHY of Chicago said that all his experience proves that early operation is most important in the treatment of these cases. The diagnosis should be promptly made and the operation follow soon after, especially when there is high temperature and evidences of systemic infection.

DR. FERGUSON of Troy, N. Y., said that there is no way of determining when the biliary tracts are entirely free from stones and that the best method of treatment is by drainage.

DR. PORTER of Fort Wayne, Ind., said there are two objections to the immediate closing of the gall-bladder: first, because in many cases permanent drainage for a long time is necessary to effect a cure; and second, one can never determine when the common duct is free from disease.

DR. WARNER of Columbus said he believes in early operation as it is accompanied by a lower mortality. The use of olive oil is a relic of barbarism and ignorance and it is an absolutely useless method of procedure.

DR. RODMAN of Philadelphia said that out of 106 cases in which he had operated only one was in a full-blooded negro.

DR. MOORE of Minnesota said there are many cases of cholocystitis in which gall-stones are a causative factor, especially as a secondary condition to the mycotic diseases.

DR. MARSHALL of Boston advocated the primary closure of the wounds in either gall-bladder or duct, and also the closure of the skin incision without drainage.

DR. MARCUS DAVIS said he had had one case of distention of the gall-bladder in a full-blooded negro.

DR. RANSOHOFF, in closing, said that but little is known of the etiology of gall-stones in the human being except that they often follow typhoid fever.

DR. A. J. ACHSNER of Chicago followed with a paper, entitled

APPENDICITIS AS A CAUSE OF INFLAMMATION OF THE RIGHT OVARY AND TUBE,

and after reviewing, at great length, the literature of appendicitis, said that he was convinced that many cases of inflammation of the right ovary and tube are secondary to a primary infection of the appendix. This is especially true in those cases in which the lesion in the appendix goes on to abscess formation. The differential diagnosis is difficult and oftentimes impossible. In 103 cases in which he removed the appendix, 53 were in females and 15 had a secondary involvement of the tubes and ovaries. In conclusion he thought that appendicitis is a frequent cause of tubal and ovarian disease, both acute and chronic, and the exact origin of every case of this character should, if possible, be determined.

DR. JOHN B. DEAVER of Philadelphia then read a paper, entitled

COMPLICATIONS AND SEQUELÆ OF APPENDICAL ABSCESS.

Of all complications of appendicitis the most frequent and fatal is peritonitis. When general this is not amenable to successful treatment. In not a single case of general peritonitis in his experience had operation proved successful, despite the fair trial of every form of treatment. This condition when present is an absolute contraindication to operation. Constitutional septic infection as the result of appendical inflammation may present clinically the appearance of typhoid fever and be difficult of diagnosis. Secondary abscesses of the peritoneum more or less localized by adhesions are not infrequent. The hepatic complications are of extreme interest and importance, and abscess of the liver, either single or multiple, may so mask the symptoms of the primary infection that only by the post-mortem examination is the surgeon made aware of the pyogenic focus in the appendix. Extension may also occur from the liver to the pericardium or pleuræ and demand operative interference for its relief. That metastatic abscesses may form in the liver, lungs, spleen, or kidney is often proved by post-mortem examination. Complications nearer the source of infection are iliac phlebitis, or rupture into one of the hollow viscera,—the intestines, the bladder, or the pelvis of the kidney. The abscess may be part cecal, or it may involve the post-peritoneal connective tissue. Appendical pus may occur in a terminal sac, or it may be a serious complication of pregnancy. Its effect upon the reproductive organs of the female are most serious. The bladder wall and the sigmoid are here perforated and the organs covered by dense quantities of exudate in which are localized abscesses. These complications of the disease are just so many strong reasons for early operative interference. If this be resorted to the seat of inflammation is removed before there is time for pus formation, and thus the terrible ravages produced by appendical pus, no matter what its situation, are prevented.

DR. ROBERT T. MORRIS of New York followed with a paper on

BAD METHODS IN APPENDICITIS,

and said that sociological conditions are of great importance. Especially bad is the practise of surgeons who make too favorable statements in regard to this disease, particularly in lay journals. The best method of treatment is immediate operation, and it should never have a higher mortality than 1 or 2 per cent.

DIAGNOSIS AND TREATMENT OF APPENDICITIS, WITH REPORT OF ONE HUNDRED CASES

was the title of the next paper by DR. W. J. MEANS of Columbus. He said that he had treated 112 cases of appendicitis, 8 by operative measures. Two of these patients died. The remaining 30 patients were treated medically and only 1 died. Appendicitis is essentially a surgical disease. The medical treatment gives relief, never a permanent cure. The only question to be decided is as to the most opportune time to operate. This cannot be settled by fixed rules. Each case must be treated on its merits, but a good working rule is to operate in every case just as soon as the diagnosis is made.

DR. W. W. KEEN of Philadelphia opened the discussion and said that a general purulent peritonitis meant to him an absolute indication for immediate operation. These cases are not all without hope, for in five cases in his experience which were apparently hopeless an operation resulted in a cure. It is not right to lay down a general rule that every man must operate on every patient ill with appendicitis, but every case must be treated as its symptoms demand.

DR. J. B. MURPHY of Chicago said that though cases might be mild for the first twenty-four hours no man can say how long they will remain so, and therefore it would seem to be best to remove the appendix while there is yet time, and so operate within the first twenty-four or at least in the first forty-eight hours.

DR. GRANT of Denver, Col., said that the mixed method of treating appendicitis has a higher mortality than 2 per cent. Each case must be treated on its merits, and operation in the first twenty-four hours gives the best chance and will give a much lower mortality.

DR. MCARTHUR of Chicago said that he had operated on 137 patients with appendicitis in the interval between attacks and in not one of them was there a fatal result.

DR. JOHNSON of Hartford said that he had performed more than 100 operations on diseased appendices without a death.

DR. GRAHAM of Chicago said that he was governed by the circumstances of the case and not by any set rules of procedure.

DR. ERNEST LA PLACE of Philadelphia said there is no fixed rule to go by. In the majority of cases prompt operation offers the best chance of life.

DR. PORTER of Fort Wayne said that he had seen patients with general purulent peritonitis recover and that operation gives them their only chance.

DR. A. J. OCHSNER of Chicago said that he has had many cases of general purulent peritonitis in which the patients were treated by opening the abdomen, but they all died. He now treats them by stopping all food by

the mouth, but feeds them by enema; cold is also applied to the abdomen. He has treated quite a few patients by this method, with very satisfactory results.

DR. DEAVER, in closing, said that he wished to repeat that he never had seen a case of general purulent peritonitis in which recovery took place. It is impossible to lay down any general rule of procedure until the belly walls are made transparent and one can see just what is going on in the abdomen. It is not right for inexperienced men to attempt to remove appendages, as it is a most difficult and serious operation.

DR. EMIL RIES of Chicago then read a paper on

SOME RADICAL CHANGES IN THE POST-OPERATIVE TREATMENT OF CELIOTOMY.

He gets his patients out of bed twenty-four hours after vaginal celiotomy, and they leave the hospital in four or five days. Large doses of salts are not given on the morning subsequent to the operation, the bowels being generally left to Nature. The patients, instead of being starved on liquid diet, are fed on meat, bread, etc., just as soon as peritonitis is found to be absent, at the end of twenty-four hours. The same after-treatment is followed after laparotomies.

DR. T. H. MANLEY of New York said that the paper was a most valuable contribution to our knowledge and is a distinct advance in surgical science.

DR. F. H. WIGGIN of New York said he had had a similar experience to the one detailed by the author of the paper, in which the patient left her bed for a few minutes ten hours after a laparotomy and no bad results followed.

SECTION ON GYNECOLOGY.

FIRST DAY—JUNE 6TH.

The meeting was called to order at 2 P.M. by DR. W. D. HAGGARD, JR., the secretary.

The Chairman, DR. A. H. CORDIER of Kansas City, Mo., then read his address and said in part: The supreme benefit of this annual meeting exists in the remembrance of the priceless works of those who attend and enter into these discussions.

One of the most important subjects coming before this Section is that of cancer of the uterus. The early detection of a gonorrhea and its proper management by the necessary local treatment and the avoidance of intra-uterine sounding has materially reduced the number of tubal and ovarian specific diseases. In all cases of ectopic pregnancy operation should be performed as soon as the diagnosis is made, unless in the latter months of pregnancy.

The subject of most importance to the Section in the line of infective processes is puerperal fever. The use of immunizing and curative doses of the streptococcic serum obtained from animals infected by a number of different streptococci, as in the laboratory of Louvain, has been the latest effort for cure in this direction. Credé ointment of silver in the treatment of puerperal sepsis has been remarkably successful.

PELVIC TUBERCULOSIS

was the title of a paper read by DR. AUGUSTUS P. CLARKE of Cambridge, Mass. The sources of contamination of the serous tissue are numerous, the principal avenues of entrance being from the intestinal tract. The adhesions of the intestines with the Fallopian tubes, and the subsequent ulceration or perforation of the united surfaces furnish one means by which the bacilli reach the adnexa. In many cases tuberculosis of the genital tract occurs in connection with the general dissemination of the disease of the other organs. This not infrequently takes place in childhood and before puberty. Tubercular lesions of the adnexa originating through the general blood-supply cannot be regarded as a common process. The forms of tuberculosis of the Fallopian tubes may be reduced to the miliary and the fibroid varieties; in the former the disease may remain latent for varying periods. Here a mere abdominal incision may be followed by apparent recovery, though it is not safe to regard such recovery as permanent. The chronic form of fibroid tuberculosis may become arrested or end in recovery.

The general infection of the organism from extraneous sources has undoubtedly been the more frequent mode of the inception of pelvic tuberculosis. Tuberculosis of the Fallopian tube has in many cases supervened upon catarrhal salpingitis. As stated by Williams and others, tuberculosis of the uterus, ovary, or Fallopian tube, must be regarded as secondary to primary areas of infection. In all cases of doubtful character the purulent exudation of the vaginal and uterine tissue should receive repeated microscopic examinations. When an exact diagnosis cannot be reached an abdominal incision may be demanded for the relief of symptoms.

DR. HOWARD A. KELLY of Baltimore said that a large percentage of our gynecological work is in this condition, and, therefore, the subject is most important. He felt sure that the condition has nothing to do with coitus. The disease localizes itself in the tubes. It is, however, found in the uterine body in a much larger percentage of cases than is commonly believed. As in tubercular disease elsewhere we ought to remove all diseased tissue. He had in two instances, however, been compelled to leave the diseased tubes, and both the patients recovered. He thought that when one opens the abdomen in tubercular cases one ought to examine the extent of the lesions, and determine how far the disease extends over the peritoneum.

DR. E. E. MONTGOMERY of Philadelphia said that he wished to put on record a case in a young girl, aged thirteen years, in whom there was tubercular disease of both ovaries and tubes. There was no involvement of the peritoneum beyond these organs. A singular feature of the case was that the girl had a tumor, apparently of the bladder, which, upon careful investigation through the urethra, was found not to involve the internal surface of the bladder. Upon opening the abdomen for the removal of the tubes, which was the first intention in the case, it was found that the tumor of the bladder was attached to its peritoneal surface, and contained a diverticulum from the bladder. The patient had been suffering for some time from inability to retain her urine. As the

peritoneum covered the surface nothing was done but a removal of the tubes and ovaries, and subsequently the bladder was distended by irrigation. Under this treatment she was able to retain her urine for at least three hours, and was much relieved. She has continued to gain in health since the removal of the diseased organs.

DR. A. GOLDSPOHN of Chicago said that he agreed with Dr. Kelly in the remark that tuberculosis of the tubes is more frequent than we have thought. He was not willing to say that the uterus should be removed when tuberculosis is found in the adnexa. The better part of operating in gynecology is to preserve the female organs, particularly in young persons, to the extent that the individuals will menstruate. As we strive to the utmost to save the uterus and a part at least of one ovary for this purpose, it seemed to him that it is rather indicated to leave the uterus and half of the ovaries even when the tubes are removed.

DR. C. C. FREDERICK said that the question of tuberculosis of the uterus and adnexa and the remarks of Dr. Kelly with reference to leaving some of the tuberculous organs in situ led him to speak of a case that he had had for about five years in a young woman who was tubercular. He removed both ovaries and uterus. Whether the cervix and the glands outside were diseased or not she made a good recovery. Subsequently there was a localized tuberculous abscess on the left side which he opened through the vagina, and which has continued to drain despite all efforts that he had been able to direct against the tuberculous process, and she now has developed general pulmonary tuberculosis.

DR. C. E. RUTH said that about four years ago he had operated upon a colored woman for a forty-pound ovarian cyst. The peritoneum was thickly studded with tubercular deposits. He simply ligated off the entire omentum and removed the tumor. The patient did well and seemed to be none the worse for the loss of the omentum, but died last winter from pulmonary tuberculosis.

DR. CARSNER said that tubercular deposit is often limited to the appendix exclusively, and certainly does not come from the vagina and tubes, which shows beyond any doubt that tubercular deposits in the peritoneum will not spread from the vagina and reach the peritoneum in that way. He agreed with Dr. Goldspohn, that it is not necessary to remove the tubes. For simple tubercular peritonitis he simply irrigates, and if there is degeneration he removes the organs.

DR. J. F. W. ROSS of Toronto said that he had found the disease to be more frequent in young unmarried women in whom there was no question of coitus, and therefore it does not come from the vagina. A cure by abdominal operation is among the marvels of our work.

CHOLECYSTECTOMY.

In a paper with this title DR. CLINTON CUSHING of Washington, D. C., said that for the purpose of the paper it would be assumed that the gall-bladder is not necessary to the health or well-being of the individual, for many cases are on record in which the gall-bladder has been removed and the patients have remained in perfect health. Investigation has shown that it is of no value to the digestive function. If the gall-bladder is so seriously diseased as to warrant surgical operation for its relief, it is better practice to remove it in toto than to leave it in place for the further accumulation of gall-stones or as a point for setting up new inflammations. Like the vermiform appendix the gall-bladder is a cul-de-sac, and having been once diseased is likely to become diseased again.

DR. DAVIS of Birmingham, Ala., said that one argument against the removal of the gall-bladder is that it is difficult to determine when the common duct is free. If one ties off the gall-bladder, one subjects his patient to great danger. If, on the other hand, cholecystotomy is performed the patient is put in the condition that the surgeon can perform the other operation later. The operation advocated by Dr. Cushing, he thought, is the one to adopt in case of marked disease of the gall-bladder. In his opinion but little advance has been made in gall-bladder surgery since the operation devised by Sims, except that the gall-bladder should be attached to the peritoneum.

DR. SUTHERLAND of Nebraska said that a great mistake is made in the early treatment of these cases by giving sedatives for the relief of paroxysms. He recently had three patients to whom he had given doses of sweet-oil internally, 8 ounces at each dose, two doses, four hours apart. In this way he had removed gall-stones almost double the caliber of the duct. The stones were passed about twelve hours after the first dose of oil. One is too prone to give hypodermic injections of morphin and allow these stones to remain.

A NEW OPERATION FOR THE CURE OF UTERINE RETRODISPLACEMENTS

was the title of a paper by DR. C. E. RUTH of Keokuk, Iowa. An incision is made at or near the median line above the pubes. The length of the incision depends upon the thickness of the abdominal wall. The uterus is brought forward and a large, ordinary, full-curved needle, or, if the operator prefers, a needle with the eye at the point, armed with a full-sized kangaroo tendon is passed under the peritoneum directly across the anterior surface of the uterus, then along the interior of the round ligaments, or when they are absent or practically so, simply along the interior of the peritoneal fold, which represents the course of the round ligament. When the abdominal ring is reached the needle no longer follows the round ligament but pierces the abdominal wall directly opposite the ring and emerges through the skin in contact with Poupart's ligament, near its middle, on one or the other side. The needle is now unthreaded, the end of the tendon split, say two inches, one-half is again threaded into the needle and passed under Poupart's ligament and the opposite side of the same, and the ends are next tied together over the ligament. The long, round ligament will thus be thrown into numerous folds and convolutions as it is taken upon the running thread.

The life of this material is at least two months and if

necessary it might probably be made longer. The operation does not expose denuded traumatized surface, and troublesome adhesions are not formed; it does not introduce any foreign material permanently; it enables the natural supports to take up the work successfully; it gives the desired position to the uterus; it leaves the uterus with ample mobility; it does not interfere with the development of any part of the uterus; it is quickly done and gives every opportunity for dealing with any ovarian, tubal, or uterine pathology with but a single wound.

WHY VAGINOFIXATION AND VENTROFIXATION AND SUSPENSION OF THE UTERUS SHOULD BE AVOIDED IN WOMEN WHO RETAIN ANY CAPACITY FOR CONCEPTION

was the title of a paper by DR. ALBERT GOLDSPOHN of Chicago. He said that these operations are unnatural, unsurgical, and unscientific. The wide range of the body of the uterus, which is so necessary, is secured chiefly by the total absence of all connections or attachments to its vertex and its anterior or posterior surfaces. Therefore the thought of opening the abdomen and inflicting fixation upon any one of these surfaces destined to be free and thereby limiting the normal mobility of the body of the uterus in some degree is repugnant to every rational instinct.

There are other surgical expedients quite generally available that are entirely within the domain of normal anatomy and physiology, that help Nature, and are assisted by Nature because they exercise a parallelism and no antagonism of forces. The only normal structures that exist and can be consistently made use of are the round ligaments of the uterus. They may be dealt with (1) by median ventral celiotomy; (2) by anterior median, vaginal celiotomy, and (3) by way of the inguinal canal.

The original Alexander operation, greatly modified and improved, is the only operation practised or proposed that not only does not borrow from things pathological and antagonistic to Nature, as do all ventral attachments, and does not create obstacles to gestation or labor, but also guarantees against a return of the retroversion afterward, provided that the operation is properly performed. And when this modern Alexander operation is combined with inguinal celiotomy by way of the temporarily dilated internal inguinal rings, for the severing of adhesions, for the resection or removal of diseased appendages, and for the permanent restoration of descended ovaries to their normal locations, it most nearly fulfils the highest ideals now entertained.

DR. C. C. FREDERICK of Buffalo, during the discussion of this paper, said that after some experience with ventrofixation, and discarding it because he feared it from the experiences of others, he since had had a number of cases of pregnancy following the operation, and none of the patients aborted and none suffered inconvenience. All went successfully through labor, and all have had an anteroposterior position of the uterus after labor, with no pain or distress. He never performs ventrofixation unless it be to sustain the uterus in cases of paralysis. He has removed the tubes and ovaries in women only who have passed the menopause. He has either shortened the round ligaments or performed the modified Alexander operation.

DR. ROSS of Toronto said that he had very pronounced views on this subject. He believes the operation of ventrofixation to be anatomically and physiologically unsound. The statistics presented by Dr. Goldspohn convinced him that his own views were correct. The large number of cases in which difficult labor and intestinal obstruction has been found to be the result of this abnormal position of the uterus, show conclusively that if the Creator intended the uterus to have a ligament in that place He would have put it there. The mechanism by which the uterus is suspended is perfect. The Alexexander operation has been too highly estimated in the opinion of Dr. Goldspohn. There are other operators who have given us adverse opinions regarding its benefits. Cases have been reported in which hernia has followed it. The only method which meets with his entire approval is the intra-abdominal shortening of the round ligaments, an operation which apparently is not entirely free from danger. He had had one melancholy experience with it within the last year. He considered that many of the young girls operated upon do not require any operation at all, and that the symptoms are not due to the flexion of the uterus.

SECTION ON DISEASES OF CHILDREN.

FIRST DAY—JUNE 6TH.

DR. HENRY E. TULEY of Louisville, Ky., Chairman.

DR. ERNEST WENDE of Buffalo, N. Y., read a paper, entitled

THE DEATH-DEALING LONG-TUBE NURSING-BOTTLE.

He has demonstrated by bacteriological experiments that it is impossible to clean the tubes of nursing-bottles. The rubber is affected by microbic action, cavities occur in it, especially near joints, and the rubber itself acts as a culture medium. Used tubes left in an incubator for twenty days become disintegrated by the action of the infecting bacilli, and in some cases liquefied, while control-tubes were practically unchanged. These changes in the substance of the rubber make all attempts at cleansing illusory.

In the discussion DR. NORBURY said that the same thing holds good in the case of rubber nipples. The surfaces to be cleansed are easier to reach, but unevenness caused by microbic action and the growth in the substance of the rubber make bacteriological cleanliness practically impossible.

DR. WENDE said that the prohibition of the long-tube nursing-bottle in Buffalo has cut the infant death-rate in two. Eight out of ten of the deaths in children that formerly occurred were in infants using the long-tube bottle.

DR. E. H. MCCLANAHAN of Omaha, Neb., read a paper, entitled

CONSTIPATION IN INFANTS.

For this there are two causes, diet and anatomical conditions. Dietary constipation is due to too little fat and too much casein. Fat should be added to the milk or if

the stools are light-colored and dry, showing too much casein, that element should be reduced and the milk peptonized. A spoonful of maltine is a good corrective under these circumstances. Of drugs, two are worth noticing, podophyllin and phosphate of soda in combination with orange-juice. For atonic intestinal conditions the insertion of the finger into the anus is not only of diagnostic value, enabling the physician to assure himself that no abnormality is present, but is also a valuable therapeutic measure, stimulating peristalsis. The greased index-finger may be introduced up to the sigmoid flexure. External massage is of great service in these atonic conditions.

DR. C. G. SLAGLE of Milwaukee, Wis., said that chronic constipation in children is often due to the use of such teas as fennel or anise, given as supposed stomachics or colic-cures, or to the abuse of laxative remedies whose after-effect was astringent, or to opiates and patent nostrums for colic. These causes must be guarded against.

DR. BARNES of Washington, D. C., said that the mother may form the child to habits of regular defecation very early in life. For this the use of simple suppositories is a great help.

DR. J. A. WORK of Elkhart, Ind., insisted on the necessity for loose clothing if the child is not to be constipated.

DR. GARRISON suggested that more water must be added to the food of constipated children, but that if plain water be given it is excreted by the kidneys; if some salt be added, for example, bicarbonate of soda, it affects the intestinal excretion favorably.

DR. FRANK X. WALLS of Chicago then read a paper, entitled

SO-CALLED CONGENITAL OBLITERATION OF THE BILE-DUCTS.

This affection is usually fatal, and is due at times to an anomalous development of the biliary tract, at times to adhesive angiocholitis. Catarrhal icterus is very rare in children, but when it occurs the serious form should be thought of at once, and if the affection does not yield promptly to treatment operative interference should be considered. The disease is commoner than the statistics indicate and its treatment is surgical rather than medical.

SECTION ON MATERIA MEDICA AND THERAPEUTICS.

FIRST DAY—JUNE 6TH.

The section was called to order by the Chairman, DR. L. L. SOLOMON of Louisville, Ky.

DR. JOHN A. CUTTER of New York read a paper on

NON-DEPRESSANT ANALGESICS.

The paper was an enthusiastic advocacy of ammonol, and met with a severe handling by the members of the section on the ground that the article recommended was proprietary.

DR. C. C. HERSMAN of Pittsburg then read a paper on

PARALDEHYD AS A HYPNOTIC AND AS AN ANTIDOTE TO STRYCHNIN.

The author recounted some animal experimentation tending to establish the efficacy of the drug as a hypnotic and an antidote to strychnin.

SOME THOUGHTS ON URETHRAL THERAPY

was the title of a paper by DR. T. A. HOPKINS of St. Louis. He spoke of the use of argonin, commending it for its analgesic and therapeutic effects. This drug, being proprietary, the paper aroused the displeasure of the listeners, and the discussion of proprietary drugs in general which followed was exceedingly warm.

DR. LOUIS F. BISHOP of New York then read a paper on

THE USE OF ACETANILID IN VARIOUS COMBINATIONS AS A SUBSTITUTE FOR MANY PROPRIETARY DRUGS AND MIXTURES.

It is better to know one drug well than many superficially. For a long time he had prescribed acetanilid in combination with such drugs as seemed to him synalgesic in the condition to be met. Acetanilid is not soluble, but is readily suspended in syrupy mixtures, so that it can be combined with ammonia in any of its forms, salicylic acid, nux vomica, digitalis, codein, creosote, potassium bromid, or indeed almost any drug, and a prescription obtained that can be much more accurately adapted to the case in hand than any of the ready-made combinations. The foundation of most of the coal-tar product combinations is acetanilid, which has been combined with bicarbonate of soda, caffein, carbonate of ammonia, etc. The combination may be chemical or mechanical, it matters little which as it is practically broken up in the body into the acetanilid radicals and the other constituents. It is much more professional and scientific to write for the mixture than to be slaves to a proprietary combination. Perhaps the most generally useful combination of acetanilid when used as an analgesic is the migraine tablet. This is the equivalent of several of the most widely used secret mixtures that are sold under a specific name. It consists of 2 grains of acetanilid and ½ a grain each of caffein citrate and monobromate of camphor. A useful combination that can be prescribed in capsule is acetanilid and quinin, 1 grain of the former and 2 of the latter. This makes a good adjuvant to other treatment in cases of coryza. In rheumatic conditions, and those in which there is a suspicion of intestinal fermentation, acetanilid and salol make a good combination in capsule. For disturbances of circulation and neuroses attending the menopause 2 grains of acetanilid and 15 grains of bromid of sodium are efficient when combined in a dram of simple elixir. When repeated sufficiently often in this form it acts as an efficient hypnotic. Acetanilid is a useful addition to mixtures for the relief of acute indigestion attended by flatulency and great distress immediately after meals. As a substitute for iodoform and a host of antiseptic dusting powders, acetanilid has been found most efficacious, especially when combined with boric acid. What is needed by the profession to-day is a better knowledge of the drugs it is using.

GENERAL SESSION.

SECOND DAY—JUNE 7TH.

The Chairman of the Committee of Arrangements made the announcement that on Thursday a memorial floral service would be held at Camp Chase cemetery, where 2500 Confederate soldiers, who died as prisoners of war here, are buried. He said that the object of the service is to show the rising generation that we are a united people. The announcement was received with enthusiastic applause.

A resolution from the Legislative Committee, suggesting the appointment of three members of the Association, one from Philadelphia, one from Baltimore, and one from Washington, to oversee all matters of medical legislation that shall come before the National Legislature, was referred to the Executive Committee.

A resolution from the County Medical Society of Philadelphia, recommending the creation of a National Bureau of Health, with a cabinet minister at its head, presented last year, was reported favorably from the committee to which it had been referred, and was adopted by the Association as the expression of its opinion. A committee was appointed to take what action it deemed necessary in furtherance of this object.

The committee to which the subject of the modernization of military sanitary science in the United States Army, as suggested by a committee from Philadelphia, had been referred, reported in favor of the appointment of a committee, not to present the matter to the President of the United States, as originally suggested by the Philadelphia committee, but to memorialize Congress, and take such other steps as would be deemed necessary. This committee will consist of one member from each State and Territory.

On recommendation of the Georgia State Medical Society a resolution to the effect that the rank of Surgeon-General of the United States should be raised to that of Major-General was adopted amid great applause.

A resolution reccommending the appointment of women nurses for the army was adopted on favorable report by the committee to which it had been referred.

DR. FLOYD B. MCRAE of Atlanta, Georgia, then delivered the address on surgery. He stated that he had decided to follow the example of some of his predecessors and not attempt a general review of the progress of surgery for the year, but to discuss only some points in the surgery of the alimentary canal. He called attention to the use of normal salt solution, saying the surgeon who would fail to give his patient the benefit of this valuable agent after a prolonged or bloody operation would be as much to blame as one who would knowingly place his patient in bed with bleeding vessels.

He called attention to the value of rubber gloves in diminishing the danger of wound-infection by the hands of the surgeon and his assistants, and gave Halsted and McBurney credit for their scientific and practical work in this field of research. He called attention to the fact that bacteriologic investigation has repeatedly shown the impossibility of absolutely sterilizing the hands. The micro-organisms of the deeper layers of the skin gradually find their way to the surface during operations requiring prolonged manipulation, and while this source of infection by surgeons who take care of their hands and clean them thoroughly must be small, it deserves consideration.

Mention was made of the four cases of complete gastrectomy now on record, namely, by Schlatter of Zurich, Bingham of San Francisco, Richardson of Boston, and McDonald of San Francisco. Attention was called to the post-mortem findings in Schlatter's case, which showed that there had been no dilatation of the upper part of the intestinal tract to take the place of the stomach which had been removed, and that death had been due to general infection and not to inanition from removal of the stomach. Further attention was called to the fact that the cases must be very few indeed that would justify the operation of complete gastrectomy. He designated the Roux gastro-enterostomy as an original procedure that has received the highest professional commendation, and gave a detailed description of the operation with illustrations. He acknowledged indebtedness to Dr. Coley in "Progressive Medicine," Vol. II., for the description and illustrations of the operation.

Attention was called to the new impetus given to the discussion on penetrating wounds of the abdomen by reports of the cases of gunshot wounds of the abdomen received during the late war with Spain in which the patients had recovered without surgical interference. He does not believe that these cases should be taken as a guide in civil practice on account of the great difference in the character of the wounds and the conditions under which the injuries were received. He claimed that in civil life practically the only hope is in prompt and thorough surgery, and that no time should be wasted in waiting for definite signs of hemorrhage or peritonitis, or in the application of the hydrogen-gas test, which has only an affirmative value.

Carefully prepared statistics were presented of 107 cases of typhoid perforation, in which the patients had been subjected to operation, with a total mortality of 79.4 per cent. The table showed a greater tendency to recovery when the perforation occurred late in the disease. It is reasonable to expect twenty-five to thirty per cent. of recoveries in operative cases, when operation is undertaken within twelve hours after the occurrence of the perforation.

In discussing the treatment of appendicitis he said it seemed manifestly wrong and unscientific to lay down dogmatic and inflexible rules for the treatment of a condition so protean in type. The time at which the diagnosis is made is very variable and the advice to operate as soon as the diagnosis is made is exceedingly indefinite. The diagnosis of appendicitis is not always promptly made. Every surgeon who sees much of this disease knows as a matter of fact that many cases have gone beyond the time for early intervention when first seen by him. The question of intervention or non-intervention, in all cases, can only be settled by the compilation of fair and impartial statistics from both medical and surgical sources, statistics that are definite in all essential details.

STATE MEDICINE.

On motion, the report of the Board of Trustees was omitted for the day, and made the first order of business for Thursday morning.

(To be Continued.)

ORIGINAL ARTICLES.

PROGNOSIS IN CHRONIC VALVULAR AFFECTIONS OF THE HEART.[1]

BY N. S. DAVIS, JR., M.D.,
OF CHICAGO;
PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE NORTHWESTERN UNIVERSITY, ETC.

THE old, constantly recurring question, What is the prognosis in chronic valvular disease of the heart? was brought freshly to my mind by happening to have, at the time your secretary asked me to prepare a paper for this society, several cases under observation which illustrated well some of the varying conditions upon which a prognosis must be based.

While preparing this paper the records of 250 cases observed in my private practice have been studied and the statistics quoted have been obtained from this source.

Most laymen anticipate sudden death when they learn that they have heart disease. Such was the expectation of physicians in the first part of this century. It is now known that sudden death from chronic valvular disease of the heart is the exception, not the rule. It is to be looked for only in cases of aortic regurgitation. According to Broadbent's statistics death occurs suddenly in about one-quarter of these cases. One sudden death also occurred in eleven of his cases of aortic stenosis. According to other observers it is very rare in the lesion of stenosis and is almost unknown in mitral lesions.

By sudden death is meant death instantly, without apparent aggravation of symptoms, or within an hour or two after the fatal symptoms manifest themselves. When angina pectoris complicates aortic regurgitation the danger of sudden loss of life is much increased. If the valvular lesion develops in one who has general arteriofibrosis a sudden demise is much more probable than if the lesion has been produced by rheumatism or an infectious disease. In other words, sudden death in these cases is not due as much to the valvular lesion as to the very frequent coincident pathological state of the coronary arteries or coronary circulation.

When a valvular lesion actually exists perfect recovery is possible. Anatomical recovery is rare, in a sense is impossible, but physiological recovery is not uncommon. If a murmur is constantly heard in one of the valve areas on the chest an anatomical defect surely exists, although the heart is not demonstrably changed in size, performs its functions perfectly and the general condition of the patient is one of health. If a murmur which has been persistent for weeks and has been associated with hypertrophy of the heart disappears, and the hypertrophy gradually lessens, the heart can be said to have recovered both physiologically and anatomically. Such apparent anatomical recovery is usually due to a slow stretching of one valve-curtain to compensate for the slight defect in another. It very rarely happens, if it ever does, that the chronic thickening, roughening, or contraction of a diseased valve disappears entirely. Therefore, even when clinical evidences point to an anatomical recovery, it cannot be said to be perfect.

My own experience with cases of apparent anatomical recovery makes me skeptical of its completeness and permanence. I have observed it twice in cases of mitral regurgitation of rheumatic origin. These patients were under observation for several years and it was found that whenever the heart's rate was increased from transient and moderate fever or violent work, the murmur would temporarily reappear. A third case, now under observation, came to me with broken compensation and mitral regurgitation of moderate extent. As compensation has improved the murmur has grown fainter. When the patient was last examined it was inaudible except when arterial pressure was increased by raising his arms or causing him to make hurried movements.

Apparent anatomical recovery only occurs in valvular insufficiency. It has been observed both in aortic and mitral affections. That this must be so becomes apparent when the nature of the lesions producing stenosis is recalled. A narrowed orifice does not stretch and cannot be compensated for. If stenosis is due in part to protruding vegetations these may break off and thereby lessen the degree of stenosis, providing they do not then cause fatal embolism. Moreover, stenosis is apt to be a progressive lesion.

Germain See is quoted as declaring he had never seen aortic lesions perfectly recovered from. Mitral insufficiency he believed incurable, but mitral stenosis, even when it was accompanied by persisting dyspnea and edema he had seen improve and ulti-

[1] Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

mately physiological recovery become perfect. As regards aortic lesions my experience accords with this statement. I do not now recall a case of aortic disease in which rapid beating of the heart or dyspnea on exertion or other evidence of lack of compensation did not exist. But I have seen most perfect compensation in both mitral lesions.

The chance of moderate, one cannot say of average, longevity is good in chronic valvular disease providing compensation is perfect. There are, however, certain symptoms and conditions which make it possible to predict the relative duration of compensation. It is generally said that if the lesion is one of mitral insufficiency the chances of longevity are greatest; and are relatively less for the other valvular lesions in the following order: Mitral stenosis, aortic stenosis, aortic insufficiency. Walsh and others reverse the order of mitral and aortic stenosis.

Of thirty fatal cases of which I have records the average age at death was fifty years for mitral stenosis, forty for mitral insufficiency, and thirty-six for both aortic stenosis and insufficiency.

Stillman[1] says the percentage of deaths from heart disease among 5000 insured persons is 1.84 between the eighteenth and twenty-ninth years, 3.97 between the thirtieth and thirty-ninth, 5.1 between the fortieth and forty-ninth, 8.9 between the fiftieth and fifty-ninth, 13.3 between the sixtieth and sixty-ninth, and 12.6 between the seventieth and seventy-ninth years. The progressive increase in mortality is marked and runs almost parallel with the mortality from urinary diseases and apoplexy given in the same tables.

Of those of my own cases of which the duration of compensation could be determined with reasonable accuracy, it was found that in mitral insufficiency it averaged 5.1 years, in mitral stenosis 11.5 years, in aortic stenosis 7 years, and aortic insufficiency to 2.3 years. The range of duration in 31 cases of mitral insufficiency was from three months to seventeen years. Seven patients lived with good compensation one year, 5 two years, 4 three years, 3 six years, 4 ten years. In mitral stenosis the range was from six months to twenty years; 3 patients lived ten years with good compensation. In aortic stenosis the range was from two years to twenty, and in aortic insufficiency from one to four. From these statistics it appears that the chances of prolonged compensation and of longevity are greatest in mitral stenosis.

The next factor which must influence prognosis in these cases is the extent of the lesion. This can be imperfectly estimated. When a murmur is systolic and the first sound of the heart is also recognizable, the valves are able to do better work than if only a murmur is audible. If in mitral insufficiency the first sound is prolonged into a murmur, it is evident that at first the valves are nearly or quite closed, but are forced asunder later when the intra-ventricular pressure is highest. Whenever a murmur only is audible in a given valve area and the other cardiac sound is inaudible, the lesion is most extensive. A loud and widely diffused murmur indicates strength in the heart muscle. On the other hand, a low murmur need not indicate weakness. It sometimes means that the lesion is not extensive. A long murmur usually signifies a comparatively trivial lesion, or one just formed. When either of the heart sounds has been accentuated, and the intensification of sound lessens, a loss of muscular strength has occurred.

Another factor to influence prognosis is the stationary or progressive character of the lesion. Congenital lesions are stationary. Those produced by endocarditis resulting from measles, scarlet fever, and other eruptive diseases are stationary. Chorea without marked rheumatic symptoms produces comparatively favorable cardiac lesions. Rheumatism is so apt to recur, and, almost without fail, to aggravate cardiac lesions at each recurrence, that chronic vulvular disease of rheumatic origin must commonly be regarded as intermittently progressive. Lesions which develop as a part of degenerations such as arteriosclerosis and atheroma of the aorta are progressive ones, and make prognosis least favorable.

Since the degenerative lesions develop only after middle life, the age of a patient is a partial guide as to his probable longevity. Although the valvular defects just described as stationary are so, a cardiac disease growing out of mitral stenosis, even in childhood produced by an eruptive fever or mild chorea is likely to be progressive, for while the child grows the left ventricle, aorta, and arteries generally do not enlarge as they should, and sooner or later by their relative small size become an additional impediment to the circulation. The right ventricle is then unable to maintain compensation.

It is interesting here to observe the time of inception of the various valve lesions. Of sixty cases of which the time of inception could be determined, forty-nine began before the fortieth year in mitral insufficiency; in mitral stenosis the ratio of those beginning before the fortieth year to those beginning later was as ten to two; in aortic stenosis they were equally divided by the fortieth year; in aortic insufficiency, on the other hand, the ratio of those beginning before the fortieth year to those after were as two to seven. The greater age at which aortic maladies have their inception is also well

[1] C. F. Stillman, "The Life Insurance Examiner," page 30.

shown by the fact that in these same cases mitral insufficiency was observed to originate from the third to the sixty-ninth year, mitral stenosis from the sixth to the sixty-seventh year, aortic stenosis from the twelfth to the sixty-second, and aortic insufficiency from the twentieth to the seventieth.

A fourth factor which will modify prognosis in cases with good compensation is the amount of hypertrophy that exists. When compensation is imperfect, without demonstrable hypertrophy, or only trifling hypertrophy, the chance of longevity is comparatively good, for we can hope that compensating hypertrophy will develop. If hypertrophy must be great in order to maintain compensation trivial changes will break it.

The state of general metabolism is a good guide as to the endurance and longevity of the heart. If a patient's muscles are firm, his blood rich, and his weight maintained the possibility of prolonged compensation is good. Whenever considerable losses or gains in weight occur, either rapidly or progressively, the danger of cardiac weakness increases. An approach to obesity is almost sure to break compensation. A considerable loss of flesh is usually associated with general malnutrition. Cardiac weakness is unavoidable under these circumstances.

The habits of a patient may increase the chances of breaking compensation. If to maintain himself or family violent physical exertion must be made, or moderate exertion continuously over many hours, cardiac exhaustion must be looked for soon. Glaring exceptions to this rule can be pointed out, but it is nevertheless a general statement that can be maintained. If one's mode of life disposes to exposure, to wet and cold, the danger of complications, such as bronchitis, pneumonia, nephritis, and rheumatism is great. These maladies are often the cause of a break in compensation, and if they recur several times are sure to cause it. The frequent or constant use of unwholesome or indigestible foods cause, digestive disorders which will increase blood pressure and the heart's work. Alcoholics are liable to provoke gastritis and consequent indigestion and higher arterial tension. They are also a cause of degeneration of the heart, and when freely used tend to produce cardiac dilatation.

Chronic valvular lesions which are not progressive, produced in early adult life, are least dangerous. As they originate nearer either extreme of life they lessen the chances of longevity.

It is impossible to estimate in weeks or months or years the length of life of individuals who suffer from any particular form of valvular heart disease. It is only possible to enumerate the number of favorable and unfavorable factors in a given case of disease, and from them to estimate the chances of prolonged life. Broadbent has said that those suffering from aortic disease lived on the average four years after they were first admitted to the hospital for the cardiac trouble. This must mean four years after compensation was lost, if it ever existed.

Of 103 of my cases of which the duration of broken compensation could be determined (I do not mean the entire duration, for many of the patients were not under observation up to the time of their death), it appears that in mitral insufficiency the average duration of broken compensation is at least 2.6 years, with a range of from six weeks to seventeen years; in mitral stenosis the average is 3.6 years, with a range of from six months to eleven years; in aortic stenosis the average is 3.8 years, with a range from three months to twenty years; and in aortic insufficiency the average is 2.75 years, with a range of from six months to seven years. This shows that after compensation is broken those having stenosis of the mitral or aortic valves have a greater average duration of life than those having insufficiency.

Cases in which compensation is broken can be placed in three groups according as compensation is imperfect, lost and characterized by edema, or more than lost and complicated by passive congestion of the liver or kidneys, edema of pleura, pericardium or lungs, or by deep anemia. Individuals in the first class may average a life of three to four years, those of the second class of six to eighteen months, and those of the third some weeks.

When compensation is broken a quick pulse and more or less dyspnea, on exertion, coexists. Often coughing occurs also, and sometimes edema. But of these symptoms dyspnea, on exertion, is oftenest the first to attract the patient's attention. Of 105 of my patients, 62 developed dyspnea as the first notable evidence of broken compensation, 33 a quickened heart's action, 6 edema, and 4 cough. The contrast between the first symptoms of broken compensation observed by patients with mitral and aortic lesions is shown by these ratios. In mitral lesions dyspnea was first observed three times oftener than rapid beating of the heart. In aortic stenosis a quick heart-beat was noticed 4.5 times oftener than dyspnea, and in aortic insufficiency it was uniformly the first symptom of broken compensation.

In all cases of ruptured compensation dilatation of the ventricles is the rule. Dilatation is dangerous in proportion as it exceeds hypertrophy rather than directly as the ventricles are enlarged.

The danger which dilatation of the heart causes is much greater when it is chronic than when it is acute. Indeed, the latter is commonly recovered from.

The ability of a dilated and hypertrophied heart to do its work is best gaged by the fulness and strength of the radial pulse, or by the degree of persistent dyspnea which may exist.

Very considerable passive congestion of the liver and kidneys indicates a permanent loss of compensation. It is true that we are often able to restore these organs to a natural size, and even to do so several times, but we cannot produce again, cardiac compensation.

When compensation is lost deep anemia, even if dropsy is not considerable, or the heart greatly dilated, makes prognosis most unfavorable, for necessarily it means that the heart as well as all other tissues is imperfectly nourished and, therefore, that exhaustion is imminent. But anemia, complicating chronic valvular disease, can be cured before compensation is lost. It may be lessened or temporarily cured when the heart first shows signs of permanent weariness, but it can rarely be much changed when cardiac exhaustion is established.

After compensation is broken the patients usually are watchful of their health and seek and heed advice. They modify their habits as far as possible to meet the requirements of their malady. Habits, therefore, at this stage of the disease's progress are of less importance than disposition. The heedless and headstrong patient is sure to be indiscreet, and the ignorant one will often unwittingly work when he should not, or discontinue treatment when it is doing him most good.

The habitual use of tobacco by those having heart disease is detrimental. If used freely it hastens and increases cardiac dilatation and degeneration. If used in moderate quantities its ill effects are usually evident. On general principles it may be accepted as axiomatic that tobacco, in cases of heart disease, is a direct cardiac poison.

In all forms of chronic valvular diseases chronic indigestion and constipation are a menace, on the one hand, to the duration of compensation; on the other, to the remaining strength of an exhausted heart. They increase arterial tension, and therefore the work which the heart has to do. These conditions should be promptly corrected, or at least mitigated.

Chronic valvular diseases are said to be commoner in women than men, but less rapidly fatal in them. Pregnancy and childbirth increase very greatly a woman's danger when the valves of her heart are diseased. I presume we all can recall mothers who have borne and reared families although anatomical defects existed in the valves of their hearts. But after compensation is weakened child-bearing is a grave complication. I have never seen a case in which it did not shorten life, and it has been my misfortune to see several in which it caused death immediately or rapidly.

Rupture of a valve produces an acute rather than a chronic valvular lesion, and is not properly included under the title at the head of this paper. This lesion causes immediate loss of compensation, and death follows usually in a few weeks, and sometimes in a few days.

In 139 of my cases no cause could be discovered for the valvular lesions. Rheumatism was the undoubted cause in 54 cases, chorea in 5, atheroma in 15, grip in 4, pneumonia in 3, scarlet fever was a possible cause in 3 cases, ague in 3, puerperal fever in 1, measles in 2, typhoid in 2, and trauma in 1. Rheumatism was the cause of mitral insufficiency, mitral stenosis, aortic stenosis, and aortic insufficiency with the following degrees of frequency, as 8 is to 4, to 3, to 2 respectively. In only three cases were mitral lesions alone observed to apparently arise from atheroma, but they were several more times associated with aortic lesion.

Combined aortic stenosis and mitral stenosis was observed three times; aortic stenosis and insufficiency five times; mitral stenosis and aortic insufficiency two times; mitral insufficiency and aortic insufficiency one time; aortic stenosis, insufficiency, and mitral stenosis one time; and both aortic lesions and mitral insufficiency two times. Incompetence of the auriculoventricular valves of the right heart was observed ten times associated with mitral lesions.

Bronchitis was the commonest complication observed. Nephritis occurred very often, but six times in aortic lesions to four in mitral. Anemia and asthma were also common complications. Tubercular disease of the lungs occurred in three cases, pericarditis in five, angina pectoris in five. Rheumatism recurred often in those cases caused by it. Grip and gastritis were also occasional complications in these cases of chronic valvular disease of the heart.

From the standpoint of prognosis it is interesting to know that the mortality from heart disease varies in different sections of this country. In 10,000 insured persons in each of the following districts the mortality was as follows: New England and New York, 6.1; Michigan, Wisconsin, Minnesota, Nebraska, 4.1; New Jersey, Pennsylvania, 7.1; Ohio, Indiana, Illinois, 4.4; Delaware, Maryland, District of Columbia, Virginia, Kentucky, Missouri, 6.3; Southern States, 6.6; Washington, Oregon, California, Utah, Dakota, New Mexico, 7.4.[1]

THE MANAGEMENT OF TYPHOID FEVER IN A COUNTRY PRACTICE.[1]

BY W. J. J. PARIS, M.D.,
OF MARION, KY.

TYPHOID FEVER is always the result of neglect or failure of prophylaxis, and the latter fails so often that the physician is of necessity more occupied in curing than in preventing the disease. I would not in any sense belittle the importance of prophylaxis. In this disease so much of the instruction given in text-books is difficult to apply in a country practice that I have thought best to speak of my experience in trying to adapt our limited curative means to our surroundings and environments.

One of the greatest difficulties we have to deal with is the lack of trained nurses. To overcome this the physician should insist on having one person take charge of the patient, and then instruct that one in the minutest details of taking temperature, giving baths, injections, etc. He should always insist on having a written record kept, not only of the temperature, but of every other occurrence in connection with the case, *i.e.*, actions of the bowels or kidneys, sweating, sleep, pain, delirium, etc. This person should provide herself with a thermometer, syringe, and bed-pan, and ruled charts with the date and hours plainly written, using a page for each day with hours running from 1 A M. to 12 M., midnight. This record should be filed for future reference as it may assist in the prognosis late in a bad case.

The physician should insist on absolute rest in bed with only a light garment on, which should reach from the shoulders to the heels, a comfortable bed with an oil-cloth under the sheet, a light, well-ventilated room, and should cause to be removed from the room everything not necessary to the comfort of the patient. Every article which is removed from the patient or bed should be put into boiling water as soon as possible. The vessels used to receive the dejecta should be scalded immediately after being used. The room should be sprinkled two or three times a day with boiling water containing five per cent. of carbolic acid, and some of the same solution should be kept constantly in the bed-pan. After each discharge from the bowels the nates should be wiped with a cloth moistened with hot water containing one per cent. of carbolic acid. Medicines and articles of diet intended for the patient should never be kept in the sick room. The patient should never be allowed to use the dishes, spoons, dipper, etc., which are used by the family, and those which the patient uses should be cleansed with hot water several times a day.

The clothing, sheets, covers, and pillow-cases should be changed and aired or washed every thirty-six hours. The mouth should be cleansed frequently with Dobell's solution, or some other good antiseptic wash. I believe that pulmonary complications are often excited by the inhalation of septic matter from the mouth, and therefore careful attention to the antisepsis of the buccal cavity may prevent such complications.

The temperature of the sick room should be kept as near 65° F. as possible. There is usually an unnecessary dread of draughts during the height of the fever. The sick room should be light, quiet, and cheerful, and if possible the bed should be so placed as to give the patient a pleasant out-door view. Never allow visitors in the sick room. No attempt should be made to amuse or entertain the patient; the senses are blunt, he suffers little or no pain, and is occupied with his morbid fancies, which are usually of a pleasant character, and may amount to delirium. This morbid occupation of the mind is perhaps beneficial in preventing the patient from worrying about his condition or his business.

These details may seem at first glance unnecessary and laborious, but any physician who will give this plan a fair trial will be convinced of its advantages. He will soon be rewarded by finding partially trained nurses over the country, whom he has inspired with confidence by the care he has given to their instruction and who will cheerfully second his efforts in caring for the sick, and thereby relieve him of much anxiety about his patients.

It is always advisable for the physician to inform the nurse from time to time of the accidents, complications and sequelæ that may arise during or following the continuance of the disease, at the same time stating that he hopes to avoid them, but should any of them occur the friends will know that it was not unforeseen by him, and will not conclude that he does not understand the case. It is also well to impress upon the minds of both patient and friends the fact that the case is necessarily very tedious, but at the same time if the patient will keep quiet and obey orders, and the nurse will studiously follow instructions, the chances are very largely in his favor.

After convalescence is established, and everybody is happy at the favorable turn in the case, and the friends think "the fever is broke," the physician should notify them that they need not be surprised nor greatly alarmed if they should at any time discover that the temperature has suddenly risen to as high a point as it had ever reached during the primary attack. The temperature record should be kept, at longer intervals, for several days after it has become normal.

It is important to know the exact date of the on-

[1] Read before the Crittenden, Ky., Medical Society.

set of the disease, as there will be a crisis in the case every seventh day. Sometimes when the case is progressing favorably the improvement in the symptoms will be very apparent to the friends, and they will naturally expect that the next day or two will show similar improvement, but the physician may inform them that there will be no further apparent improvement for another week at which time he hopes to see another favorable turn in the case. The physician's resources are often more severely taxed in the management of the friends than of the patient.

Of all the articles of diet recommended in this disease milk is to be preferred. It should be given in small quantities and at regular intervals of about three hours. If it disagrees and causes pain and flatulence and curds or undigested casein are vomited or passed from the bowels the quantity should be diminished, or liquid pepsin given after the milk. Buttermilk is often well borne by patients who cannot take the sweet milk. It is perhaps because the buttermilk does not form a large curd in the process of digestion as the casein is broken up during the separation of the cream in the form of butter. If the milk is from a Jersey or Alderney cow it should be skimmed and diluted with an equal volume of boiled water. It is necessary for the physician to investigate the source of the milk-supply and see that the most scrupulous cleanliness is observed in the handling of the milk, and even in the feed and water given the cow; and the care of the stable in which she is kept.

The nurse should never carry more of anything, food, water, or medicine, to the patient than is intended shall be taken at one time. No cup, spoon, or glass should be used the second time until it has been cleaned with hot water. The patient should be fed at regular intervals without regard to the desire for food. Many typhoid patients would starve to death if not fed until they called for food. Water should be given in liberal quantities. The patient should be urged to take it freely. Patients will often take it in the form of lemonade when it is difficult to induce them to take clear water. The tissues dry up and wither and die from lack of water just as vegetation dies from drouth. Other articles of diet which may be given to vary the monotony are beef-juice, beef-tea, chicken- or mutton-broth, etc. White of egg or the whole egg thoroughly beaten with an equal measure of skimmed milk and a little sugar and a teaspoonful of whisky or brandy is often relished. Starchy and fatty articles should be prohibited because they cannot be digested.

Medicinal treatment should consist in efforts at antipyresis, antisepsis, asepsis, and such measures as will prevent complications, control urgent symptoms, and support the strength of the patient. The Brand method of controling hyperpyrexia, or some modification of it, is the only one worthy of serious consideration at the present time. It is impossible to carry out this method in a country practice like ours, but I find that sponge-bathing, when properly done, will produce just as good results. I begin the bathing early, often before I am certain of my diagnosis because I find that it produces equally good results in any febrile condition. The sponge bath possesses the advantage of easy application. Any intelligent person can be taught in a few minutes to apply it. The bath should be used every three hours when the patient's temperature is above 102° F. I begin with hot water and gradually reduce the temperature until I find that which produces the best effect on the individual patient, for I find that every case requires a temperature suited to its own peculiarities. The patient's temperature should be taken just before and an hour after the bath and carefully recorded each time in order to note the effect of the latter. When the proper degree is found the bath should be continued at that temperature. It should be applied gently and continued thirty minutes unless the patient complains of chilliness. In this way it does not produce shock, and there will be no prejudice against it. The patient should be protected from draughts during the bath, and every part of the body should be thoroughly bathed. There need be no fear of a little moisture left on the sheet or the body of the patient.

I sometimes keep the patient's chest and abdomen covered with a large towel wrung out of water at the proper temperature when the periodical baths fail to reduce the temperature. Children are often much worried by the sponge bath, in which case the wet pack may be used. In many cases the wet pack is superior to the periodical bath because of its continuous action. When using the hot bath it is necessary to take the patient's temperature in the mouth or rectum after the bath, or if taken in the axilla the attendant should be sure that the heat of the bath has disappeared from the body before it is taken, otherwise the record may be incorrect. A rubber bottle filled with ice-water should be kept to the head during the bath, or all the time, if it is agreeable to the patient.

Among remedies used for the purpose of intestinal antisepsis I regard thymol as far the best. It is open to the objection that it sometimes produces an intolerable burning in the throat and stomach and must be given in pill or capsule form, and is administered to children with difficulty. When it is dissolved in olive oil this difficulty is

almost entirely overcome. It may then be given to children by mixing it with syrup of acacia. My favorite formula is the following:

Thymol	gr. xvi
Menthol	gr. xvi
Ol. terebinth.	ʒ ii
Ol. olivæ	q.s. ad ℥ i.

M. Sig. Ten drops in capsule every four hours.

Thymol, if well borne, may be given in doses of 1 grain every four hours. The drug is not absorbed in the stomach and therefore reaches the intestines in its original form. Being incorporated with the oil increases this property. It is well enough to give a mild purgative of calomel if the case is seen early, but not after the tenth day. I usually give $\frac{1}{10}$ of a grain every hour till 3 or 4 grains have been given.

Other antiseptics are naphthalin, which is highly lauded by Wolff of Philadelphia; salol, charcoal, iodoform, creasote, iodin, carbolic acid, guaiacol, and beta naphthol. I have had some experience with most of them and found them unsatisfactory. The late Dr. William Pepper used nitrate of silver in doses of $\frac{1}{5}$ to $\frac{1}{4}$ of a grain from the beginning to the end of an attack of typhoid fever and claimed wonderful efficacy for it. Tincture of the chlorid of iron, 8 to 20 drops every four hours, from the end of the first week until convalescence is well advanced will preserve the strength of the patient, shorten the stage of convalescence and make the recovery more satisfactory. Alcohol may be used in the later stages of the disease when it has a salutary effect, improving the volume and reducing the frequency of the pulse and relieving delirium and subsultus, and when there is a tendency to subnormal temperature. It should be given in such quantities as are suited to the individual case. An intemperate person will require more than a temperate one, an old person more than a child.

Most complications of typhoid fever may be prevented by proper management. Diarrhea is best treated by the administration of opium, gallic acid, nitrate of silver, sulphate of copper, salicylate and subnitrate of bismuth, etc. Sometimes small doses of castor oil, by clearing the ailmentary canal of offensive matter, will check a diarrhea, relieve tympanites, reduce the temperature, and soothe the patient into a quiet sleep. Castor oil is also the best agent for relieving constipation, as it removes dried accumulations and impactions from the semiparalyzed intestines and lubricates the inflamed mucous membrane better than any other purgative. Often when the bowels seem to be sufficiently active there is constipation above the ileocecal valve. When enemata fail to relieve tympanites a dose of oil should be given. Tympanites should be treated by enemata of from 1 to 4 pints of sterilized water repeated every day as long as the condition lasts. Intestinal hemorrhage should be treated with ergot, acetate of lead, gallic acid, cold drinks, cold compresses to the abdomen, and absolute rest in bed.

Pulmonary and cardiac complications call for supporting treatment—strychnin, alcohol, nitroglycerin, and frequent change of position. Epistaxis, thrombosis, parotitis and bed-sores should be treated as in other conditions, but the latter should never be permitted to occur. The best remedy for the severe collicky pains in the stomach and bowels which sometimes occur during convalescence is extract of cannabis indica, $\frac{1}{3}$ of a grain every six hours.

The management of convalescence requires almost as much skill, tact, and patience as any other stage. The return to solid diet should be very gradual as the slightest indiscretion in this particular may bring on an alarming and even fatal relapse. The patient should be kept in bed at least a week after the temperature has become normal. After the third week it is necessary to keep a close watch for the occurrence of subnormal temperature and when it occurs alcoholic stimulants should be given in such quantity as is necessary to raise the temperature to normal. For the colliquitive sweats which sometimes occur during this stage I have found nothing better than 10 drops of aromatic sulphuric acid every six hours in a wineglass of water.

When a case is properly managed it is seldom necessary to give sedatives, but in spite of the most careful attention a sedative is sometimes called for to relieve restlessness. The best combination I have ever tried for this purpose is the following:

℞	Chloral	gr. viiss
	Tr. opii camph.	f ʒ i.

M. Sig. Every hour until quiet. It should be given well diluted with sweetened water or syrup. The free use of opiates as practised by some cannot be too strongly condemned.

THE DIETETIC MANAGEMENT OF SOME OF THE DISEASES OF INFANCY.[1]

By CHARLES GILMORE KERLEY, M.D.,
OF NEW YORK;
ASSISTANT PHYSICIAN TO THE BABIES' HOSPITAL; LECTURER ON DISEASES OF CHILDREN IN THE NEW YORK POLYCLINIC.

THE immense importance played by the diet in the management of an illness in a baby is surprisingly little appreciated. When ill, adults and older children, those beyond the bottle age, are placed upon a reduced diet. A man with gastro-enteritis, pneumonia, or any severe illness with fever, is not allowed roast beef and potatoes; in fact, such a diet

[1] Read before the Hospital Graduates' Club of New York.

would be rejected by the patient and other medical aid summoned. When the baby in this same family is ill with gastro-enteritis, pneumonia or any severe illness with fever, how many parents and physicians are there who discontinue with the child what to it is the equivalent of roast beef and potatoes? The full milk diet is generally allowed. The child is thirsty and eager for fluids and more milk is taken oftentimes than in health.

In every illness in infancy the digestive capacity is diminished to a considerable extent, variously estimated from one-half to two-thirds. The full milk diet causes indigestion and intestinal toxemia, increasing the fever and prostration, in short, giving the patient just so much the more to bear. During the exanthemata, pneumonia, and severe bronchitis, or in any severe illness with fever, I reduce the milk mixture one-half with water, so that the amount of fluid taken remains the same. Two or three times a day the milk-feeding is substituted by an animal broth or barley water.

In the management of the gastro-intestinal affections of the young, the diet, as would naturally be expected, is a most important factor. Among the derangements of the nursing age there are few that cause more annoyance or are harder to manage successfully than constipation. This trouble has been attributed to various causes by many writers. The comparatively long, large intestine folded on itself in a narrow pelvis offering an obstruction to the intestinal contents is thought by many to be the chief cause of the trouble The lack of development of the muscular structure of the intestine is supposed by others to be the producing cause. The lack of nervous power due to an undeveloped sympathetic nervous system is thought to be an important factor. In all probability the agents referred to may all be looked upon as predisposing factors, but I doubt exceedingly if any one of them was ever an immediate cause of constipation. One who has seen many cases of summer diarrhea in active operation will not question the muscle and nerve power of the intestine, or believe that the folding of the colon on itself offers any great obstruction.

Constipation in infants is due in a large measure to the element of casein in the child's nourishment, which, of course, is milk. Casein in excessive quantities, a higher percentage than normal with normal fat, will cause constipation. A child fed on a milk containing normal casein and low fat will probable be constipated. Infants may be constipated on a perfectly modified milk because of the difficulty of digesting cows' milk casein; or it may be due to the heating of the milk to an excessive degree.

Among the breast-fed, the dietetic management of this disorder is difficult, for it is hard to change the character of the mother's milk. Much may be done, however. Examine into the daily life of the mother and you will usually detect an inactive habit, a good feeder, usually a tea drinker, and probably constipation. An examination of the milk of these mothers will show that the normal relative proportions of the fat, proteid and sugar have not been maintained. The proteid will usually be found higher than normal with low or normal fat. The first step in treatment is to regulate the habits and life of the mother. The bowels must be evacuated daily with a laxative if necessary. She must be placed on a fresh meat, fresh vegetable and cooked fruit diet; a malt liquor with luncheon or dinner is advised. She is instructed to take at least three hours' exercise daily in the open air. This régime will diminish the proteid, increase the fat and not only relieve constipation in the child, but furnish it with better nourishment and a later weaning than would otherwise be necessary. The treatment of the mother will answer in a considerable number of cases, but when we fail, the further treatment is with the child. My first step is to give cream. Not purchased cream, but cream which has been produced from the best milk obtainable. I give from one-half to two teaspoonfuls in quite warm water immediately before nursing. The use of the gluten suppository at the same hour of the day for several days will do much to establish the habit of a passage at a certain time. In case the cream does not agree or is ineffectual, pure cod-liver oil 15 to 30 minims, three or four times daily, may be found useful. When the means enumerated fail, as they will in a small number of cases, medication will be required. Cod-liver oil is used as a food, not as a medicine.

In the bottle-fed and in the "run about" children the management is much easier and more fruitful in results. The treatment is simple and resolves itself largely into a manipulation of the fat and proteid. Given a bottle-fed child six months of age, suffering from obstinate constipation—the proteids are at once cut down to a minimum by prescribing cream, water, and sugar mixture. For this purpose a 16-per-cent. cream is desired. The nurse or mother is instructed to allow the milk which is delivered in bottles at about six o'clock in the morning, to rest in the refrigerator until twelve o'clock, when the cream is removed. If the milk is good the cream will contain approximately 16 per cent. of fat; if it varies from this figure it will probably be a lower percentage. I use the pint (sixteen ounces) for a standard. If we mix 1 ounce of this 16-per-cent. cream with 15 ounces of water, we will have a 1-per-

cent. fat mixture. If 2 ounces of cream are mixed with 14 ounces of water, a 2-per-cent. fat mixture will result; if 4 ounces of cream with 12 ounces of water, we will have a 4-per-cent. fat mixture. But our 16-per-cent. cream contains more than fat. It contains approximately 3.2 per cent. proteid and 3.2 per cent. of sugar. If then we were to prepare a food for this six-months',constipated baby, I should endeavor to give a high fat mixture, 4 per cent., with as low a proteid as possible. In order to do this we use 4 ounces of cream and 12 ounces of milk. This, as will easily be seen, would furnish us a 4-per-cent. fat, .8-per cent. proteid and .8-per-cent. sugar. The fat is as high as we wish it, the proteids low where they ought to be, and the sugar low, which we increase by the addition of milk or cane sugar.

A word about the low proteid, .8 of 1 per cent. Compared with the mother's milk it is low, but we must remember that in our modifications we are not dealing with mother's milk. It is unwise to attempt to give in many cases as high a cow proteid as is contained in mother's milk, for the reason that it is more difficult of digestion and by reason of its higher nutritive properties it is not required. In case the reduction of the proteid is impracticable or does not furnish relief, I add to each feeding of the cream or milk mixture one or two teaspoonfuls of Mellin's food or malted milk, which will often act as a satisfactory laxative. This is the only use to which I ever put either of these articles. In older children, eight or twelve months of age, diluted cream with water is often given with oatmeal jelly, one or two tablespoonfuls to each feeding. It is extremely rare for a child to resist this treatment. When such is the case I find the stool usually soft when voided. The cause of constipation in these cases is doubtless due to deficient peristalsis. In these infants medication is required.

In "run about" children the use of cream and water mixtures, rare meat, green vegetables, stewed fruit, zweibach, and bran biscuit renders the management of constipation at this period exceedingly simple. The meals must be given at stated intervals, crackers, bread, potatoes, and other coarse starches excluded. The more milk is heated the more does it act as a constipating agent.

In no illness of childhood is the diet of more importance than in acute gastro-intestinal diseases of summer. In these disorders we have, as is now recognized by all workers in this field, a gastro-intestinal infection primarily to deal with, a poisoning process brought about through the agency of bacteria; direct infection by means of bacteria swallowed; indirect or auto-infection so-called, whereby the bacteria, always present in the intestine, are given an opportunity for growth and development through the withdrawal of the normal digestive disinfectant juices. Such a condition may be the result of any febrile illness, or through the action of heat, cold, fright, or any means which may indirectly prevent the normal amount of the substances being furnished to the intestinal canal in their usual strength. We know that for the vigorous growth of bacteria a culture field is required. There must be warmth, moisture, and a favorable medium. If, then, we know there is an infection, through the means of which our patient is made ill, it is our duty to make the field as inhospitable as possible. Our first step then in the management of summer diarrhea, whether the child is nursed or bottle-fed, is to discontinue the milk at once. In the scramble for intestinal disinfectants we have lost sight of the fact that bacteria may be killed by other means than direct contact. To digress a moment, I can imagine nothing more ridiculous than the physician giving a child with summer diarrhea cooked milk, which is difficult of digestion at any time, and giving the child resorcin, salol, etc., drugs which disturb digestion and are of questionable utility in the intestine, if they ever reach it.

As before mentioned, we may kill bacteria in other ways than by direct contact. We will withdraw all favorable culture media and give non-irritating drugs that will render the culture field as inhospitable as possible. The diet allowed must be of such a nature that it will be absorbed largely by the stomach; keeping the intestine empty and giving it as much rest as is possible. I prescribe barley water, rice water, chicken-broth, beef juice, diluted one in ten, wine whey, and the liquid peptonoids in barley water. It is well to prepare three or four articles of diet and then alternate them. The child will soon tire of one of these substitutes if given at every feeding. I find it a very good scheme to use barley water as a base, with the addition of a teaspoonful of beef juice or a teaspoonful of liquid peptonoids; with the barley water may also be mixed a small quantity of chicken broth.

The patients are fed every two hours if they require it, in quantities equal to that which they are accustomed to in health. White-of-egg mixture I rarely use. I look upon it with almost as little favor as milk. Upon resuming the milk diet, which may be allowed when the stools approximate the normal, care must be exercised that the child is not put on the customary strength at once. If this is done our treatment will probably have to be repeated. I usually begin with one-half an ounce of milk to the feeding of five or six ounces of barley water and increase one-half ounce daily if it is well borne. Many children will not be able to take this small amount.

With these it may be necessary to continue the above-named substitutes for a considerable period of time.

CLINICAL MEMORANDA.

EMPYEMA OF THE PLEURAL CAVITY.[1]

By W. J. BREEDING, M.D.,
OF TAYLORS, TENN.

CASE I.—Mr. B., aged forty-five years, recently came under my observation with a large abscess pointing in the infrascapular region. This was freely opened; it discharged three pints of offensive pus. The abscess was kept open and drained freely, and was found to communicate with the pleural cavity. The opening, however, was not sufficiently large to drain the cavity, which was found upon examination to be full of pus. The resection of a rib was advised, but the patient's consent could not be obtained. Later I was called again and informed that the patient had been passing a peculiar, bloody, offensive material almost constantly from his bowels for several hours. The nurse said that the material was identical with that discharged from the external abscess.

Physical examination of the chest revealed an absence of the former dulness, respiration was almost normal, and soon the patient was much better. The discharge from the external opening also ceased, and he gained steadily for about thirty-five days, but finally died, evidently from an infection involving the gastro-intestinal tract.

I have searched diligently for literature on the subject of a pleural abscess rupturing into the alimentary canal, but find on record only one case, reported in the MEDICAL NEWS for June 24, 1893, by Dr. N. T. Dulaney of Bristol, Tenn. The empyema in this case was produced from a gunshot wound through the lung. The abscess pointed on the back to the left of the spine. This was incised and drained of pus and débris. A rupture into the intestinal canal was proven by injecting permanganate of potash solution into the bowel, which was forced through the external opening communicating with the pleural cavity.

It appears very rational to my mind that in surgically neglected cases of empyema the force of gravity could press an inflamed pleura downward against the diaphragm, where it could become adherent, and that the opposite surface of the diaphragm from irritation could form an adhesion with the colon. The pressure from above might in this manner cause a pointing and rupture into the intestinal canal. However, I have never seen this theory expressed in medical literature.

CASE II.—Miss A., aged eighteen years, student in a boarding-school. Family history good. Came under observation February 8, 1898. She gave a history of having been confined to her bed some three weeks, during which time she was very properly treated by a competent physician for pneumonia. The history and temperature charts, so far as I was able to ascertain, did not show a sudden crisis, but the continuance of an irregular temperature.

I found her very much emaciated, lying on the affected side, respiration about 24 per minute, pulse 120, and temperature in the afternoon 102.5° F. My physical examination revealed what appeared to be fluid in the pleural cavity, extending as high as the fifth intercostal space in the axillary line. I was informed that a microscopical examination had demonstrated the presence of tubercle bacilli in her sputum. In view of this opinion I was somewhat undecided as to the diagnosis, the question being whether it was consolidation from tuberculosis or empyema. I was inclined, however, to the latter opinion. Repeated physical examinations revealed a gradual increase of the pathological condition upward until it had involved the entire left side. The absolute flatness on percussion, displacement of the apex downward and to the right, with other corroborative symptoms, led me to a positive diagnosis of empyema. The patient's condition at this time contraindicated the resection of a rib, so I decided to aspirate. On March 1st the needle was introduced between the eighth and ninth ribs, posteriorly, and something more than one pint of pus withdrawn. This aspiration was repeated four different times. Severe coughing and symptoms of collapse always prevented the withdrawal of more than one pint. These aspirations seemed to have a favorable effect on her temperature and general condition for a few days, when the symptoms and physical signs would return as before.

Realizing that more thorough drainage must be secured, on March 15th an incision about one and one-half inches long was made into the pleural cavity between the seventh and eighth ribs. Through this opening quart after quart of creamy pus was discharged. It was kept open by means of gauze packing, and after the opening became smaller an intubation-tube was introduced and retained by means of adhesive strips. Two days after this opening was made a rupture into a bronchial tube occurred, as was shown by pints of pus pouring from the mouth and the gurgling of air in and out at the external opening.

The patient now passed rapidly into a grave condition. Her pulse was 140 per minute, very irregular, and at times could not be counted at the wrist. Evacuations from the bowel and bladder were involuntary. She was unconscious and unable to swallow liquids for three days. Subsultus tendinum was very marked, her temperature was subnormal, and her abdomen became as tympanitic as a drum. Hypodermic injections of strychnin and nitroglycerin were given every three or four hours.

I gave an unfavorable prognosis. The friends made arrangements for the funeral and expressed a hope that death would soon end her suffering, as this end seemed inevitable. From this extreme condition she gradually regained consciousness. As soon as she was able to swallow tablet triturates of calomel and soda were given with the object of partially disinfecting the foul alimentary canal, turpentine stupes were applied externally, and turpentine enemas administered. An excessive diarrhea ensued, lasting five days. The abdomen assumed a

[1] Read before the Upper Cumberland Medical Society, at Gainsboro, Tenn., May 2, 1899.

scaphoid shape, and her appetite became ravenous. On March 30th, fourteen days after the thoracotomy and the coincident rupture into the bronchial tube, the following report was made: Pulse, 106, much stronger and not so irregular; temperature in the afternoon, 99.5° F.; appetite good; urine three and one-half pints in twenty-four hours and normal in appearance. Two or three discharges from the bowels daily, showing good digestion. The opening discharges half a pint daily. The cavity is packed with gauze twice in each twenty-four hours. The patient is anxious to sit up in a chair this morning, and wants to know when you will allow her to go home.

A physical examination the next day revealed unmistakable evidences of fluid at the apex of the lung, while the lower region, being constantly drained, showed no signs of fluid. I was forced to the opinion that I had to deal with another pus cavity at the apex, which was undoubtedly separate and distinct from the one below; consequently a thoracotomy was performed, and more than a quart of pus withdrawn from this cavity. The opening was packed daily, with a continued improvement in the patient's condition for some two weeks, when evidences of fluid were detected between the two points mentioned. Another opening was made between the fifth and sixth ribs anteriorly on May 1st. The pus was very superficial in this locality, and could be seen pushing outward when the patient coughed. Large quantities of pus drained from this opening, with a much more rapid improvement in the patient's condition. She now had three openings into her pleural cavity, one between the first and second ribs, one between the fifth and sixth, and one between the eighth and ninth ribs. These openings were all packed twice daily with sterile gauze. When the packing was removed the patient's position was changed, and all the cavities drained thoroughly.

After the last operation her temperature remained almost normal, her pulse about 100, her appetite became ravenous, and her strength gradually increased until she was able to go to her home in North Carolina on June 18, 1898, three and one-half months after she came under my observation.

At my last examination I found the lung gradually expanding, and there were no symptoms of pus in the pleural cavity. She was instructed to keep the openings packed to prevent closing as long as a discharge continued. My last letter from her states that she is practically well, weighs 134 pounds, walks one and one-half miles to church, does housework at home, and expects to begin teaching school soon. All the openings have closed except the one at the apex, which still discharges a thin, watery fluid occasionally.

I think we can draw the following logical conclusions from this case: First, aspiration is useless except as a palliative and diagnostic measure. Second, thoracotomy is often preferable to the resection of ribs, or Eastlander's operation, in cases of extreme asthenia. Third, there is a possibility of recovery after rupture into a bronchial tube. Fourth, there is a possibility that distinct pus-cavities may be formed by pleural adhesions, and such cavities must be drained and treated as separate pus cavities. Fifth, in cases of separate abscesses it is much wiser to make a simple incision between the ribs into the pus cavity when there is sufficient intercostal space rather than subject the patient to the very grave risk from an anesthetic and the resection of ribs for the purpose of drainage. Sixth, one should never despair of such cases, however desperate they may appear.

BULLET WOUND OF THE LIVER AND LUNG; OPERATION; RECOVERY.[1]

By P. R. BOLTON, M.D.,
OF NEW YORK;
INSTRUCTOR IN SURGERY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE; ASSISTANT SURGEON TO BELLEVUE HOSPITAL.

PATIENT, male, aged forty-two years, a pedler by occupation. Family history negative. No previous serious illness. On September 8, 1898, he received a pistol wound at close range, the thirty-two-caliber ball entering the abdomen just to the right of the median line and about two and one-half inches below the tip of the ensiform cartilage. On admission to the Hudson Street Hospital there was a considerable degree of shock, but no further symptoms significant of intestinal injury or injury of the lung. Temperature 100° F., respiration 26, pulse 106.

Under ether anesthesia the wound of entrance was enlarged to four inches by extending it up and down through the rectus muscle and the peritoneal cavity opened. The anterior surface of the left lobe of the liver presented a horizontal laceration two and one-half inches in length and one inch in depth, from which fairly active bleeding was going on. There was a considerable amount of free blood in the peritoneal cavity. Digital exploration of the liver wound failed to disclose the path of the bullet, and it was tightly packed with gauze, which easily checked the hemorrhage from it.

No intestinal wound was discovered, and after sponging out the peritoneal cavity the incision of the abdominal wall was closed by suturing in tiers, the gauze packing of the liver wound being brought out at the original wound of entrance. A dry dressing was applied and retained in place by a bandage applied snugly about the abdomen and lower chest in order to exert as much direct pressure upon the gauze packing as practicable and to limit respiratory movements as much as possible.

The patient was returned to bed, but slightly more shocked than before operation, and reacted well from the ether. His afternoon temperature on the following day rose to 102° F., then gradually fell to normal after a few days. His general condition was excellent throughout convalescence. The gauze packing was entirely withdrawn on the third day and primary union of the suture line occurred without incident. On the sixth day the patient himself discovered the bullet beneath the skin overlying the sixth intercostal space in the right axillary line, and a small incision served to remove it from this position.

Examination of the chest now showed that the pleural cavity of the right side contained a moderate amount of

[1] Read at a meeting of the Surgical Section of the New York Academy of Medicine, May 1, 1899.

bloody fluid, which was probably the cause of the slight cough and local pain which the patient had previously mentioned. But there was no recognizable evidence of a lesion of the lung though this organ must have been traversed by the bullet in its path from the epigastrium to the position from which it was extracted. The pleura was emptied of blood by aspiration, and at the time of his discharge from the hospital all signs of its presence had practically disappeared.

The case presents at least two points of interest: first, a wound of the lung unaccompanied by hemoptysis; second, the readiness with which bleeding from the liver wound was checked by packing with gauze.

One not infrequently sees subcutaneous fractures of the ribs associated with cellular emphysema, in which there is no hemoptysis, but with the more extensive injuries of the lung bloody expectoration is the rule but not without exception, for several of the men shot through the chest with Mauser bullets at Santiago last Summer, who came under my care at Bellevue Hospital after their removal North, gave no history of having spit blood at any time, while in at least one of these individuals hemoptysis was a conspicuous feature. One may, therefore, justly infer that the absence of hemoptysis by no means excludes penetration of the chest-wall and lung by bullets in wounds of the thorax in which the path of the ball is in doubt.

The control of bleeding from wounds of the liver is often most difficult by either the cautery, suture, or packing, though success oftenest follows the last-named plan. The cautery is almost useless in closing the orifices of the gaping hepatic veins. Sutures, in order to compress the veins sufficiently to obstruct them, usually cut out and thus add to the difficulty. Gauze, on the other hand, firmly crowded into the liver wound, supplemented by digital compression for a few moments, usually succeeds. Whether tightly bandaging the abdomen and lower ribs and enforcing costal breathing to prevent dislodgment or loosening of the packing by movements of the diaphragm is conjectural, but it seems at least worthy of consdieration.

THERAPEUTIC NOTES.

Treatment of Catarrhal Ulcerations of the Large Intestine.—RICHTER (*Therap. Monatshefte*, March, 1899) says that it must be admitted that most of the food taken during the day finds its way, by the following morning, into the large intestine. If, therefore, one would employ remedies to heal ulcers in this portion of the alimentary tract it is best to give an early morning injection, and then to administer astringents, subnitrate of bismuth, etc., by the mouth, before the patient is allowed to have any nourishment, the breakfast being postponed for a few hours. By this means he has been able to cure, he says, some cases which were rebellious to other methods of treatment.

Extraction of a Hat-pin from the Urethra.—BROUSSIN (*Centralbl. f. Chir.*, April 8, 1899) was able to extract a hat-pin from the male urethra under apparently unfavorable circumstances. The pin had been introduced head foremost and had slipped wholly into the urethra, so that its point was about an inch inside the meatus. Clamps were placed upon the lips of the meatus and drawn upon in order to make the urethra tense, and to draw out of its wall the point of the pin. A rubber catheter which had been cut off square was then slipped into the urethra and over the point of the pin. When the tension on the urethra was relieved and the penis drawn backward the catheter covering the point of the pin was crowded out of the penis and, the point of the pin thus being obtained, the whole was easily withdrawn.

The Use of Salicylic Acid and Salicylates in Children.—COMBY (*Rev. de Therap.*, April 1, 1899) gives a number of prescriptions in which salicylic acid and its compounds may be used with advantage in the treatment of diseases of children.

For infantile eczema:

℞ Vaselin . . . . . ʒ j
Lanolin . . . . . ʒ iv
Zinci oxidi . . . . . gr. lxxij
Ac. salicyl. . . . . gr. xij.

M. Sig. Rub in morning and evening.

Or the following:

℞ Ac. salicylcii . . . . . gr. iij
Pulv. lycopod. }
Pulv. amyl. } aa . . . ʒ j.
Pulv. talc. }

M. Sig. Dust the affected parts three or four times a day.

In tonsillitis a bandage around the throat may be kept wet with the following mixture:

℞ Ac. salicylici . . . . . gr. xij
Alcohol . . . . . q.s
Glycerin . . . . . ʒ j
Infus. eucalypti . . . . . ʒ iss.

In articular rheumatism an application of vaselin containing salicylic acid, one dram to the ounce, may be made over the affected joint. Or a 33-per-cent. mixture of salicylate of menthol in liquid vaselin may be used. Rheumatism in infants is particularly susceptible to salicylate of soda administered internally. For this purpose the daily dose is 7 grains for each year of the child's age. If the stomach does not tolerate the drug it may be given rectally after an evacuation.

For intestinal antisepsis the salicylate of bismuth may advantageously replace the subnitrate of bismuth. The usual dose is 3 grains a day for each year of the child's age.

Cold Water to Allay Persistent Vomiting.—MITCHELL (*Virginia Med. Semi-monthly*, April 14, 1899) reports the successes he has had with cold water in the treatment of persistent vomiting. It is applied to the epigastrium by means of towels wrung out of ice-water, which are changed every minute until the vomiting ceases. In fifteen or twenty minutes the cold will be successful, and the treatment may then be discontinued, to be resumed later if necessary. By these simple measures Mitchell has succeeded in stopping dangerous vomiting, in a number of instances, after child-birth for example, when medicines and other external applications had failed to give relief.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

UNNECESSARY STREET NOISES AT NIGHT.

NEW YORKERS have learned to put up with almost any amount of noise on their streets without a murmur. The liberty thus accorded has been abused more and more until now there is no city in the world which is less suitable for the habitation of people with ordinary nerves. Preventable noises have occupied heretofore only the daylight hours, but now they are becoming a part even of the night and especially of the precious early morning hours when tired city people should have an opportunity to rest undisturbed.

So-called newspaper enterprise has made the night hideous with cries of "extras" containing very little that is extraordinary and as this has been allowed with impunity further invasions into the nightly silence are presumed upon. We had last week a most flagrant violation of public order in this matter. For days the city had been sweltering in a torrid heat that affected every one seriously and extending into the night made rest almost impossible. On the first reasonably cool night after the heated spell, when an exhausted community hoped to regain some of its lost sleep, it happened that what the police department of the city considers a boxing-match was "pulled off." The result was a series of newspaper "extras" which were announced by demoniac howling on the streets of the residence portions of the city from twelve to two o'clock in the morning.

It seems useless to protest against unnecessary noises in the daytime. A certain callousness in the matter has developed in New Yorkers' ears and minds amidst the buzz and burr of the street cars, the rattle of wagons, and the roar of the elevated trains. But these night alarms in the quieter residence districts of the city are uncalled for and should be suppressed.

This is an eminently suitable field of work for the New York Board of Health that of late has shown a tendency to busy itself about many things not exactly in its line. It is well known that heat prostrations are due much more to the exhaustion incident to insufficient sleep on successive hot nights than to the actual intensity of the daily heat. Anything that is calculated to add further to nocturnal disturbance and wakefulness deserves especial attention during the heated season, when the necessity for having windows open makes all street noises so pervasive. Children in particular are easily disturbed by unwonted noise and are not easily quieted again, and so Nature's reparative purposes at night are sadly disturbed. We are just entering on what promises to be a summer of extremes in temperature; let us at least be saved the nuisance of unwarranted nightly disturbance.

THE ANTIVACCINATION PROPAGANDA.

WE noted some time ago that a prominent English antivaccinationist was in this country and at work endeavoring to spread the teachings of his baneful sect. We understand now that members of the Legislatures of various States are being quietly labored with so that when antivaccination measures shall be proposed in the near future they may not be without their strenuous advocates. We have reason to know the tireless energy and persistence of these people in many matters, and it behooves the medical profession not to be taken unawares.

The full purpose and the ultimate object of the recent antivaccination legislation in England was not fully comprehended until the law had already been enacted and conscientious objectors were multiplying

beyond all possible expectation. The vigorous protest of the British medical profession has come too late to be of any avail to check the progress of this movement. It will now require much greater effort to undo this wrong than would have been necessary to prevent it. The Jenner Society has begun some efforts at organized education of the public regarding vaccination, but it is meeting with great opposition, and especially with a thoroughly funded set of lecturers who are effectually carrying out the supposed "educational work" of the Antivaccination League, which has been aroused to renewed efforts.

In America it behooves the medical profession to organize thoroughly to prevent any dangerous legislation in the line of obstructing vaccination from being enacted. State and National societies, whose meetings are so frequent now, should see that their legislative committees are instructed to keep a vigilant eye on this special feature of legislation. Owing to ineffective vaccination laws and inefficient enforcement of those that exist, there is much more smallpox in this country than is justifiable in the light of the knowledge we have on this subject. Let us not be compelled to face the possibility, as our English friends are destined to, of practically a large part of an entire generation being permitted to go unvaccinated. To secure this, however, we must not permit antivaccinationists to gain the public ear because we despise their efforts, nor supinely allow them to get any, even the slightest, legislative aid for a purpose that can only be redeemed by precious lives in after years.

VIOLENT EXERCISE AND THE KIDNEYS.

WHETHER albuminuria is always pathognomonic of some lesion of the kidney is still an open question. Professor Senator of Berlin, the distinguished specialist in kidney diseases, advocates the existence of a physiologic albuminuria. This occurs directly after large quantities of some simple albuminoid food, as white of egg for example, has been taken or is noted after a heavy meal in which albuminous material has been plentifully consumed, followed by considerable physical exercise. But the learned professor so hedges about his diagnosis of a physiologic albuminuria with precautions against the possible existence of a pathologic albuminuria, as to make its significance of no great importance. The majority of the authorities on urinary diseases concede at once that albuminuria is always extremely suspicious, and practically always indicative of a kidney lesion.

It is interesting to note then the condition of the urine after violent exercise is taken, violent in this connection being a very relative term and meaning rather unusual. For one who is unused to it a spin on a bicycle somewhat more hurried and prolonged than usual may constitute violent exercise. It was first pointed out, we believe, by Senator that each unusual physical exertion was often followed, even in individuals who had no pathological condition of the kidneys, by albuminuria. In these cases the amount of albumin passed was easily discoverable by the ordinary tests. Then Chvostek in Vienna showed that severe physical exercise is not infrequently followed by traces of blood in the urine, and occasionally by the occurrence of small blood casts as well as albumin. These disappear after a few hours and do not seem to be pathognomonic of any lesion of the kidney.

At the recent meeting of the American Climatological Association here in New York Dr. Harold Williams of Boston in a paper on the effect of violent exercise upon the heart brought out incidentally some interesting facts regarding its effect upon the kidneys. In each one of some thirteen runners examined carefully after a twenty-five-mile cross-country race albumin was found in the urine; in about one-half of the cases hyalin and even small granular casts occurred, though the urine had upon examination before the race been found perfectly normal. These abnormal urinary constituents disappeared within forty-eight hours, and the effect upon neither the heart nor the kidneys proved serious or persistent.

Whether the repetition of conditions that bring about such changes in the urine will not eventually lead to permanent pathologic alterations of the secreting substance of the gland no one is prepared to say. It seems clear, however, that upon the already weakened kidney of a chronic nephritic condition the call made by the necessity for the excretion of unusual amounts of the products of muscular metabolism can hardly fail to work serious injury. The advisability of extreme caution in this matter of ex-

ercise in cases of kidney disease is evident. In our day it is so common for patients to take the inconsiderate advice of friends and even to adopt certain notions of their own with regard to exercise that it would seem well to place before every patient suffering from nephritis the danger of unusual or prolonged exertion.

This warning seems especially appropriate just at this season of the year when patients are about to take their vacations. In the idleness of summer, foolish over-exertion is apt to be indulged in, the more so as the advice to keep the skin active in order to relieve the kidneys of some of their work usually includes the prescribing of a certain amount of exercise. Such exercise, however, must be taken regularly, must begin very gently, and only become more prolonged by degrees and under the careful supervision of the physician so that it may be modified before it causes a deterioration of the secretion of urine. Even diseased kidneys may be trained to excrete considerable amounts of the products of muscular metabolism, but the burden of excretion must not be thrown on them suddenly and without preparation.

ECHOES AND NEWS.

Lawson Tait Dead.—It is reported from London that Dr. Lawson Tait died suddenly at his home, June 13th. Dr. Tait was in his fifty-fifth year.

Ophthalmia among Immigrants.—"Egyptian ophthalmia" is the most common of the diseases among immigrants landed at the port of New York. All who are found to be suffering from this disease are deported. In May 45,000 immigrants were landed, and of these 285 had granular conjunctivitis.

Yellow Fever at New Orleans Suppressed.—No cases of yellow fever have been reported from New Orleans since the one of May 30th. The Marine Hospital Service reports that the State of Texas has removed its quarantine against freight from New Orleans, which was promptly declared upon the announcement of the case of yellow fever occurring there May 30th.

Dr. Cleaveland's Case Reopened.—A second examination of Dr. Trumbull W. Cleaveland of 45 West Fiftieth street, who is charged with having caused the death of a child, Violet Carhart, on April 13, 1897, by prescribing improper medicine, has been begun in the West Fifty-fourth Street Police Court. Two indictments against Dr. Cleaveland have already been dismissed for lack of evidence.

The American Proctological Society. — This society was organized at Columbus, Ohio, on June 8th. Its purpose is to study the diseases of the lower intestine. Among its members are prominent specialists in the leading cities of the United States. Dr. Joseph M. Mathews of Louisville, Ky., the retiring President of the American Medical Association, was elected president, and Dr. James P. Tuttle of New York City, vice-president.

Increase in Death-rate.—According to statistics in relation to the death-rate, compiled by the New York City Health Board, there was an increase in the death-rate from diphtheria of one hundred per cent. for the week ending June 3d over the corresponding period of 1898. For the same week there was an increase in the total death-rate in the Boroughs of Manhattan and the Bronx of two per cent., and in Brooklyn for the same time 1½ per cent.

Appointments in the Marine Hospital Service.—Dunlop Moore of Pennsylvania and Halstead A. Stansfield of California were commissioned assistant-surgeons May 31, 1899. James C. Ballard of Mississippi was appointed acting assistant-surgeon, and stationed at Natchez, Miss., May 23, 1899. S. R. Thomas, H. W. Wickes, and H. S. Cumming have been commissioned passed assistant-surgeons; W. P. McIntosh has been commissioned surgeon.

Red-Cross Nurses.—The Red Cross Society for the Maintenance of Trained Nurses, which was organized as an auxiliary to the Red Cross Relief Committee, has issued an enlarged report of its operations, including the work done in the Philippines. On January 4th there was an unexpended balance of $19,874.12, which was used in sending twelve nurses to Manila. The Society was organized on May 18, 1898, and its work officially closed on March 1st of this year.

The Noble Red Man.—The statement that "a full-blooded Indian lunatic never lived" has been accredited to United States Commissioner William A. Jones, who has been inspecting the site recently purchased by the Government near Canton, Indian Territory, for an Indian insane asylum. Mr. Jones states: "The occupants of the hospital soon to be opened will all be mixed breeds. Probably there never was a case of insanity in any tribe until the malady was introduced by mixing with the whites."

A Stutterer Cured?—Private H. E. Redwood, who is now serving in the Philippines, was, when he enlisted, so affected with stuttering that the recruiting officer was tempted to leave him off the rolls. At the battle of Mariquina he was shot in the face, the bullet passing through his mouth. and making its exit near the back of the neck. He recovered from the wound, and it is stated that he now stutters no more, and that he is busy completing the telling of stories which he has never been able to finish on account of his halting speech.

Food Investigation.—The New York State Board of Health will conduct an investigation regarding the adulteration of food products. For this purpose $4000 has been appropriated. Dr. Willis G. Tucker, the State Chem-

ist, will analyze hundreds of samples of teas, coffees, flour, sugar, fruit syrups, baking powders, and other food products which will be collected during the next few weeks. Violations of the law prohibiting food adulterations will be reported to the District Attorney of the county in which the adulterated article is purchased.

Obituary.—Dr. Ezra R. Pulling died on June 5th at his home, 84 Washington Place, New York City. He was seventy-one years old. He was graduated from the College of Physicians and Surgeons in 1853; he served in the Civil War as a surgeon, was a member of the staff of the Lying-in Hospital, and was a member of the Physicians' Mutual Aid Association.—First Lieutenant William B. Westredge, Surgeon, United States Army, died at Manila on June 10th of typhoid fever. He was graduated from Rush Medical College, Chicago, in 1896.

Cancer Mortality.—The great increase in the mortality from cancer in Great Britain has led to the formation of a society to combat the disease, at whose initial meeting in London on June 7th it was pointed out that the number of deaths from cancer in New York City has doubled during the last ten years, and that it is calculated, if this increase is maintained, there will be more deaths from cancer in 1909 than from consumption, smallpox, and typhoid fever combined. In Great Britain during the past ten years the ratio per million has risen from 385 to 787.

Dr. Woodbury's Mission to Germany.—On June 8th it was reported from Washington that Dr. John McG. Woodbury of New York, lately Chief Division Surgeon of Volunteers, United States Army, and acting chief surgeon of the army in the field, and who is at this time Clinical Professor of Orthopedic Surgery in the Cornell University Medical Department, has been designated a Commissioner on behalf of the United States of America for the purpose of observing and reporting upon the medico-military organization of the German Army in active operation during the autumn maneuvers.

Sanitary Work in Havana.—Captain Weber, in dredging the upper end of the harbor of Havana, has cut a 200-foot channel, and a hundred-years' accumulation of old Spanish dumpage has been removed from the Santa Cataline branch of the harbor. This former yellow-fever breeder has been thoroughly cleansed, the shore scraped, and the deposit taken out to sea. Some 10,000 barrels of lime have been used. The army health report for the city of Havana is very gratifying. Less than two per cent. of the 2000 men are sick. This is a better average than is usual anywhere in the United States.

Cornell's Medical College Commencement.—The first commencement exercises of Cornell University Medical College were held in Chickering Hall, New York City, on June 7th. There were fifty-eight graduates. Ten of these were women, of whom two were among the ten "honor men." Gratitude was expressed toward Colonel Oliver H. Payne for his gift of $1,500,000 for a building, which will enable the college to become one of the best equipped institutions for medical instruction in the world. This building is now in course of construction at First avenue, Twenty-seventh and Twenty-eighth streets.

The Status of Electricity in Gynecology.—In the discussion before the Obstetric Section at Columbus recently the following opinions were expressed: Dr. Wathen of Louisville: "I think electricity has done untold harm. The treatment that we ought to develop for myomatous tumors of the uterus is that of myomectomy." Dr. Reamy of Cincinnati: "I call a halt to the denunciation of electricity in these conditions, and I protest against the dogmatism that denounces everything that is not surgery as unscientific." Dr. Marcy of Boston: "I am sorry to cross swords with my friend Reamy. In the observation of a large number of cases under the treatment of electricity I have not found a single patient whom I thought materially benefited."

Camp Crematories.—Latrines in military camps have always been both conspicuous nuisances and prolific sources of disease. Dr. G. W. Bissell of the Seventy-fourth Regiment, Buffalo, New York, has made a study of the conditions in the various camps last summer that produced the outbreaks of typhoid. Since then he has perfected a plan which he expects will obviate the dangers to health resulting from the use of latrines. During the practice marches which are to be made from the Peekskill camp of instruction in the week beginning June 12th, no sinks will be dug, but instead light portable furnaces, in which almost any substance can be cremated in a few seconds, will be employed. If successful this system will very likely revolutionize military camps.

Another International Congress.—An international congress for childhood will be held in Buda Pest, Hungary, during the latter part of September, 1899. It will continue through five days, and there will be five sections. The medical section will be presided over by Dr. Bokay Janos. The questions proposed for discussion are: (1) The hygiene of the infant in the family; (2) the care of foundlings, morally abandoned children, or paupers; (3) the care of sick infants and of those with bodily defects; (4) places for play and recreation; (5) school hygiene; (6) the hygiene of minor children employed in factories and other establishments, and (7) alcoholism. In addition there will be sections having no immediate connection with medicine—judicial, pedagogic, charitable, and philanthropic.

Dr. Kohler's Paper on Tuberculosis. — At the International Congress at Berlin for the prevention and cure of tuberculosis Dr. Köhler stated that in Germany phthisis pulmonalis is responsible for 2.25 and, including various other diseases of the respiratory tract, which he considers generally due to tuberculosis, for 4 9, out of a total mortality of 21.8 per 1000 annually. Of the various countries of Europe, England, Belgium, the Scandinavian countries and Italy, show the lowest, and Russia and Austria, the highest mortality from consumption. In England, the actual death-rate is only 1358 per million, as

against nearly 4000 in Russia. Of the fourteen largest civilized cities in the world London has the lowest mortality from consumption, with the exception of Naples and Buenos Ayres, the highest mortality being shown by Moscow, St. Petersburg, Vienna, and Buda Pest. Statistics fail to show that elevation above the sea-level has any effect on the spread of tuberculosis, but the percentage is higher in towns and industrial districts than in the country. Tuberculosis is more destructive to males than to females, and, compared with other diseases, is responsible for the largest number of the deaths that occur between the ages of twenty and thirty.

American Medical Association.—The officers for the ensuing year are as follows: President, Dr. W. W. Keen of Philadelphia; first vice-president, Dr. Charles A. Wheaton of Minneapolis; second vice-president, Dr. E. D. Ferguson of Troy, N. Y.; third vice-president, Dr. J. M. Allen of Liberty, Mo.; fourth vice-president, Dr. W. D. Middleton of Davenport, Iowa; treasurer, Dr. Henry Newman of Chicago; secretary, Dr. George A. Simmons, editor *Journal of the American Medical Association*, Chicago; librarian, Dr. George W. Webster of Chicago; chairman of committee of arrangements, Dr. Philip Marvell of Atlantic City; trustees of the *Journal of the American Medical Association*, Dr. E. E. Montgomery of Philadelphia; Dr. H. L. E. Johnson of Washington, D. C.; Dr. C. A. L. Reed of Cincinnati. Judicial council: Dr. J. W. Griffith of Kansas City; Dr. J. E. Cook of Cleveland; Dr. J. H. Baillache of Washington, D. C.; Dr. J. B. Lewis of Topeka, Kan.; Dr. F. H. Wiggin of New York City. Address on general medicine at the next meeting of the Association, Dr. J. A. Witherspoon of Nashville, Tenn.; on surgery, Dr. W. L. Rodman of Philadelphia; on State medicine, Dr. Victor C. Vaughan of Ann Arbor. The place of meeting next year will be Atlantic City, N. J.

CORRESPONDENCE.

THE MEDICAL STUDENT ABROAD.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—For years it has been more or less a practice among American medical men of means and ambition to pursue, after the usual medical education of this country, a period of post-graduate work in some of the medical centers of Europe. That there has been in the past even greater advantage in such a practice in broadening and impressing professional attainments there can be no doubt; but even at the present day, although American schools and American methods are well in the van of progress, much may be gained by even the best educated American physician through a careful comparative study of foreign work, foreign medical ways and manners of doing, and foreign ideas. If for no other reason the writer would wish that every American physician might go abroad to learn how really well American medicine and American institutions compare with the best abroad.

In many particulars America is distinctly in the lead; yet there are unquestionable advantages offered by this or that foreign center. Even were the advantages not as great the broadening of our field of vision by comparison of ideals among teachers, methods, and schools, will amply repay considerable time and sacrifice by its effects upon future estimates of such men and matters. Then, too, the general mental broadening and culture to be had by travel, by association with other types, constitute a most valuable addition to any man's education.

While the absolute necessity for it no longer obtains as it once did, there is sufficient general and special advantage in the tendency of our profession to thus flock to the older centers of medical and general education; and it is probable that for years to come there will be the usual number of Americans annually moving on the docents and agregé of Germany and France.

When should one go to Europe to obtain the best possible results? Of course one may obtain some advantage at any time; but unquestionably the more fixed the principles the more may time be devoted to the niceties and details, so readily acquired in such places as Paris, London, Vienna, and Berlin.

Surely such a professional pilgrimage had best be postponed after graduation until at least a full year's internship in a good hospital or several years' work in general dispensary and private practice has been experienced. These will have fixed one's basic data and will have brought forward one's deficiencies clearly, thus permitting a reasonable selection of the special character and amount of work required or desirable in European institutions.

One goes to Germany, Austria, France, or England, or to all if the time permits. If in the spring, one had perhaps best go to Germany for it is possible to find some place to work during all the summer in some of the smaller University towns, or even in Berlin for that matter.

If time be valuable it is well to push on to Vienna by the middle of September. One need not have letters in Vienna; but go to the General Hospital and watch for men who do not raise their hats in saluting; address them in English, for they are Americans (or Englishmen), and they will give all the information required about work desired. I believe that we Americans are greatly over-rating Germany and Austria, and that we are losing sight of Paris as a great medical center. We attach too much importance to the mathematical results of the Germans, results which are unfortunately often as fallacious as statistics. We fail to recall that France has produced more master minds in medical science than any other nation, and that the flocking of medical students from all over the world to Paris would indicate that in other countries at least Paris is regarded as the equal of Germany. Then, too, work in the hospitals in Paris is more useful to us, because the French, like the Anglo-Saxon, regard therapeutics as of very great importance, and the sentiment and desires of the patient count for something. When we come home to practise we want results, and neither we nor our patients can be satisfied by simply proving a scientific theory, with no consideration for the

future condition of the client. Another great advantage in favor of Paris is that one learns the language; a very valuable acquisition. In German countries many Americans never get beyond the essential dialogue with the "kellner," because the German teacher, who lives chiefly by American dollars, always knows enough English to satisfy his client; and the habit of monopolizing courses by small American syndicates makes it essential that the American student hold his American friends. Therefore, they speak English too frequently and German too little to learn the latter. I have known many American students to live in German countries for a year on a vocabulary of 100 words.

In Paris one does not need American friends; in fact is better off without them. Letters should have been obtained to Parisian doctors, and if ever needed, their help may be readily obtained; and the medical visitor will not find the hands of professors extended for guldens and marks. Any one may hear the greatest professors in Paris as easily as can the Matriculate of the University of Paris. Arrived in Paris it is best to go to a hotel in the Latin Quarter, a most convenient and congenial place in which to live. It will be well to get a "Guide Médical à Paris" from one of the medical book-stores in which the quarter abounds; after which it is the proper thing to take one's diploma to the secretary's office in the Faculté and ask for a student's card. This will give admission to any lecture, clinic, or demonstration given under the auspices of the Faculté. The card will not be asked for often (maybe never), but it is better to be armed for a possible demand. On Boulevard St. Germain No. 166, there is an excellent reading-room (Salle de Lecture of *La Médicine Moderne*), where all the principal medical journals of all countries may be had from 9 A.M. to 11 P.M.; and to which a permanent card of admission may be obtained on presentation of visiting or student's card. The library of the Faculté is open afternoons and evenings to every one.

If one does not know French on going to Paris it is best not to be too dignified. Students profit more by accepting the freedom accorded them in Paris; meals should be taken in some small restaurant and one should talk to his table companions. They are always agreeable and often quite useful, and one will find that in a few weeks he is speaking the language well enough to be understood, and understanding French quite well. Working in some special line one will naturally select places of study where such specialties are given prominence. One may obtain a desk in the Pathological Laboratory of the College de France on application and without cost except for materials used, where a microscope may be kept and opportunities afforded for any pathological or bacteriological work. This is a decided advantage for any one desiring to carry on laboratory work in connection with his clinical observation. A small fee to nurses and porters will obtain any material desired from clinics and post-mortem examinations. It is true that one has not the same facilities for work in pathological anatomy as in Vienna or some German towns, but the present attitude of Professor Brouardel, dean of the Faculté, will undoubtedly work an efficient change in that direction in the near future, his plan being to establish a pathological laboratory in every hospital in Paris. At present the laboratories in the Hôpital Necker, Hôtel Dieu, Salpétrière, Charité, Pitié, and St. Louis are well equipped, and privilege and admission to work may be obtained on proper introduction. The great demand on the Institute Pasteur makes it difficult to obtain a place in that institution, unless application is made at least a year beforehand; however, a strong letter to one of the directors will seldom fail to procure a place for an American. There is certainly no better course in bacteriological technic given in the world, and it goes over the whole field of theoretical, practical, and experimental bacteriology. It is conducted by the great masters Roux and Metchnikoff, and other specialists in selected subjects.

If one has not been able to obtain a place for work, the demonstrations and lectures may be seen and heard daily without any formalities whatever.

For one desiring experience in genito-urinary work a place with assignment to a table where treatment is executed under the direction of the Chief of Clinic may be easily obtained in Professor Guyon's out-clinic, where one may become familiar with the methods and practices of this great specialist at first hand.

The Salpétrière with its specialists for every branch of the science of neurology certainly cannot be excelled anywhere. In Charcot's clinic, conducted by Professor Raymond, the classical instruction instituted by the great master is still given in the same interesting manner. Here too one may follow the courses of Déjerine and the brilliant young psychologist, P. Janet, who conducts a clinical course in supplement to his classic lectures given at the College de France. Besides these there are a number of neurologists here and in other institutions who have made special and valuable study in various lines.

The St. Louis clinic and wards give one a superabundance of any variety of skin diseases, and the museum and library contain the finest collection of models and literature pertaining to this subject in the world.

In eye work students may obtain positions as assistants and places in the Pathological Laboratory under the celebrated oculist, Panas, in the Hôtel Dieu.

In the Hôpital des Enfants Malade one may find an enormous wealth of material in all children's diseases, including infectious diseases, with special instruction in intubation and laryngotomy.

Work in medicine, surgery, and gynecology is abundant and found in all the hospitals. The guide and bulletin of *La Médicine Moderne* give the exact hours of the lectures and the names of the lecturers in all the hospitals and institutions. Other places of equal and perhaps superior advantage may be obtained in some of the many institutions. I have simply named these as the first in my mind.

In Paris one has simply to follow the accepted methods on entering the courses; it costs nothing, but he cannot have the manner of instruction changed to suit his American ideas as he may in some of the German places. One must go along with the Frenchman in his ways, and if

one adapts himself to these easily he will obtain the best results.

WILLIAM GAMMON, M.D.

GALVESTON, TEXAS,
June 9, 1899.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

THE QUESTION OF THE REMOVAL OF THE MUNICIPAL HOSPITAL—JENNER'S STAIN FOR BLOOD—FILTERS FOR THE PUBLIC SCHOOLS—LUCIEN MOSS HOME FOR INCURABLES — PREVALENCE OF CEREBROSPINAL MENINGITIS AND ENTERIC FEVER—CHANGES IN THE MEDICAL FACULTY OF THE UNIVERSITY OF PENNSYLVANIA—DR. S. WEIR MITCHELL.

PHILADELPHIA, June 12, 1899.

WHILE every one agrees that the Municipal Hospital for Contagious Diseases should be speedily removed from its present location in a built-up residence section of the city, the question of its actual removal excites such apprehension in the minds of the citizens in whose neighborhood it is proposed to build the new institution, that the problem seems no nearer solution than it has been at any time during the past two years, when the change was first seriously contemplated. This week a committee of citizens from the northwestern section of the city, where the Municipal Hospital is situated, was organized to urge its speedy removal from their neighborhood, but other committees are springing up with equal alacrity, to protest against its being situated in their part of town. Nobody wants the pest-house near them, and arguments and counter-arguments are launched with such rapidity by various interested citizens, that the authorities are bewildered, and hesitate to act. Meanwhile, the hospital continues its work of caring for the infectious and contagious diseases of the municipality as best it can, cramped as to space, ill-equipped in many ways, and altogether handicapped for the important work it was designed to perform. The only way to settle the question seems to be for the city to make up its mind to immediately purchase land in an isolated section of the city, unlikely to ever be used as a residence part of town, and to there erect a large and modernly equipped hospital for the reception and care of contagious cases.

Although announced in the *Lancet* some four or five months ago, by its author, but little attention seems to have been paid to the question of blood-staining by Jenner's method. The simplicity of the stain for clinical purposes, its wide range of application in hematology, and the dispensing with heat for fixing the blood-films, so important for rapid clinical work, should fully atone for the difficulties of its preparation. For the past two months Jenner's stain has been used in the medical clinic of the Jefferson Hospital, and in the laboratories of the German Hospital, for differential counting, with uniformly satisfactory results. The stain should be made as follows: *Solution A.* Eosin (water soluble) 1.2 to 1.25 grm., distilled water 100 c.c. *Solution B.* Methylene blue (zinc free) 1 grm., distilled water 100 c.c. *Solution C.* Solution A., solution B. equal parts. Stir thoroughly with a glass rod, and set aside for 24 hours. Filter, and dry the residue in an incubator. Scrape the residue off the filter-paper, and wash on the filter, after shaking up with distilled water. (The washing should be of a thin, dirty, purplish color.) Dry powder, and preserve in suitable bottles.

Solution D. (To be used for staining.) Powder from Solution C., .5 grm., methyl alcohol (pure), 100 cc. Mix and filter. To stain spread the blood-films in the usual way; dry in air, without thermic or chemical fixation; cover the film with the stain for from one to three minutes; wash in distilled water until the cover-glass is a faint pink color; and dry, mount in xylol balsam. The erythrocytes are colored terra cotta; nuclei of the leucocytes, blue; neutrophilic granules, red; basophilic granules, dark violet; blood-plaques, mauve; and all bacteria, malarial organisms, and the embryo of the filaria sanguinis hominis, blue.

Provision having been made by the City Councils to expend a sum of $37,000 for placing a system of filters in the public schools, the authorities are now engaged in considering the proposals which have been submitted to them for installing the apparatus. The provisions of the ordinance for the adoption of the new filters stipulate that they shall have the approval of the Board of Health, must be capable of removing ninety-five per cent. of bacteria from the water, and shall be subject to a rigorous practical test before acceptance. It is proposed to equip every school-house in the city with a complete set of apparatus before the opening of the next term in September.

Ground will soon be broken for the erection of the new building of the Lucien Moss Home for Incurables, a branch of the Jewish Hospital. The new building will be of fire-proof construction, four stories high, and built after plans secured in Berlin, of a famous German sanatorium. The institution will be ready for the reception of patients in the fall.

Inasmuch as the weekly statistics of the City Health Department, through the peculiar orders of the Director of Public Safety, are no longer available to the public, information concerning the prevalence of infectious diseases must be derived from the figures published monthly by the State Health Board. Last month's report from this body would seem to indicate that cerebrospinal meningitis prevails to a dangerous degree in this vicinity, there being 22 cases existing in this city at the time the report was made public, with a total of 14 deaths during the preceding four weeks. Enteric-fever cases numbered 412 for the month; of which 58 were fatal. Judging from the large number of yellow signs required by law on infected houses, one sees throughout the city, and from the recent decrease in the population of the public schools, scarlet fever and other infectious diseases are also numerous. According to unofficial newspaper reports, during the week ending June 10th, there were reported 95 new cases of enteric fever, with 21 deaths; 85 cases of diphtheria, with 12 deaths, and 21 cases of smallpox, without fatality.

As forecasted two weeks ago, the changes in the medical faculty of the University of Pennsylvania in consequence of the death of Dr. William Pepper, were officially declared by

the trustees during the present week. Dr. James Tyson has been elected professor of practice of medicine; Drs. John H. Musser and Alfred Stengel, professors of clinical medicine, and Dr. Gwilym G. Davis, assistant professor of applied anatomy.

Dr. S. Weir Mitchell, who has been absent in Europe for several months past, arrived in this city this week, and will immediately leave again for his summer home on the New England coast.

OUR LONDON LETTER.

[From Our Special Correspondent.]

CONGRESS ON TUBERCULOSIS — CONSULTATIONS BY WHOLESALE — AMBULANCE ACCIDENT EXTRAORDINARY — "DEATH FROM TIGHT BOOTS" — REDUCED DEATH-RATE IN INDIAN ARMY — CANARIES AND TUBERCLE — PSEUDO-TUBERCULOSIS — FAILURE OF THE INEBRIATES ACT.

LONDON, June 5, 1899.

THE principal medical interest of last week centered in the great Congress for the Prevention of Tuberculosis, which occurred in Berlin, opened by the German Secretary of State and attended by the Empress in person. Next to the Peace Congress it was the chief point of interest of the day in all circles, lay as well as professional. Much gratification and surprise, even in the profession, is expressed at the unexpectedly high standing of England in the geographical distribution of tuberculosis as set forth in Dr. Köhler's opening paper. Her death-rate is the lowest in Europe, and that of London the smallest of the fourteen largest cities in the civilized world, with the exception of Naples and Buenos Ayres, neither of which would really seem to have any right in the same class with her. This seems an emphatic refutation of the popular impression that tuberculosis is a disease of civilization, and as such, one of its necessary accompaniments. The real condition of importance is the type of the civilization and the *higher this is the lower will be the death-rate.* It is no mere coincidence that clean, sanitary England, densely populated as she is, heads the list, while filthy, undrained, unventilated, unwashed Russia, with her population scattered through a thousand reeking villages stands at the foot with nearly four times the death-rate.

There seems to be one city in England that can keep its hospital fund up to a successful level, and that is Birmingham. The results of her Hospital Saturday collections last year reached the handsome total of $88,000. But all success has its undesirable side and there are murmurs, not loud but deep, especially from the profession, that this victory has been won at the expense of an extensive "hospitalization" of the well-to-do working classes, who are being led to regard the hospitals as a sort of sick club, to whose advantages they may acquire a right by a subscription of a few shillings per annum. And flushed by its success the Fund Committee is proposing a new and hitherto unprecedented departure which has already brought a storm about its ears. This is nothing less than a sort of wholesale consultation company, by which it is proposed to bring expert medical opinions within the reach of the masses. The plan proposed is to hire two medical experts, a physician and a surgeon, at a proposed salary of $2500 a year each, furnish them with a joint office, and advertise "consultations at all hours" for the modest sum of half a guinea ($2.50) each. This astonishing scheme is calmly announced as "likely to yield a handsome profit," but if not, the still more astonishing committee that hatched it proposes to make good two-thirds of the deficit from the hospital fund!! Comment is superfluous. Not content with robbing the struggling young practitioner of his artisan practice, they would deprive him of the fruits of his hard-earned reputation for special skill in the shape of consultation fees. It is to be hoped that the scheme will fail of realization, if from no other cause, by inability to find men of any reputation and competence so lost to the sense of the dignity of their profession as to accept a position as hired consultant.

Much as the discovery of Koch's bacillus may have done for consumption it has certainly added a new hardship to the lot of the consumptive. From South Africa comes the news already familiar to us in California that employers of labor are refusing to engage consumptive applicants on the ground of danger to their customers or goods. Boarding-houses and hotels are objecting to receive them as inmates, and passengers are refusing to take state-rooms on board ships which are believed to have been occupied by tuberculous patients traveling in search of health. At this rate these poor unfortunates will soon become absolute pariahs and made to feel that their terrible disease is as much of a disgrace as of a misfortune.

Another painful illustration has just occurred of the singular tendency of officialdom, unchecked, to callousness, not to say brutality. A patient seriously ill with bronchitis and heart-mischief was ordered taken by ambulance to the hospital. The vehicle came in charge of an ignorant boy, with no assistant, and the poor patient was let fall upon the stairs in the effort to get him into it. Then it drove off at such a speed that in spite of the frenzied remonstrances of the victim's wife, who accompanied him, an attack of heart-failure was brought on by the jolting and the patient was dead when the hospital was reached. And the coroner's jury merely said that the ambulance-service was "*unsatisfactory*" and advised the supervisors to be more careful in future to send competent drivers.

The General Medical Council, the official High Court of the English profession, meets this week and as this is its first full session since the disgraceful Hunter case some stirring scenes are anticipated. The Penal Committee seems likely to be severely criticized, if not formally censured for its dishonorable zeal. Action will also probably be taken on the relation of the profession to friendly societies and sick clubs, for since the latter organizations, at their recent meeting, rejected the olive-branch held out to them by the profession, by absolutely refusing to fit any wage- or income-limit to their membership, it seems as if aggressive combination is the only hope of the doctor.

Truly the headline is a wonderful agent of science. The papers recently have had much to say under the gruesome heading, "*Death from Tight Boots*," which on inspection is found to be anent a man at Bradford, who was taken into a hospital for a varicocele operation. The operation was well borne and recovery rapidly progressing when his temperature suddenly rose, spasms followed, and death by tetanus closed the scene. Upon examination the operation-wound was found soundly and securely healed and no other lesion was found until after a careful search a small, partially healed ulcer on the dorsum of one of his toes was discovered. This, which had resulted from a tight boot, was believed to be the point of entrance of the tetanus infection. Cultures, however, from both this and the operation-wound yielded only negative results. The man was in perfect health, indeed was seeking operative relief from his varicocele to qualify himself for enrolment in the police force, to which this was the only hindrance.

Quite a hopeful and reassuring contribution to the tropical colonization problems of both Anglo-Saxon races has just been made by a report of the War Office here. In this the death-rate of the English Army of Occupation in India since 1840 is given and a most gratifying decline shown. Previous to 1857 the average rate was 60 per 1000 living per annum, simply murderous for vigorous male adults; in 1896 it had fallen to 14.8 per 1000, or less than one-fourth of the previous figure. This is about equal to the general mortality of a healthy country district, and only some 4 or 5 per 1000 above the ordinnary garrison rate at home.

A rather sensational article upon canaries as a source of tuberculous infection by Dr. Tucker Wise appears in the *Lancet*. Some thirty cases of such transference are described, but as the principal proof of connection in nearly all of them is merely the statement that birds were kept in the house its conclusiveness obviously leaves something to be desired, especially as he closes with the statement that experts estimate that 400,000 canaries are kept in England alone.

From New South Wales comes a cordial appreciation and corroboration of the work done by the pathological staff of our Department of Agriculture upon the nature and treatment of Texas fever. Indeed the new name of "Tick fever" is proposed for it in allusion to its means of spread, first discovered by our Washington investigators.

An important note has just been issued by the London Pathological Society upon the nomenclature of pseudo-tuberculosis. In accordance with the report of a special committee they recommend that in future the term "tubercle, ' as applied to anatomical lesions, be dropped and the term "nodule" substituted, reserving the term "tubercle" and "tuberculosis" solely in their clinical sense as designating the conditions resulting from infection by Koch's bacillus. By this change "tubercular" and "pseudo-tubercular" lesions of all sorts will simply be known as "tuberculous nodules," "glanders nodules," "aspergillus nodules," as the cause may vary. As there are no less than fifteen different forms of "pseudo-tuberculosis," and even four of five "pseudo-tubercle bacilli" this change would avoid much confusion.

A most suggestive study has just been made by Professor James Ritchie upon the relation between the activity of germicides and their molecular composition. He finds a curiously constant relation between the germicidal activity of elements and their atomic weights, the lighter, such as sodium and calcium, being almost inert, while the heavier, such as mercury and bromin, are extremely active. The same rule extends to their salts and to the salts of the organic acids which vary according to their molecular weights. Acids vary according to their chemical "avidity" or "displacing power." The increasing activity of the heavier elements is most significant when it is remembered that nearly all known elements can be arranged in a curious progression-series according to their atomic weights, which would again run parallel with their boiling-points and other characteristics.

Hull has just been suffering from an incipient smallpox epidemic brought there by passengers of the steamship "Port Darwin" from Alexandria. Thirty-seven cases in all occurred before the outbreak could be surrounded and stamped out by the health authorities. Only four patients died, three of whom were unvaccinated, and the only proof of vaccination in the fourth was a dim and not at all characteristic scar.

An unexpected danger threatens the London School of Tropical Medicine. It has been discovered by the energetic member that it is within hacking distance of his little hatchet. Last week in Parliament one of him solemnly rose and proposed that the School ought to undertake, at once, a study and explanation of the nature of arrow-poisons! The suggestion was taken under advisement and a week or so later the Colonial Secretary replied in the House, that inasmuch as only *one* case of such poisoning had been brought to his notice in the past five years, he thought there were other problems which might be regarded as more immediately pressing.

It looks seriously as if the Habitual Inebriates Act of last year, providing for their permanent detention in reformatory institutions after a certain number of convictions, were going to prove a failure. The sole cause is the unwillingness of county authorities to contribute the funds for their maintenance in such establishments. The magistrates are willing to sentence and various philanthropic organizations have supplied buildings in which they can be cared for, but the penuriousness of the county councils seems likely to block the reform, which was such a welcome concession to our professional view of drunkenness.

DIFFICULTIES IN SWALLOWING AND THEIR AVOIDANCE — INJECTIONS OF GELATIN IN ANEURISM AND FOR HEMOPTYSIS—TUBERCULOSIS OF THE THORACIC DUCT AS A SOURCE OF MILIARY TUBERCULOSIS—LUPUS OF THE NOSE AND ITS TREATMENT BY HOT-AIR CAUTERIZATION — HEMORRHOIDS A GENERAL DISEASE—THE SPREAD OF ANCHYLOSTOMA DUODENALE.

AT the Union for Internal Medicine, April 24, 1899,

MENDELSOHN and GUTZMANN spoke of swallowing in the different positions of the body and its significance. Difficult swallowing may affect the prognosis in sickness by limiting the amount of nourishment received, by causing pneumonia, or even death in children, from inhalation of fluids into the bronchi, and by the increased blood-pressure caused by the coughing to expel foreign material. This may cause heart failure in cases of cardiac weakness, and aneurism or hemoptysis in pulmonary disease. Experiments showed that a normal soft palate and epiglottis can completely close the upper and lower air passages during swallowing, even though the act be performed when the patient is lying down or even standing on his head. The trouble experienced in swallowing in a horizontal position is not due to imperfect closure, therefore, but in part to attempts to breathe at the same time (and this may be avoided by forethought) and in part to the fact that the posterior part of the throat is far more sensitive than the sides and anterior portion, and hence reflex action is much more likely to follow if a person tries to swallow when lying on his back. The practical conclusion is that bedridden patients should swallow lying on the side, rather than in dorsal decubitus, even though the head be slightly raised.

FRAENKEL showed a patient with aneurism of the aorta whom he had treated by injections of a one-per-cent. solution of gelatin in normal salt solution. The injections were at first very painful, but the patient afterward became accustomed to them, and they were given twice a week. A two-per-cent. solution excited far greater pain. The results of treatment were gratifying. By the X-ray it was seen that there were two large sacs of the aorta, one of which had eaten away a spot in the sternum as large as a quarter of a dollar. After some weeks' treatment one of the sacs had disappeared entirely, the sternum no longer bulged forward, and pulsation was much less. During the whole time the patient remained in bed, but received no medicine.

KLEMPERER said that he had tried the method with two patients, but that one gave up the injections on account of pain. The second patient kept on until eight injections had been made, but the result was doubtful.

BURCHARDT had tried the injections in a number of patients for hemoptysis. None of them has as yet died, but he did not feel justified in saying that the injections had had any favorable influence upon them.

At the Berlin Medical Society, April 26th, BENDA showed two preparations of tuberculosis of the thoracic duct, as illustrations of his theory that tuberculosis of the thoracic duct is the source of miliary tuberculosis. As the tubercles in the duct in both cases were very abundant, and in various stages of development and decay, there seemed no doubt that they contained a sufficient amount of infective material to account for the miliary tubercles. The orgin of the thoracic tuberculosis was in one instance retroperitoneal lymph-glands, and in the other retroperitoneal, mesenteric, or mediastinal glands, all of these being affected with tuberculosis; but in neither case was there a direct spread of tuberculosis from an adherent gland into the thoracic duct.

HOLLAENDER denied that lupus of the nose leads to destruction of the organ. If left to itself it goes on to form tubercular spongy granulations, which, however, show no tendency to fall to pieces. Lupus of the skin rarely spreads to a mucous membrane, so that nasal lupus is almost invariably a primary affection. If the diseased area is small, excision is the best treatment. If it is more extensive it may be treated by Finsen's method or by that of Röntgen, or, as he preferred, by the application of hot air, a stream of air at 300° to 400° C. (572° to 752° F.) being directed upon the lesions. As a result the diseased tissue, with its contained bacilli, becomes necrotic and is cast off. A number of patients were shown who had been cured of extensive areas of lupus by this method.

LASSAR said that he had become very dissatisfied with the excision of lupus of the nose. Unfortunately, patients were not seen until the disease was well started, and when repeated operations had removed the whole nose and a new one had been built up, it too generally became affected by the lupus. The hot-air treatment he had used upon thirty patients during the past year, and he thought the possibility it affords of burning away the diseased tissues, while not disturbing the healthy ones, is a great therapeutic gain. The degree of cauterization which succeeds best must be learned by each operator. In the beginning he was inclined to go too fast. As a result deep ulcers were formed which took weeks to heal. The principle of heat can also be used in the thermocautery by passing the point close to the mucous membrane without touching it. The hot air is so painful that narcosis is necessary.

At the Vienna Medical Club, April 26th, FEDERN spoke of hemorrhoids and the predisposition to them. The ancient idea of hemorrhoids as a general disease to be treated by constitutional measures has given place to the idea that they are a local trouble to be cured surgically, and the good results which follow operations support this view. In the opinion of Federn these good results are rather to be attributed to the changed mode of life which follows such operations than to the operations themselves. The high tension in the blood-vessels is the real cause of the trouble. This produces congestion in the veins, and the well-known symptoms follow. Certain persons, either by heredity or otherwise, exhibit a predisposition to hemorrhoids, but without the high-blood pressure they would not develop them.

At the Imperio-Royal Society of Physicians of Vienna, May 5th, GOLDMANN related his experiences with anchylostoma duodenale. This parasite was originally confined to Brazil, India, Borneo, and Egypt, but at the time the St. Gothard tunnel was dug it was found to be the cause of the "tunnel sickness," and since that time it has been spread by the wandering of the mountaineers to almost all the mountainous districts of Europe. The symptoms of the disease were also spoken of. The prognosis is in general good, but is worse the farther north the patient lives. Extract of felix mas has been found to work admirably in expelling the worms, especially if given in divided doses, preceded by calomel, and followed

by calomel and turpentine. There are undoubted spontaneous cures, but on the other hand the parasite has been known to live for six years, and in cases of so-called spontaneous cures the eggs can usually be demonstrated in the stools of the patient.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fiftieth Annual Meeting, Held at Columbus, Ohio, June 6-9, 1899.

(Continued from page 752.)

GENERAL SESSION.

THIRD DAY—JUNE 8TH.

PROMPTLY at 11 A.M. the President called the meeting to order, and, as had been resolved the day before, announced the first business to be the reading of the report of the Board of Trustees, which had not been presented at the preceding general session because of the scanty attendance at the end of the session owing to the heat. Certain important business contained in it made it advisable that as many members of the Association as possible should hear and take action on it.

The minutes of the Association having been kept in the past irregularly, that is, without the order and signatures necessary to make them the valid minutes of the Association in a legal sense, and the fact that the secretary resided in one city while the *Journal* of the Association was published in another and distant city having led to delays in the publication of the official accounts of the proceedings of the Association, as, for example, those of the Denver meeting last year, the Board of Trustees, to whom a motion increasing the secretary's salary had caused the reference of the whole matter, thought it better to recommend to the Association the election of the editor of the *Journal* as official secretary, making him responsible for all the business connected with the office. The present secretary arose on a question of privilege, and explained that the minutes had been kept in accordance with the custom of his office, and the delay referred to last year had been caused by the dilatoriness of the chairman of a committee in sending in his official report. DR. HAPPEL for the trustees explained that there was no personal animus in the matter, and the only idea of the trustees was to establish a secretaryship that would at once facilitate the business of the Association and of its *Journal*, and at the same time make it responsible.

On motion the recommendation of the Board of Trustees that the editor of the *Journal* of the Association become the secretary of the Association without increase of salary was adopted.

The recommendation that a committee be appointed to codify the constitution and by-laws, and have them printed before the next meeting of the Association, was adopted.

The recommendation that a legislative committee be appointed composed of one member each from Washington, Baltimore, and Philadelphia, their expenses not to exceed $250, to be paid out of the funds of the Association on vouchers from the local member of the Board of Trustees for the district was adopted.

On motion of DR. HAPPEL of the Board of Trustees the retiring secretary, DR. W. B. ATKINSON of Philadelphia was placed in charge of the bureau of registration at the annual meetings of the Association. He shall be in attendance twenty-four hours before the opening of the annual meeting, and shall receive $100 in addition to his expenses for this work.

The Committee of Public Health reported that the outlook for the passage during the next year of a bill creating a Government department of Public Health, with a cabinet minister at its head, was excellent. They asked for the moral support of the members of the Association and their influence with their Congressmen and Senators. They also asked that $500 be appropriated to pay the expenses of a committee to properly urge the matter at Washington when the bill shall come up for consideration at the next session of Congress.

The Executive Committee reported as to the suggestions made by the president of the Association in his annual address.

First, as to the selection of a permanent meeting-place for the Association, Washington being suggested as the most likely place for the meeting; in the negative. The negative report was received with applause.

Second, that no clinics or entertainments shall be held at annual meetings that shall conflict with the regular business of the Association or its sections; reported favorably. On motion, the Association decided unanimously that such clinics or entertainments shall not be held in future.

Third, as to employing paid agents to solicit members for the Association; report unfavorable, as such means would be liable to secure an undesirable class of members.

Fourth, as to Government and State aid for the repression of tuberculosis; report favorable. On motion, the suggestion that a committee of five be appointed to draft a pamphlet setting forth the situation, to be sent to the President of the United States, to Congress, and the Governors and Legislatures of the various States was adopted.

Fifth, with regard to the repression of syphilis, the suggestion that the measures adopted by the congress on this subject to meet at Brussels next fall be carefully weighed by the American Medical Association, and the proceedings carefully followed by a special committee was accepted.

Sixth, with regard to vaccination it was decided to send to the various health boards of the country a pamphlet setting forth that it was the sense of the American Medical Association that compulsory vaccination was the safeguard of the country against smallpox, and as such must be fostered and enforced.

The special committee appointed to consider at the suggestion of a delegation from Philadelphia the question of the optician as a practitioner of medicine, reported that the proper fitting of glasses requires a knowledge of ocular pathology and therapy, and so must not be left to a mechanic, and that the American Medical Association

encourage by every means in its power the repression of the abuses that have crept in in this matter.

The report of the nominating committee was then adopted, electing the officers as given elsewhere in this issue.

A resolution was then offered deprecating the "leakiness" which this year had culminated in complete committeerial incontinence of the proceedings of the nominating committee before they had been presented to the Association, and making absolute secrecy obligatory on the members of the committee. On motion of DR. LOVE of St. Louis, who pleaded that the publication and discussion of the report before its presentation at the general session gave a favorable opportunity for the correction of errors, etc., the previous motion as to secrecy was laid on the table.

DR. J. C. WILSON of Philadelphia then delivered the address on Medicine[1]. Surgeon-General Sternberg then exhibited a series of stereopticon views illustrating the hospital-ships, hospitals, etc., of the Spanish-American War and since then, in this country, Cuba, Puerto Rico, and the Philippines.

Very striking views of the wards, the operating-rooms, and the arrangements of the various hospital-ships were shown and the fact demonstrated that the new problem of making a steam floating-hospital, with all the essential features of a modern hospital had been solved very effectually by the Medical Department. Transports were shown, the differences noted, and the fact that for these the Army Medical Department was not responsible but the Quartermaster's Department was brought out.

The present hospital at Camp Columbia, near Havana, at Ponce in Puerto Rico, and at Manila were shown, and it was made clear that the best possible arrangements, as far as climate and circumstances will allow, for the care of sick and wounded are in operation. The views of the convalescent hospital on Corregidor Island show an inviting place for patients to get well in, and illustrate the judicious care and solicitude that is directing present military medical affairs. All of these hospitals contain laboratories for the study of tropical diseases, so some progressive scientific work may be expected to issue from them as soon as conditions have become somewhat more favorable for study.

With regard to the employment of female nurses in the Army Medical Department General Sternberg took the occasion to remove a misunderstanding that seems to exist in many minds as to his position with regard to women nurses. He does not believe that they should accompany the column on the march when they are apt to be of hindrance rather than service, but just as soon as hospitals are established he believes that no better or more efficient aid could be found. Women nurses have done excellent work during the war. They were used in the first field-hospitals established and it is clear that they will be of service always if employed in hospital work.

SECTION ON PRACTICE OF MEDICINE.

SECOND DAY—JUNE 7TH.

The proceedings were opened by DR. ARTHUR ELLIOTT of Chicago who read a paper, entitled

TREATMENT OF THE HEART IN CHRONIC INTERSTITIAL NEPHRITIS.

The conditions met with are thickened and inelastic arteries subjected to the strain of a heightened tension, and a hypertrophied and sensitive heart-muscle. The patient is exposed to the risk of rupture of the vessels, and also to failure of the heart. Both the increased tension and the cardiac enlargement are compensatory, and any effort to qualify either may prove mischievous. There should be no intervention so long as there are no definite subjective symptoms. An increase of tension in the arterial system beyond the bounds of safety becomes manifest in dizziness, ringing in the ears, headache, disturbed cardiac action, fulness of vessels, occasional epistaxis, or it may be temporary emblyopia. A flagging heart shows in the soft, irregular, and frequent pulse. Dyspnea, post-sternal weight, and discomfort, cough on exertion, and diminished urine are additional signs.

All the small details and habits of the patient's life should be regulated, including the diet, clothing, exercise, and baths. The patient must be cautioned against heavy meals, and the regularity of the bowels must be scrupulously maintained, an occasional mild mercurial purge being administered. At the earliest signs of cardiac embarrassment some restriction in activity should be insisted upon and, when compensation seems threatened, absolute rest in bed must be enforced. The medicinal measures are at first limited to the vasodilators, the effect of the remedies being largely mechanical, dilating the capillaries, lowering peripheral resistance, and diminishing the work of the heart. To meet alarming symptoms a free catharsis is efficacious. Some preparation of mercury is to be preferred. To meet emergencies nitrite of amyl may be inhaled, but nitroglycerin is usually the drug of choice. Iodid of sodium and iodid of potassium, in 5- to 10-grain doses, given well-diluted one hour after meals, may be used. Heart tonics of the digitalis group should, of course, never be used during the stage of cardiac hypertrophy, being only admissible when there is indication of failing compensation. A vasodilator should be simultaneously administered in order to prevent the dangerous augmentation of the peripheral resistance.

THE TRANSMISSION OF SYSTOLIC MITRAL MURMURS, WITH SPECIAL REFERENCE TO THE NATURE OF THE SO-CALLED ANEMIC MURMURS

was the title of a paper by DR. HORACE B. ARNOLD of Boston.

He summarized his studies as follows: Mitral systolic murmurs may be heard not only at the mitral area at the apex and extending toward the axilla, but also at the mitral area in the back, along the left border of the heart, in the second left interspace, at the base, and at the "valvular" area. Anemic murmurs are not confined alone to the pulmonary area and second left interspace. They extend by varying gradations around the left border of the heart, to the apex, and to the mitral area in the back, thus gradually assuming the characteristics of a true mitral regurgitant murmur. The transmission to the

[1]See abstract in last week's MEDICAL NEWS, p. 717.

mitral area in the back may exist, whether the murmur is heard at the apex or not, and even in what appear in front to be typical anemic murmurs. We cannot find a dividing line between the so-called anemic murmur and the mitral murmurs. The presumption that these different gradations in the distribution of the murmurs all have a common origin is strengthened by finding these different gradations successively in the different stages of the same case. It is practically proved by finding all these gradations in healthy hearts which have been subjected to the same severe exhausting strain. Weakened muscular action of the heart exists in anemia as a result of poor nutrition. Weakened muscular action is an adequate cause for mitral insufficiency, whether dilatation exists or not.

DR. GEORGE W. WEBSTER of Chicago then read a paper, entitled

THE CAUSES AND DIFFERENTIAL DIAGNOSIS OF ACCIDENTAL HEART MURMURS.

Every theory in physical diagnosis should be the realization, not the violation, of a physical law. He argued that no single theory accounts for all accidental murmurs, and that it is probable that all accidental murmurs are, like those of organic disease, due to the production of "fluid veins." This may be due to temporary dilatation of the pulmonary artery, relative insufficiency of the tricuspid or the mitral valves, and possibly other causes. The diagnosis rests on: (1) The exclusion of organic disease as shown by (*a*) absence of a history of antecedent causal disease; (*b*) absence of the results of valvular defects as evidenced by hypertrophy and dilatation, or by broken or damaged compensation. (2) By (*a*) history of such disease or conditions as acute intoxications, chorea, the anemias, etc., with which these murmurs are frequently associated; (*b*) the characteristics of the murmur as shown by rhythm, point of maximum intensity, area of audibility, posture, exercise, etc.

He drew the following conclusions: (1) Accidental heart murmurs may occur when there is neither anemia nor fever, as in certain forms of intoxication. (2) Accentuation of the pulmonic second sound may occur in accidental heart murmurs. (3) An accidental murmur may be diastolic in rhythm. (4) The term "accidental" should be employed to designate all those cardiac murmurs which cannot after careful examination be clearly demonstrated to belong to the organic class, it being clearly understood that as our knowledge extends and increases the number of "functional" maladies gradually diminishes. The latter term is simply a cloak which covers up our lack of knowledge. True, the same may be said of the term "accidental," and yet there is this to be said in its favor: It commits us to no theory of causation, indicates no pathology, avoids a discussion of the question whether functional disturbances occur without pathological change, and, above all, it erects no barrier in the way of progress. (5) While I do not believe we are perfectly acquainted with all the physical conditions that can give origin to either cardiac or vascular murmurs, and while the error may be one of either observation or interpretation, I incline to the view that no single theory can be said to reasonably account for all accidental heart murmurs. I believe that there is a relative insufficiency of either the mitral or tricuspid valves, due to incomplete contraction of the heart, the latter due to degeneration, fatigue, or to the effects of toxic agents as in pyrexia, alcoholism, etc., and that under the circumstances the murmur may not vary in any of its essential characteristics of quality, pitch, and intensity or in point of maximum intensity and area of audibility from regurgitation due to organic disease at the same orifice. The vibrations accord with physical laws. Tricuspid regurgitation is probably of much more frequent occurrence than mitral. (6) The theory of Potain in regard to cardio pulmonary murmurs seems a possible explanation of some of the accidental murmurs. (7) In all cases of organic disease the vibrations originate in the fluid blood, due to the formation of "fluid veins." The theory that the accidental murmurs originate in vibrations in the walls of the vessels or of the cones, and are not communicated to the moving column of fluid, and so not carried by it, does not seem quite reasonable, but might serve to explain the limited area of audibility of some of these murmurs. (8) The wide diversity of opinion in regard to rhythm, point of maximum intensity, and area of audibility would seem to indicate careful, accurate observations improperly interpreted, or else an attempt to explain all accidental murmurs by one theory. (9) In many cases, especially of apex systolic murmurs, or in those heard over the body of the heart, a correct diagnosis cannot always be made without awaiting the results of treatment.

DR. GEORGE DOCK of Ann Arbor, Mich., read a very interesting paper on

THE USE OF QUININ IN MALARIA.

In the tertian or quartan intermittent, or any combination or duplication of these, quinin should be given in the decline of the paroxysm if possible, or not later than the end of the apyrexia. The difference depends upon the time the patient is seen or the diagnosis made. The dose should be given at one time or in parts at short intervals, in such a form that absorption may be confidently expected. He has found it very satisfactory to give the full dose in the form of the hydrochlorate, in capsules, followed by 15 drops of dilute hydrochloric acid. In patients who have been unable to retain other preparations he had been successful in giving three 5-grain capsules half an hour apart, with a small dose of dilute hydrochloric acid after each, with directions to repeat in half an hour if any dose was vomited. The question of quinin in malarial hemoglobinuria must be settled by careful clinical observation and experiment, and statements regarding it must be given credit in proportion to the accuracy with which the observations are made. In the meantime quinin can be used cautiously, if parasites are present, giving the drug in the form most likely to be absorbed, in doses within the limit of safety, and stopping its administration as early as the microscope shows this to be proper. A temporary increase in the severity

of the symptoms should not alarm the physician. It is necessarily due to the drug. At the same time the specific is being given other methods of treatment must not be forgotten. The quinin is given to check the malaria, not for any particular symptom or complication.

DR. G. A. FACKLER of Cincinnati, Ohio, read a paper, entitled

THE UNSATISFACTORY RESULTS OF THE HYPODERMIC ADMINISTRATION OF QUININ IN THE TREATMENT OF MALARIA.

He offered the clinical facts elicited by a review of twenty cases, confirming the cursory previous observations made as to the unreliability of quinin administered hypodermically in malaria. A general résumé of these 20 cases furnished the following data: Three cases in which quinin hypodermically was successful; 7 cases in which quinin by mouth was successful; 10 cases in which quinin by mouth was successful after hypodermic injection had failed. A total of 17 cases in which quinin by mouth was successful as a curative measure in the treatment of malaria. In only 3 out of 13 cases in which the remedy introduced subcutaneously was an abeyance of symptoms noted.

SYMPOSIUM ON PNEUMONIA.

DR. EDWARD F. WELLS of Chicago read the first paper, entitled

THE PNEUMONIA QUESTION; SOME INTERESTING CONSIDERATIONS.

In pneumonia the treatment should resolve itself into reasonable prophylaxis; in making the patient comfortable; in preventing excessive formation of toxins, in neutralizing them, in encouraging their elimination and increasing the resisting powers of the system against their action; in preventing, or managing properly, the complications which may arise. Bleeding in this disease as a remedial resource he did not believe had any substitute. Venesection should not be performed, as a rule, in the very young or the aged, the weak or anemic, nor in cases where the evidences of obstruction of the pulmonary circulation, or of increasing toxemia is present. Simultaneous with the venesection, or immediately after a solution, in distilled water, of chlorid of sodium, 7 per cent., chlorid of potassium, 23 per cent., and chlorid of calcium, .03 per cent., is injected subcutaneously in quantities appromimating that of the amount of blood withdrawn. The speaker believed that the immediate future would demonstrate pneumonia to be, certainly, a preventable and, largely, a curable disease.

DR. ROBERT H. BABCOCK of Chicago followed with a paper, entitled

PNEUMONIA IN THE AGED.

He considered pneumonia in the aged as being more frequently lobar than catarrhal. Its symptomatology is often unlike the typical form, and may be said to constitute a form of its own. The physical signs are often obscure, and the diagnosis often depends upon history and the symptoms. He emphasized four points, *viz.:* (1) It was his conviction that aged pneumonic patients bear well and require large doses of strychnin. (2) Stimulants, as alcohol in small or moderate doses, and ammonia in frequently repeated doses, are usually highly beneficial. (3) As little medicine as will meet the indications should be given for fear of upsetting the stomach, and thereby destroying what few chances the patients have at the best. (4) Because of the tendency to renal insufficiency the nourishment should be largely fluid, and nothing is so suitable as milk and properly prepared beef-juice.

DR. H. A. HARE of Philadelphia next read a paper, entitled

THE TREATMENT OF PNEUMONIA.

When called to care for a patient through an attack of illness, especially pneumonia, the physician should be a watchman all the time, and a therapeutist only when necessity arises. In all infectious diseases, especially croupous pneumonia, the patients may be divided into three classes: (1) those who are so mildly ill that all they need is good care and little or no active treatment; (2) those who are so ill that nothing can be done which will bring about a cure; (3) those cases which lie between the two, and which are capable of cure but only when the individual is aided by the most skilful treatment. As to the use of the abortive treatment by the use of bleeding or circulatory sedatives, such as aconite and veratrum viride it is evident that few patients can receive this treatment, because only a few patients have a sufficiently bounding pulse to justify its use, and few are seen early enough to be benefited by it. When consolidation has taken place one should attempt to prevent the hyperpyrexia by cold sponging with friction, and the use of the ice-bag over the heart and to the head. Ice to the precordium slows the heart and protects it perhaps from the ill effects of the fever. Ice to the head diminishes the pain and keeps the mind clear and controls the temperature. The antipyretic drugs are of use in that they allay nervousness, and not because they reduce the fever. If any one is tempted to give a patient stimulants, and before doing so feels his own pulse he will sometimes be surprised to find that his own is the weaker. Digitalis often fails as a stimulant because it loses much of its regulating power over the heart in the presence of high fever. It acts better when the temperature is reduced by hydrotherapy. If the pulse be gaseous and relaxed belladonna in 5 to 10 minim doses, every four or eight hours, may be useful. Strychnin goads the system to increased endeavor, and is especially of use when the patient seems to be sinking into the slough of death. The value of nitroglycerin seems to be in direct proportion to the degree of arterial tension. The value of oxygen is problematical. This disease cannot be treated by any routine method.

In the discussion of these papers DR. J. H. MUSSER of Philadelphia said that he felt sure that pneumonia has been taken out of the category of lung diseases and now is considered as belonging to the infectious diseases. From its clinical course pneumonia is considered a systemic disease and no longer a local one. There are many cases which begin with chills, fever, vomiting, and abdominal pain which is localized about the seat of the appendix, and sometimes it has been said that the patient

was suffering from appendicitis. In a great majority of the cases pain located in the upper part of the abdomen is misleading. One must not be misled by the severity of the symptoms. Too much stress cannot be laid upon the occurrence of peritonitis during the course of this disease. It is too often overlooked on account of the insidious development of the complication. Regarding the treatment he advised cupping freely and continuously; cup in the morning and evening and the next day. Cold compresses should be used; they should be wrung out of ice-water. When the temperature is not above 102° F., and when there is no general infection or marked evidence of toxemia, it is probably not necessary to use these applications. The effect of this is upon the circulation and the nervous system. He was convinced that toxic symptoms are controlled by the use of cold. He never gives aconite or veratrum viride and never finds it necessary to use cardiac sedatives. Large amounts of water should be given. He has used strychnin and nitroglycerin but has had no experience with digitalis in the treatment of pneumonia.

DR. STOCKTON of Buffalo confirmed the statement made, that leucemia does not always mean that a fatal issue is to be expected. In one case he noted there were no more than 6000 leucocytes counted and the patient recovered. This case was an extraordinary one in that there was a relapse—the only case of relapse the speaker ever saw. It was one of lobar pneumonia and the child sustained three relapses. The late Dr. Flint stated that this disease was one in which there is no relapse. The speaker had stated to his class that patients may die of lobar pneumonia and yet not have any inflammation of the lungs. He had seen two patients approaching death in whom no pneumonia could be made out; one was a case of the lobar form but showed no evidences of it until the sixth day, and the patient died on the seventh.

Regarding the treatment of pneumonia some cases he had seen were cases of toxemia, and one man was so discolored that he appeared as one bitten by a serpent; there was vasomotor paresis and evidences of the most serious process. Death took place in the beginning of the disease, and it was practically one from toxemia. He wished to emphasize the fact that pneumonia is a toxic disease and the treatment should be directed toward opposing the toxic condition. Large doses of alcohol he deemed of more importance than any other stimulant. Strychnin, in doses of $\frac{1}{20}$, $\frac{1}{15}$, or $\frac{1}{10}$ of a grain, given hypodermically, and until there is no longer any vasomotor paresis, he thought would rescue patients from death when attempts by any other means would prove futile.

DR. GEORGE DOCK said that he wished to voice the opinion already expressed regarding the value of strychnin in the later stages of pneumonia when given judiciously. This also applies to the use of alcohol. He spoke highly of the use of ice-bags in cases of frank croupous pneumonia. Formerly he treated these cases as he did typhoid fever, *i. e.*, with the cold bath, but this is difficult to carry out although the method is valuable. Two years ago he began to use ice-bags and his results have been good.

DR. A. M. HOLMES of Denver spoke of the influence of altitude in these cases. Denver is one mile above the sea level, and the celebrated Cripple-Creek region is higher. At this place there is a great and rapid increase in the population and a great deal of exposure and much pneumonia in consequence. The mortality-rate is very high, and it is now customary to send the patients to a lower altitude as soon as a diagnosis of pneumonia can be made.

DR. J. M. ANDERS of Philadelphia said it had recently been pointed out that while the mortality-rate in typhoid fever, diphtheria, and other acute infectious diseases has been decreasing, that of pneumonia, unfortunately, has been increasing during recent years. All bacteriologists and clinicians agree that pneumonia is due to various toxins. The pneumococcus is present in about ninety per cent. of all cases, and the pneumococcus alone in about seventy-five per cent. of the cases. In many instances it is a mixed infection. It is a well-known fact that these micro-organisms have a direct bearing upon the course and prognosis of the disease, also upon the treatment. One cannot expect to obtain good results from pneumococcic serum when there is a streptococcus infection. He had found a moderate leucocytosis during the pseudocrisis which occurs about the fifth day of the disease. He had observed that in two cases it occurred in the streptococcus infection rather than in the pneumococcus infection. During the past winter he saw a case of influenza in which pneumonia developed as a complication. The sputum in this young man was examined, and he failed to find any recognized pathogenic organism, so it probably was a pneumonia due to an organism other than the pneumococcus or streptococcus.

SECTION ON DISEASES OF CHILDREN.

SECOND DAY—JUNE 7TH.

DR. E. E. MAYER of Pittsburg, Pa., read a paper, entitled

HYSTERIA IN CHILDREN.

Hysteria is not so uncommon as formerly thought; the Children's Crusades, the dancing manias of the middle ages, and the story of the Pied Piper of Hamlin, show that it has always existed. Anglo-Saxons are not so free from it as has been supposed, and their comparative freedom from it is due to our better methods of training than to any special absence of heredity. The disease is psychical, but is modified by the physical conditions. One authority has said that he has never seen hysteria without chlorosis. This psychic element is most important. Imitation of neurotic conditions in parents is of etiologic import. The diagnosis of hysteria in children is not easy. The ordinary stigmata of the disease, the anesthetic patches of skin and of fauces, the concentric narrowing of visual fields, are not usually present. The affection often runs a non-symptomatic course. The variability of symptoms, however, and the suggestibility of the patients makes the diagnosis comparatively easy after study of the case. In the so-called hysterical palsies the gait is jerky, not hesitating; it is not weakness

but over-action of muscle that is noted on movement. Patrick has shown that the limits of the anesthetic and hyperesthetic varies almost from minute to minute. The treatment of hysteria in children is moral. Underlying physical conditions must be treated in the usual way, but parents must be impressed with a proper sense of responsibility and made to train their children so that their emotional side does not run away with them, but no corporal punishment must be employed. The prognosis is better than in hysteria in older people, but great firmness is necessary in not yielding to the child in the slightest degree. For this reason the specialist often succeeds where the family physician fails.

DR. SLAGLE of Minneapolis said that ideopathic hysteria, *i.e.*, hysteria without a physico-pathological factor is not common in children. Secondary hysteria, especially in members of neurotic families, is quite common. The treatment, of course, is to rule the exaggerated nervous symptoms, but primarily to treat the underlying condition of anemia, indigestion, constipation, and the like. Look for the physical cause; it is not easy to find. Dr. Slagle has seen hysteria develop in children while he was administering strychnin even in minute doses.

DR. GARRISON said that she has seen hysteria develop in nervous children while taking strychnin as a tonic.

DR. ROSA ENGELMAN of Chicago said that hysteria in children, because of its difference from hysteria in the adult, is difficult of diagnosis. Some of the manifestations of it are most surprising. She has a case under observation in which polyuria is the prominent symptom. At one time, for days, thirty pints of urine were passed, and the polydipsia kept the child from sleep. That is over a year ago, yet the child is still passing six pints of urine daily. There is no sugar and no other abnormal constituent. The malarial organism was found in the blood, and the malarial toxemia was concluded to be the pathological basis on which the hysteria rested.

DR. C. G. SLAGLE of Minneapolis read a paper, entitled

INFANTILE CONVULSIONS; THEIR CAUSE, NATURE, AND MANAGEMENT.

He said that a neurotic constitution nearly always precedes convulsions, and that there is such a thing as a convulsive temperament which is inherited. Nearly always irritation of the digestive tract is the cause. It must be borne in mind, however, that mothers' milk may prove the irritant more than once. He has seen convulsions succeed applications to the breast within an hour under circumstances that excluded other conditions. For treatment during the convulsion, if severe, an anesthetic should be used, then an emetic, and after that a calomel purge.

DR. COTTON of Chicago said in discussion that he reported last year at Denver some fifty cases in which coitus, excessive or prolonged, had caused deterioration of the mother's milk, producing irritation of the gastro-intestinal tract in her nursling. He has now had some seventy cases in which he believes that this cause has been at work in making the breast-milk noxious to children. This certainly deserves careful investigation.

DR. EDWIN ROSENTHAL of Philadelphia read a paper, entitled

TREATMENT OF SEPTIC CONDITIONS IN CHILDREN.

Dr. Rosenthal recommends local applications as preventives of general infection, especially the use of antiseptic poultices and of 30-per-cent. ichthyol ointment, with lanolin as an excipient, when the first sign of an inflammatory process is seen. For well-established infection antistreptococcic serum is very effective and produces marvelous results.

DR. DILLON BROWN of New York said that antistreptococcic serum cannot be effective in general septic conditions because we have not, in these cases, simple toxemia, with toxins in the blood, but the bacteria themselves are present in the blood and against them the antitoxin can do nothing as it is not antiseptic.

DR. BLECH of Chicago said that another reason why antistreptococcic serum is not effective is that a mixed infection frequently is present besides the streptococcus, the various forms of streptococci, and other pyogenic micro-organisms. Against their toxins the streptococcus antitoxin has no effect.

DR. ROSA ENGELMAN of Chicago said that the antistreptococcus serum is necessarily made from one form of streptococcus while a number of forms exist, and it is not easy to differentiate which special variety is at work. The different forms are variously virulent too, so that too much assurance of success cannot be founded on the use or any special serum.

DR. COTTON of Chicago said that antistreptococcic serum produces marvelous results in certain cases, though it utterly fails in others. Our clear duty in the matter is to use the remedy in every case where streptococcic infection is suspected.

DR. GUSTAVUS M. BLECH of Chicago read a paper, entitled

COMPARATIVE THERAPEUTIC VALUE OF RECENT ANTISEPTICS IN PEDIATRIC PRACTICE.

He considers that four forms of antiseptics are feasible, for the urinary tract, for the respiratory tract, for the intestinal tract, and general antisepsis. For the urinary tract he has found urotropin most useful and it has none of the irritating properties of some urinary antiseptics, and besides its use does not interfere with local treatment of the bladder.

Guaiacol carbonate is an excellent respiratory antiseptic for use in various forms of bronchitis. It does no good in pulmonary consumption, however, for which he considered Kleb's tuberculocidin to be practically a specific in the first and second stages.

As an intestinal antiseptic eudoxin has proven the best in his hands. It is split up in the stomach into bismuth suboxid and nosophen, and the nosophen is an excellent practical intestinal antiseptic. As a general antiseptic compounds of iodin and silver are available. Of these, iodin, that God-given drug, as some one has called it, is the best. Two of the recent forms in which it is employed, antinosin and nosophen, do not free nascent iodin when in contact with the tissues and hence

are good unirritating antiseptics, locally or internally, never producing symptoms of iodin intoxication.

Dr. Cotton of Chicago has also used eudoxin, and has been pleased with his results, and expects to use it even more freely in the future.

Dr. Slagle of Minneapolis considers that there are but three intestinal antiseptics that are effective—calomel, sulphur, and sulphite of soda.

Dr. Rosa Engelman of Chicago read a paper, entitled

MEMBRANOUS TONSILLITIS OF INFLUENZA AND ITS BACTERIOLOGICAL LESSONS.

It has been known for some time that in addition to the diphtheria bacillus other micro-organisms, notably the streptococcus, can produce a membrane in the throat. The pseudo-diphtheria bacillus can very probably also produce a membranous deposit. It was not until the investigations of the Chicago Board of Health last winter that it was known that there is a diphtheritic form of influenza. In a number of cases where there was a membranous pharyngitis, but the clinical symptoms, if the disease were to be considered diphtheria, were anomalous, the influenza bacillus of Canon and Pfeiffer was found in the lesions.

This emphasizes the necessity for bacteriological diagnosis of all throat conditions. Incidentally it may be remarked that diphtheria and influenza may occur simultaneously, or diphtheria may begin in a mixed infection. Cultures from throats of patients in Chicago last winter that at the eighth hour were surely diphtheria bacilli, at the twenty-fourth hour were completely overgrown by the diplococcus lanceolatus. It is necessary to follow cultures from hour to hour in order to be sure what micro-organisms are present.

During epidemics of influenza a number of suspicious cases of diphtheria will prove to be grip. It is true that there is a pseudo-influenza bacillus described by Pfeiffer which also produces a pseudo membrane in the throat. To distinguish this the most careful bacteriologic diagnosis is necessary.

Dr. Cotton of Chicago said that for the practitioner when there is doubt as to the nature of the process in the throat, it is advisable to treat it as if it were diphtheria. Diphtheria antitoxin can do no harm, and it will always do good if there is any diphtheria present.

Dr. Rosenthal of Philadelphia thought that the influenzal membranous tonsillitis can be distinguished macroscopically from that of true diphtheria by the fact that it has a more granular look, and is less evenly distributed over the surface of the tonsils.

Section on Neurology and Medical Jurisprudence.

First Day—June 6th.

The Chairman, Dr. Frederick Peterson of New York City, presented the annual address. He spoke of the impossibility of touching upon all the recent advances in neurology and psychiatry. In one subject alone, the cytology of the nerve-cell, it would be necessary to examine 400 different contributions, books, and journal articles by 280 authors in order to write an exhaustive critique. He presented a bibliography of neurology and psychiatry and allied subjects for the year 1898 and the early part of the year 1899, limited to books of more than fifty pages, including 201 works in all. He referred especially to "Die Psychiatrische Clinik zu Giessen," published in Berlin during this year, describing a psychopathic hospital in a German city on the community plan, containing laboratories for pathologic, microscopic, chemical, photographic, and psychophysical work, besides a mechanical workshop, clinical auditorium, library, and polyclinic or dispensary for out-of-door patients.

Dr. John Punton of Kansas City, Mo., presented a paper on

THE RELATIVE CURABILITY OF NERVOUS DISEASES AND THEIR THERAPEUTIC INDICATIONS.

The relative curability of any given nervous affection is based upon the accuracy of its early diagnosis. To this end there should be an accurate scientific classification of diseases of the nervous system, dividing them into two great classes, organic and functional. In the cases covered by the first class the nervous elements are not, as a rule, primarily affected, but are so secondarily. As to the second class, the chief lesions affecting the nervous apparatus can be arranged under six groups, namely, vascular, inflammatory, degenerative, toxic states, congenital malformations, and functional or unclassified lesions. In the last group are included hysteria, chorea, neurasthenia, paralysis, catalepsy, epilepsy, etc., and by reason of the purely subjective character of their clinical phenomena, their diagnosis is often very obscure and misleading. The statistics and authorities as to epilepsy, for example, are utterly at variance. It is highly desirable that a text-book authorized by this or some competent association be furnished the medical profession in which is set forth reliable data based on actual facts as demonstrated by practical clinical observation and experience in order to prevent the fraud and deception now practised on the helpless neurotic incurable by those claiming to have a "sure cure for fits."

Dr. T. D. Crothers of Hartford, Conn., read a paper on

THE MEDICAL SIDE OF CRIMINAL MORPHOMANIA,

which was followed by one on

A RATIONAL TREATMENT OF CHRONIC MORPHINISM,

by Dr. A. J. Pessey of Cleveland, Ohio.

Dr. Crothers spoke of the physiological action of opium and its alkaloids in causing "palsy of the higher psychical centers," temporarily destroying the former personality of the patient and causing him to act from a different point of view. He related a number of instances in which the morphin-taker had been guilty of various fraudulent and secretive crimes, displaying a cunning, judgment, and apparent honesty in avoiding discovery, so long as not deprived of the drug, but breaking down completely and showing marked mental aberration when the morphin was taken away. These cases included arson, dishonesty, speculation, forgery, false impersonation, and

all sorts of swindling. Morphin criminals are regarded as most dangerous by the police, having full control of their nerves and acting a double part so clearly as to disarm suspicion. Cases of will mania, delusions of sudden death, etc., are among the mental results of the use of morphin. A new personality appears; some psychic trance state, in which great mental clearness, self-possession and cunning, with unusual frankness and candor are the prominent symptoms. There should be an exact study of the criminal side of morphin cases.

Dr. Pressy's treatment of morphinism is by the gradual withdrawal of morphin until it is only given in infinitesimal doses, the patient being unaware that the amount is being reduced. The patient is usually taking more than is necessary to produce the desired results, and the dose can usually be markedly reduced at the start. The patient is kept on as small a quantity as will make him comparatively comfortable, without making his dose so small as to keep him in misery until the next hour for morphin. The doses are given four times a day just previous to meals and bed-time.

DR. CHARLES H. HUGHES of St. Louis said that as to treatment, the safe rule is to endeavor to gage the dose according to the capacity of the patient for reduction.

DR DANIEL R. BROWER of Chicago said that morphin, very much more than alcohol, disturbs, deranges, or alters the personality. He thought that morphin patients can be treated very successfully in hospitals.

DR. E. S. PETTYJOHN said that under the influence of morphin doctors of divinity are just as prone to tell what is not true as any one else. He advocated continuing the small doses for a somewhat longer time, cutting them down to $\frac{1}{10}$ or $\frac{1}{20}$ of a grain.

DR. HAMLIN of Tennessee agreed with Dr. Pettyjohn and said that the dose should be even cut down at the last to $\frac{1}{32}$ or $\frac{1}{64}$ of a grain. He related the case of an intelligent, well-bred Southern woman, who secretly contracted the morphin habit and, being accidentally deprived of the drug, one night went entirely mad and was found wandering on the streets of the city, attempting to sell her virtue to a druggist for a dose of morphin.

DR. TUCKERMAN of Cleveland suggested that there are many cases of morphinism which must be treated by the general practitioner, as it is impossible for the individuals to go to a hospital. He related the case of an opium fiend in a private family who was treated by a mixture of opium and thoroughwort, the proportion of the former being gradually reduced.

DR. A. E. STERNE advocated the immediate withdrawal of the drug, in the absence of any contraindications, the unpleasant symptoms being obviated by the use of bicarbonate of soda to relieve the acidulous condition of the system.

DR. WILLIAM N. BULLARD of Boston, Mass., presented a paper on

RELIEF OF INTRACRANIAL PRESSURE IN NON-TRAUMATIC CASES WITHOUT LOCALIZING SYMPTOMS.

Trephining is often advisable in cases of increased intracranial pressure when the cause of such increase is uncertain. A married woman, aged thirty-eight years, the daughter of a nervous invalid, applied for operation to relieve the intolerable condition of her head. For years she had been subject to a sensation as if the brain were being compressed. There was no evidence of any affection of the optic nerve. The cranium was trephined on the right just in front of the coronal suture and about an inch below the sagittal suture, and the button removed. The dura was very tense, bulged, did not pulsate; the cranial opening was enlarged, and the dura cut. The brain, which was very blue, protruded an inch or more beyond the cranial opening, suggesting very marked intracranial pressure. The protruding portion of the brain, which was 2 x 3 inches in length and breath and an inch or more in thickness was cut off and the wound closed without stitching the dura. The patient made an uninterrupted recovery, and since the operation has had no recurrence of the symptoms. A year after the operation she became the mother of a healthy child, her first, though she had been married for more than ten years.

Dr. Bullard's conclusions were as follows: (1) There exist certain non-traumatic cases of increased intracranial pressure of unknown or doubtful origin. (2) Whenever an excess of intracranial pressure exists such as to cause serious symptoms, the question of its relief by opening the cranium and cutting the dura should always be considered. (3) In certain non-traumatic cases of excessive intracranial pressure more or less permanent relief, or even cure, may be obtained by proper surgical interference. (4) In cases of acute severe optic neuritis of unknown origin the question of opening the cranium and relieving the excessive intracranial pressure should be considered.

DR. W. A. JONES of Minneapolis, Minn., spoke of a case of injury followed by mild optic neuritis, mild hemiparesis and hemianesthesia, which, with a great deal of headache, seemed to demonstrate the probability of an acute pressure either from abscess, tumor, or something of that sort. On trephining nothing but a very small quantity of fluid was found, but there was a perfect recovery, and all the subjective and objective symptoms disappeared.

DR. TUCKERMAN of Cleveland related an instance of a young woman with symptoms similar to those of Dr. Bullard's patient, who was relieved by exploratory trephining. The brain did not bulge; the dura was not opened, but was adherent to the skull very firmly under the site of an old injury, and the skull was somewhat thickened. An opening of about an inch and a half was made, and a gauze drain inserted. There was a free seepage of cerebral fluid for three or four days. The headache, the sleepy symptoms and the convulsions from which the child suffered disappeared very promptly.

DR. FISHER said he understood from Dr. Bullard that the button was not replaced, and thought that was the reasonable course to pursue. Cutting away portions of the brain could not, of course, be indiscriminately done.

DR. TOMLINSON thought that if there is a general pressure, giving rise to generalized symptoms, there is just as obvious a reason for the operation as in tumor, abscess, or local accumulation of fluid, the object in each case being to relieve the pressure.

DR. BULLARD, in closing the discussion, said that curiously enough in his case there was no excess of fluid found underneath the dura, nor did the specimen of the brain show anything peculiar under microscopical examination. There were none of the symptoms of grand hysteria in the case, nor was there any shock following the operation.

SECOND DAY—JUNE 7TH.

The entire day was given up to a

SYMPOSIUM ON HEADACHE.

The following papers were read:

"The Diagnostic Importance of Headaches," by DR. FISHER. "The Headache of Gastro-Intestinal Disorders," by DR. FRANK BILLINGS of Chicago. "Headache Due to Affections of the Eye," by DR. SAMUEL D. RISLEY of Philadelphia. "Migraine," by DR. SAMUEL J. WALKER of Chicago. "The Relation of Uric Acid to Migraine," by DR. JOHN A. LICHTY of Clifton Springs, New York. "The Mental Element in the Treatment of Headache," by DR. PHILIP ZENNER of Cincinnati.

Dr. Fisher's paper dealt with the distinction between so-called continuous or constant headache and the paroxysmal headache, the former being present in Bright's disease, nephritis, and arterial disease. Of course even in the cases of continuous headache there are occasional exacerbations.

Dr. Billings maintained that gastro-intestinal disturbance is a very common cause of headache. The treatment is by the application of the laws of hygiene, modified to suit the individual case; a selected diet for each individual, the free use of water as a diluent, and recreation in the form of physical exercise or physical rest commensurate with the mental activity or physical tire of the individual. These he advocated in connection with the correcting of irregular habits of sleep, of time of taking food and of exercise, the withdrawal of tobacco, tea, coffee and alcoholic drinks, lavaging the stomach when necessary, and overcoming the constipation by hygienic measures, if possible without drugs. In conditions of malnutrition and anemia, restorative tonics and an abundant simple diet are indicated.

Dr. Risley's conclusions were as foliows:

1. Abnormalities of the ocular apparatus are in a large group of patients the sole and sufficient cause of headache.

2. These abnormalities of vision may be the unsuspected cause, and therefore, the absence of symptoms obviously referable to the eyes does not exclude them as an etiologic factor in headache, insomnia, vertigo, petit chorea in children and certain stomach derangements.

3. The recent or sudden development of symptoms, *e.g.*, after attacks of severe illness, as typhoid fever, the exanthemata, etc., or in association with more or less acute exacerbations of some general dyscrasia, is not sufficient evidence against ocular participation in causing the symptoms.

4. The participation of the eyes as an etiological factor in headache can be positively excluded only in the absence of ocular diseases or after the most painstaking correction of any existing error of refraction or abnormality of binocular balance.

5. For the relief of reflex symptoms, accurate corrections are essential, and these can be secured only by the more or less prolonged use of a strong cyclophlegic.

6. Immediate relief by these corrections in a large group of patients is not to be expected since the pain is frequently due to associated pathologic conditions of the fundus oculi and these require time for cure.

Dr. Walker of Chicago in his discussion of migraine, detailed a number of cases coming under his own observation and seen in the practice of Dr. Hugh T. Patrick, and noted an apparent relation, which he did not attempt to define, between migraine and epilepsy.

Dr. Lichty of Clifton Springs, in speaking of migraine from the uric-acid standpoint, presented studies of the uric-acid conditions in three cases of migraine. Both uric acid and urea were diminished during the height of the headache, but their relation was not disturbed. After the headache, the urea increased to about what it was between the attacks, while the uric acid increased much more, thus changing the former ratio. Dr. Lichty concluded that the increase of uric acid which is associated with migraine is the result, and not the cause, of the headache. He referred to Gowers' statement that "When all has been said that can be, mystery still envelops the mechanism of migraine."

Dr. Philip Zenner, in his article on "The Mental Element in the Treatment of Headache," referred to cases in which patients suffering from brain tumors were compelled to undergo gynecological operations, which were followed by complete relief from headache. This was attributable to the mental impressions produced by the operations.

The discussion of these papers was opened by DR. NORMAN BRIDGE of Los Angeles, Cal., who said he did not believed that there is any relation between migraine and uric-acid diathesis. He suggested that in order to explain Dr. Zenner's cases it was not entirely necessary to assume that the surgical operations relieved the headaches by mental impression, as we know that surgical operation does interrupt various nervous phenomena, owing to the chloroform, the wound, the shock, etc.

DR. CHURCH of Chicago was of the opinion that there is a certain relation between migraine and epilepsy.

DR. HUGHES of St. Louis did not believe that migraine and epilepsy are at all associated diseases.

DR. JOSEPH V. KOFRON of Cleveland, Ohio, related cases in which the migraine had been cured in children by relieving a diseased conditions of their tonsils.

DR. A. E. STERNE believed that in almost every case the cause could be discovered and removed, but even after its removal there is a secondary state following upon the chronic. If the difficulty is dilatation of the blood-vessels, the stretching may have gone to such an extent that the vital rubber has lost its contractility.

DR. F. SAVARY PEARCE of Philadelphia thought there is no doubt about the hereditary element, to which is superadded the exciting cause, whatever that may be.

DR. EVANS thought that the medical profession to

day is in a state of extreme uncertainty as to the causal factors in the production of migraine. In his opinion there is no relation between migraine and epilepsy. There being so many cases of each under observation, it is only to be expected that patients should occasionally be found who have suffered from both.

DR. HUGH T. PATRICK of Chicago agreed with Dr. Walker as to the likelihood of some relation between migraine and epilepsy. He pronounced a warning against accepting the statements made by Haig in his book, as thus far they are not borne out by facts.

The report of the Nominating Committee was unanimously adopted, and the following officers elected for the ensuing year: Chairman, Dr. Hugh T. Patrick of Chicago; secretary, Dr. F. Savary Pearce of Philadelphia.

A vote of thanks was extended to those members who came from other sections to participate in the symposium.

SECTION ON OPHTHALMOLOGY.

FIRST DAY—JUNE 6TH.

THE first day's session opened with probably the largest attendance in the history of the Section, all portions of the country being represented.

The address of the Chairman, DR. CASEY A. WOOD of Chicago, was concerned chiefly with the rapidly increasing number of papers which are yearly offered to the Section and he discussed the various ways of dealing with the problem.

Of the papers presented at this first meeting but two elicited much discussion. DR. H. MOULTON of Fort Smith, Ark., reported "A Case of Quinin Blindness in a Child Aged Three Years," and while there was nothing unique in the case save the age of the patient, which with one exception is the youngest on record, it excited an animated discussion in which part was taken by many until the chairman was obliged to postpone further comment until the morrow.

The paper by DR. C. H. WILLIAMS on "The Examination of the Vision and Color-sense of Railway Employees" also elicited an animated discussion, which was of greater interest than the paper itself.

Among the various opinions expressed was that of DR. GIFFORD of Omaha, who urged the use of the ophthalmoscope and an examination of the lids to detect possible exciting causes of corneal irritation. DR. REYNOLDS of Louisville regarded the color-test as outlined by the writer as insufficient and advised its being made in both a light and darkened room. DR. ALLPORT of Chicago believed that the examination of railway employees should be made by an oculist and not by a lay servant of the company. DR. RANDALL of Philadelphia commended the system in vogue on the Pennsylvania Railroad, of submitting the result of the examination to a jury of fellow-workmen, and DR. JACKSON of Denver urged the necessity of such tests that would disclose the presence of scotomata.

After the appointment of a nominating committee the Section adjourned. The Section dinner was served at the Columbus Club and more than fifty sat down to the board.

REVIEWS.

GEBURTSHUELFLICHE TASCHEN-PHANTOME. (OBSTETRIC POCKET PHANTOMS.) By DR. K. SHIBATA. Fourth edition. Munich: J. F. Lehmann, 1898.

THE fourth edition of this little work is a good indication of its usefulness. For the student who has difficulty in learning the obstetric positions and the mechanism of labor in various presentations, the book has a distinct value. The miniature fetuses and pelvis enable him to study the mechanism correctly and as often as he choses.

PRACTICAL MATERIA MEDICA FOR NURSES. By EMILY A. M. STONEY, Late Superintendent of Training School for Nurses, Carney Hospital, South Boston, Mass. Philadelphia: W. B. Saunders, 1899.

WE have always believed that our trained nurses were compelled to learn too much that is theoretical to the enforced exclusion of much that is practical. It is sometimes a serious thing to be obliged to employ a nurse who knows all about gelsemium but who does not know how to lift a patient from the right to the left side of the bed. There is some justification for making nurses learn something of the armamentarium they daily use; but there is no sense in compelling them to become half-fledged medical students in the attempt. If all nurses were made to know thoroughly the contents of the book before us, they would be good students of materia medica, no doubt. As long as the present system of instruction prevails among training-schools, such books as Miss Stoney's will have a good reason for existence. It is thorough, complete, and concise, and contains much that will be of benefit to an intelligent nurse who is interested in her work.

THERAPEUTIC HINTS.

Care of a Young Child's Teeth.—Beginning at the age of two years, the teeth should be rubbed every morning with a cotton tampon wet with the following dentifrice:

℞	Thymol	ʒ iss
	Ac. benzoici	gr. lxxx
	Ol. menth. piper.	*m.* xl
	Ol. anisi	*m.* xxx
	Tinct. coccionellæ	ʒ iss
	Spiritus (80 per cent.)	ʒ viii.

M. Sig. Add enough to a glass of water to make the water cloudy.—*de la Carrière.*

Formula for Oil of Wintergreen When Given in Rheumatism.—

℞	Ol. gaultheriæ	ʒ iv
	Spiritus, Syr. simplicis aa	ʒ iv

M. Sig. One teaspoonful in vichy three times a day.

Suppositories for Infantile Dysentery.—

℞	Aluminii	ʒ v
	Plumbi acetatis	gr. lxxv
	Ol. theobrom.	ʒ v
	Melted wax	gtt. xx.

M. Ft. suppos. No. X. Sig. Insert one suppository every three or four hours.—*Guida.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIV. NEW YORK, SATURDAY, JUNE 24, 1899. No. 25.

ORIGINAL ARTICLES.

FEVER IN ASEPTIC SURGERY.[1]

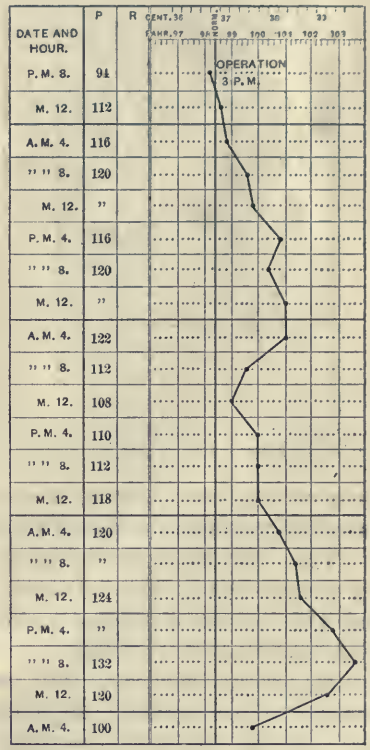
BY B. FARQUHAR CURTIS, M.D.,
OF NEW YORK;
PROFESSOR OF CLINICAL SURGERY AND ADJUNCT PROFESSOR OF THE PRINCIPLES OF SURGERY IN THE UNIVERSITY AND BELLEVUE MEDICAL COLLEGE.

IN the surgery of pre-antiseptic times when nearly all wounds healed with some inflammation, it was the rule to have a rise of temperature, at least in the early stages of healing. When antiseptic methods enabled the surgeon to obtain primary union, or healing by granulation, without local inflammation, it was natural to suppose that there would be no accompanying elevation of temperature, as the prevailing theories at that time ascribed the fever to the inflammation. It was soon discovered, however. that fever often accompanied healing by first intention, and Billroth ascribed it to the absorption of tissues in and near the wound which had broken down because of the impairment of their vitality by traumatism, and gave to it the name "traumatic fever." But the term "aseptic fever," introduced by Volkmann, has been more generally accepted.

In hospital services in which primary union of wounds is the rule it will be found that the majority of wounds heal without a rise of temperature to 101° F., and that in those cases in which this height is reached a certain proportion will still heal by primary union, while the rest will show some signs of infection, although it may amount to nothing more than a drop of pus around a single suture.

Recent investigations have demonstrated that the difficulty of sterilizing the skin of the patient and of the surgeon's hands, as well as the catgut, is so great that very rarely can absolute freedom from pyogenic bacteria be obtained. They have also shown, however, that even when considerable numbers of bacteria are present, primary union may occur, and Welch has proven that blood has sufficient bactericidal powers to destroy virulent pyogenic germs by injecting cultures of staphylococci into the blood-clot filling the cavities of wounds and observing that the wounds healed aseptically in spite of the infection. The effect of pyogenic infection upon the wound depends upon the number of germs present, the "dose" of poison, so to speak. A slight infection of operation-wounds is almost inevitable, and, if the line of safety in dose is not overstepped, primary union will take place without any reaction, or with some local hyperemia and edema and a rise of temperature. A certain proportion of cases of primary union, accompanied by fever, are really instances of slight infection, and as it is of bacterial origin the febrile movement cannot be called aseptic fever. Even absolute primary union is not a proof of complete freedom from bacterial infection.

FIG. 1.



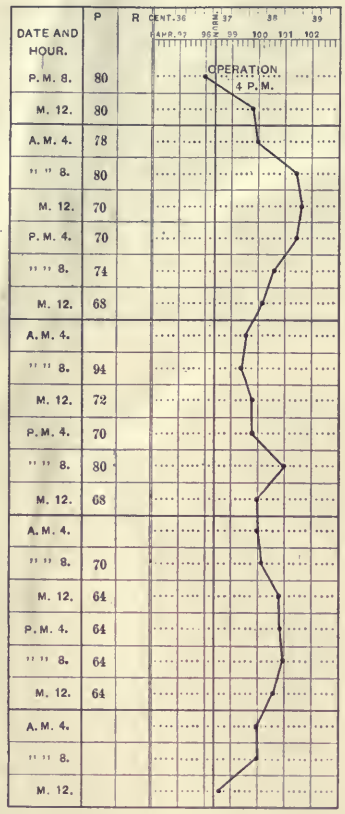
Temperature curve after ventral fixation.

In any large series of cases of wounds, therefore, we shall expect to find on the one hand a purely aseptic fever, on the other an inflammatory fever caused by undoubted infection, and between these typical cases, a series of cases of gradually increasing infection, in many of which it will be difficult or impossible to say whether the rise of temperature is aseptic or pyogenic. A further proof of this theory is the fact that there is a constant diminution of the number of cases of primary union accompanied by

[1] Read at the ninety-third annual meeting of the New York State Medical Society, held at Albany, January 31 and February 1 and 2, 1899.

fever, as the aseptic methods of the surgeon improve. We have been accustomed personally to look upon the occurrence of an increasing number of cases of apparent aseptic fever in our wards as a danger sig-

FIG. 2.



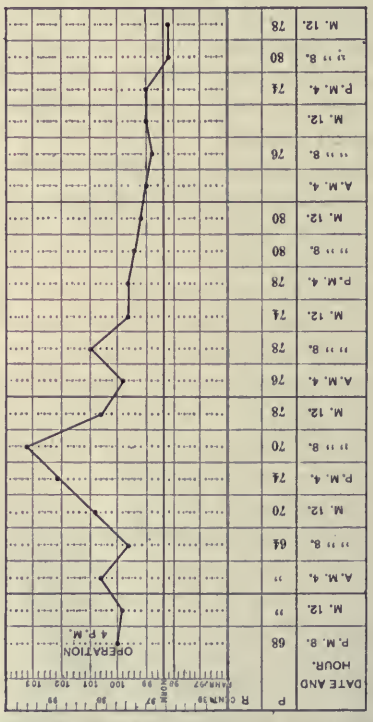
Temperature curve after abdominal hysterectomy.

nal of some error in our methods, and to make a thorough investigation and endeavor to improve our technic. This additional watchfulness has more than once reduced the number of cases of aseptic fever and also increased the proportion of cases healing by absolute primary union.

We cannot claim, however, that all cases of "traumatic fever" are caused by slight infection, for proof to the contrary has been too abundantly furnished from the time of the studies of Volkmann and Genzmer down to our own. Fever too often accompanies simple fractures and other subcutaneous injuries with extravasation of blood, in which infection is impossible unless it take place through the medium of bacteria circulating in the blood. According to the experiments of Köhler, Angerer, Edelberg, and others it seemed probable that the pyrexia was caused by fibrin-ferment set free in the extravasated blood and absorbed by the surrounding tissues. These results have been questioned recently by Schnitzler and Ewald, who drew blood from animals and human beings with well-marked aseptic fever accompanying subcutaneous injuries and found no free fibrin-ferment in the specimens. Hammerschlag also examined the blood of nineteen patients with fever due to other causes than traumatism and found free fibrin-ferment in it, and finally others have claimed that free fibrin-ferment could be found in some individuals without fever. It is, therefore, considered probable by these observers that another substance, found in blood-clot and dying, breaking-down tissues, known as nuclein is the cause of aseptic fever. The absorption of nuclein causes an increase of a peculiar nitrogenous body in the urine, and also produces leucocytosis. Schnitzler and Ewald found the increase of this nitrogenous constituent of the urine in three out of four cases of osteoclasis. In six similar cases they also found a marked leucocytosis, the increase of white cells being fifty per cent. of the number observed before the operation. The leucocytosis took place immediately and sometimes reached its maximum within four hours and passed away generally in two or three days. In some cases the number of leucocytes reached 37,000.

Whether aseptic fever is caused by fibrin-ferment

FIG. 3.

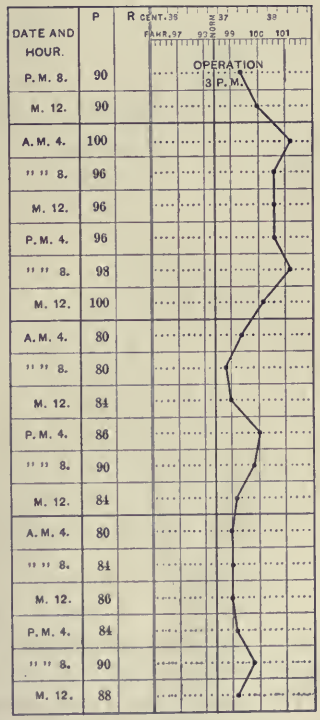


Temperature curve after amputation of the forearm.

or by nuclein may not be of much importance to the practising surgeon as both may be the result of blood-clot and breaking-down tissue in aseptic wounds, and the fact remains that the absorption of these sub-

stances is capable of causing a rise of temperature. But these studies may yet lead to important consequences if they will furnish us with a clinical test capable of informing us immediately after an operation whether the fever in a certain case is due to this absorption or to a beginning infection. The early dressing of serious wounds is a frequent cause of infection and we are, therefore, accustomed to postpone it for several days at least, and to rely upon the thermometer, together with certain symptoms to indicate the presence of infection and the necessity for an early dressing. It is of the greatest importance for us to be able to interpret correctly any rise of temperature which may occur and not to be compelled to expose a wound unnecessarily if the fever is due to some other cause than infection. This is especially true since surgeons have endeavored to abolish drainage of aseptic wounds as far as possible, for if there is an unusual amount of secretion or a slight infection the whole course of the wound may depend upon relieving the tension by opening the wound and establishing secondary drainage, and if we should accept the hypothesis of aseptic fever to account for a rise of temperature in such a case, and

FIG 4.

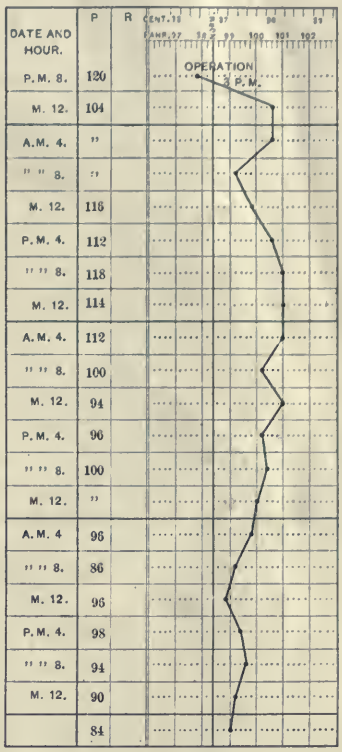


Temperature curve after nephrorrhaphy.

allow the wound to remain untouched, we would run far greater risk than that incurred by a premature dressing.

As practical surgeons the point which interests us is the recognition of infection and beginning inflammation of wounds at the earliest possible moment, and there can be no question of the value of the thermometer in indicating this condition. But to

FIG. 5.



Temperature curve after laparotomy for pyosalpinx.

properly estimate the presence of fever we must exclude all other causes for it, as well as the absorption of pyogenic substances from the wound. The ordinary disturbances and diseases which cause fever should first be excluded, and this is sometimes a task of the greatest difficulty. We have seen malarial fever, gastro-intestinal disturbances with absorption of ptomains, constipation, bronchitis (often from the ether), rheumatism, typhoid fever, and in children the various infective fevers, cause the greatest number of errors in this regard. We cannot dwell here upon their distinguishing points, but wish to emphasize the importance of careful examination of the blood in all cases, for valuable information may be gained by finding the malarial parasite, the typhoid-fever reaction, or the presence of leucocytosis. Some good authorities lay great weight upon leucocytosis as a sign of pyogenic infection, but there are so many other conditions in which it occurs that the greatest precaution should be taken before an increase in the white cells is accepted as evidence of wound infection. We have just mentioned the fact that it occurs immediately

after such operations as osteoclasis, where infection by pyogenic germs is out of the question. Further study of this subject, with a large series of cases, is very desirable.

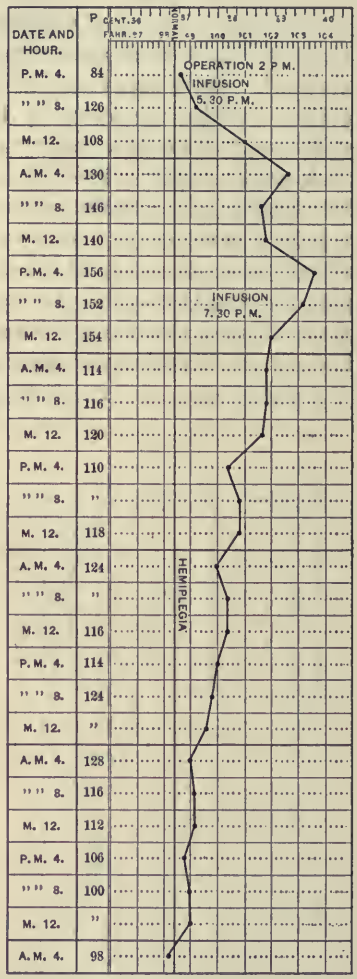
As an illustration of a pyogenic temperature take Fig. 1, a case of ventral fixation for complete prolapse of the uterus in a very fleshy woman, forty-seven years of age, operated upon at St. Luke's Hospital last December, in which the abdominal wound became accidentally infected. The rise of temperature began about twenty hours after the operation and progressed to 103° F. on the third day, being temporarily held in check by catharsis on the second day. The pulse kept pace with the temperature, running up to 120 and 130 beats to the minute. The symptoms gradually subsided after the wound had been freely opened. On the fifth day there was a leucocytosis of 21,800.

Figs. 2, 3, and 4 are illustrations of aseptic fever, of which I could show many more. Fig. 2 is from an abdominal hysterectomy for supposed malignant degeneration of the placenta, with a dead, poorly developed, three-months' fetus. The abdominal wound healed absolutely by primary union without a sign of peritonitis. The patient had had a temperature of 99° to 99.4° F. before operation. Sixteen hours after operation it had risen to 101⅘° F., then gradually fell, but did not fully reach normal for eighteen days. The pulse at no time rose above 80 and was only 70 when the temperature was at its highest, 101.6° F.

Case III. was an amputation of the forearm for recurrent epithelioma of the hand in a farmer, eighty-one years of age, but in vigorous condition. The wound, with very thin flaps, compressed firmly by the dressing, healed by first intention absolutely, and it would seem as if there could not have been a cavity large enough to cause any absorption. The operation produced no shock whatever. But the temperature rose at once and in twenty-four hours reached 103° F., the pulse then marking 70 beats to the minute, but subsequently reaching 78. A careful examination of the chest on the second day revealed some scattered subcrepitant râles, but there was no cough, and not change enough to explain the temperature (Fig. 3).

Case IV. was a rather poorly nourished but apparently healthy youth of nineteen, with bilateral floating kidney which occasioned him annoyance and positive pain. November, 1898, nephrorrhaphy was performed on the right side by the split-muscle incision of Abbe, similar to McBurney's incision for removal of the vermiform appendix. Chromicized catgut sutures were passed directly through the kidney substance. Within twelve hours the temperature rose to 101.2° F., with a pulse of 100. The lad has a naturally high pulse of 80 or more. The temperature fell very gradually (Fig. 4). This month (January, 1899) I operated by a similar method upon the other kidney, and the patient presented a temperature curve almost exactly identical with the one shown. It might be argued that the wound of the kidney by the needle might explain his temperature, but we have a chart almost exactly the same

FIG. 6.



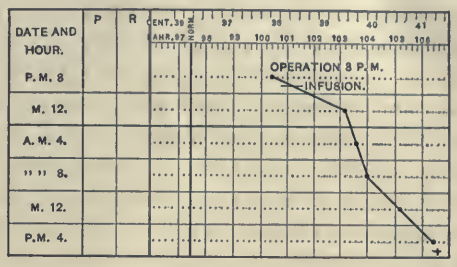
Temperature curve after amputation of the upper extremity.

as his, from a woman thirty-nine years of age, from whom we removed a small pedunculated myoma from the fundus uteri by a laparotomy, and then secured the uterus to the abdominal wound (ventral fixation). This patient had a temperature of 101° F. in eight hours, gradually subsiding, with a pulse of only 96, no sign of peritonitis, and primary union of the wound.

Fig. 5 shows another sort of absorption fever, a very common type. The patient was a colored woman, twenty-eight years old, with large and very

adherent double pyosalpinx, and a tubo-ovarian abscess on one side, which were removed, together with the uterus above the cervix, by a median laparotomy. The tubes burst and the pus freely escaped into the pelvis, but the rest of the abdomen was well protected by pads, and we ventured to close the wound without drainage after thoroughly

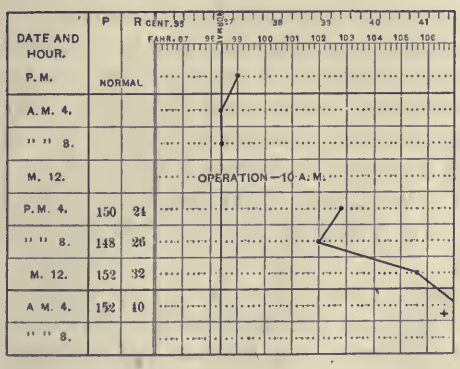
FIG. 7.



Temperature curve after abdominal hysterectomy.

wiping and washing out the pus. The stump of the cervix had been previously covered with peritoneum. The operation was difficult and tedious, and was followed by severe shock, but there was no sign of peritonitis, and the patient made a good recovery with absolute primary union of the abdominal wound. The temperature rose to 100.6° F. within six hours, but meanwhile the pulse had been reduced from 120 to 104 by an intravenous saline infusion and stimulants of various kinds; 101° F. was recorded about twenty-four hours after the operation with a pulse of 118. The fall of tempera-

FIG. 8.



Temperature curve after laminectomy.

ture and pulse was slow, lasting four or five days, but no bad symptoms were present.

Many other varieties of absorption fever could be quoted. In Case V. the temperature was probably due to the toxins of the pus in the tubes, absorbed by the peritoneum. Absorption of urine when a distended kidney bursts during nephrectomy, absorption of the bile after operations on the biliary passages when the wound is left open and packed, absorption of thyroid juice after thyroidectomy, all cause a rise of temperature. We have seen two cases of a fatal result after partial thyroidectomy for exophthalmic goiter, caused by acute thyroid poisoning from absorption of the juice of the gland, accompanied by very high temperature, in one case reaching 109° F. before death, with absolute asepsis of the wounds. Fever is often seen after operations for tubercular peritonitis and arthritis, caused by the absorption of the tuberculin toxin.

The peculiarity of all these absorption fevers, including aseptic fever with them, is their prompt beginning immediately after operation, whereas inflammatory fever requires twenty-four hours or more before it begins, as shown in Case I. A virulent infection, such as occurs in a poisoned wound (such as a surgeon might obtain in operating upon a septic subject) might cause an almost immediate rise of temperature, but we are discussing operation wounds in which great pains are taken to avoid infection, and in them the infection will be slight and slow in development. But it is not altogether safe to assume that the slight infection seen in operating wounds may not cause some of the pyrexia generally known as aseptic fever merely because the latter begins so promptly. The chill and sharp rise of temperature seen after urethral instrumentation is so sudden that it seems impossible to explain how it can be caused by infection, and yet it can be almost entirely prevented by proper cleansing of the urethra and sterilization of the instruments and surgeon's hands. There may be a nervous element in it, but the main cause must be infection, otherwise aseptic precautions would not so greatly influence its occurrence.

All the cases in which a sudden rise of temperature follows operation, however, cannot be charged to absorption, and a certain proportion of them seem to us to be caused by shock. The classical picture of shock with a subnormal temperature followed by a reactionary stage with a febrile movement after some hours, may be correct for accidental injuries, but it does not portray the symptoms observed in shock after modern surgical operations. This may be due to the great difference in the conditions of ancient and modern surgery. In old days an operation resembled an accidental injury in many points—the patient was conscious and endured great pain. In the case of accidents, the patient often receives a severe mechanical shaking and concussion, and generally lies somewhat exposed or has to be transported after the accident. These conditions

would tend to lower temperature. In the modern operating-room the patient is anesthetized after preliminary starvation and evacuation of the bowels and bladder, he is generally kept warm, and stimulation by strychnin, alcohol, and other means is supplied at once if the pulse weakens. There is little to cause a subnormal temperature (except prolonged etherization), and it is rather the exception to have it go below 98°. On the other hand, the anesthetic acts in a complicated manner on the bronchi, heart, kidneys, and stomach, and may easily produce effects which result in a febrile movement. The older surgeons warned against the danger of too free stimulation in shock for fear of a dangerous reaction, but although the heart may be exhausted by over-stimulation, we know that excessive dosage of alcohol, strychnin, and digitalis cannot elevate the temperature, and that the fever which they called reactionary fever is to be considered one of the nervous phenomena of shock. It is to be associated with the great ante mortem rise of temperature seen in many diseases, for instance in tetanus, and is a sign of nervous exhaustion.

Fig. 6 is an example of a high temperature apparently purely the result of shock. The right upper extremity was entirely removed (except the sternal half of the clavicle) in a married woman twenty-two years of age for sarcoma of the scapula. The patient was in profound mental depression from anticipating the loss of her arm and had a rather sluggish circulation. She lost only eight or ten ounces of blood during the operation, and the pulse remained slow, but became very compressible and feeble. A venous salt infusion was given about two hours after the operation. When she left the operating-room her temperature was 98.6° F., in four hours it was 99.2°, in eight hours 101°, and in twelve hours 102.6° F. The pulse-rate had risen continually from 90, 120 to 130. The temperature fell a little, but the pulse-rate rose to 140. In twenty-four hours the temperature was 103.6° F., and the pulse over 150. Another intravenous infusion was given, and both temperature and pulse-rate then slowly fell. On the third day the picture was complicated by complete hemiplegia of the left side, without change in pulse or temperature, probably caused by thrombosis slowly developing in the cerebral arteries, or possibly an embolism from a clot extending back into the carotid from the point of ligation of the third part of the subclavian. The wound was healing by first intention, but on the tenth day some infection was observed at the upper angle, probably a late infection, for the wound had been somewhat exposed at that point by slipping of the dressing, and the temperature had meanwhile become quite normal. It is seldom that one sees a patient with such a severe case of shock recover, and the house-surgeon of St. Luke's Hospital, Dr. Wadsworth, deserves great credit for the result. The usual picture of severe shock with high temperature after operation is that shown in Figs. 7 and 8, ending fatally.

Fig. 7 is the chart of an abdominal hysterectomy patient, a very tedious and severe operation with great shock, terminating fatally with a rapid rise of temperature to 106.4° F. Fig. 8 is the chart of a man thirty-one years of age who fell forty feet and sustained a fracture of the upper dorsal vertebræ. One week after the accident a laminectomy was done, removing the broken spines and arches of the fourth and fifth dorsal vertebræ, and the broken spines of the three bones above. There was an extradural clot which was removed, but the membranes were not opened. The autopsy showed that the cord was crushed at this level. Severe shock developed during the operation. Previously the temperature had been normal, but four hours afterward the temperature was 102.8° F., with a pulse of 150, and respirations of 24 per minute. In twelve hours the temperature reached 105.6° F., the respiration 32, and the pulse the same. Just before death the thermometer marked 107.4° F.

In Case VIII. the high seat of the injury renders it possible to imagine an irritation of some spinal or medullary heat center, but the fact that the dura was not opened and the only change made in the conditions produced by the accident itself was the removal of some depressed bone and blood-clot, made this highly improbable, especially as the man's temperature before operation had been normal. It is more reasonable to ascribe it to the shock, which was increased by the patient lying on his face during the operation. We have come to look upon a sudden and great rise of temperature as a frequent and very dangerous sign of severe shock after operation, for it is seldom that such patients can be revived.

In making the diagnosis of aseptic fever, then, we can distinguish it from shock by the good quality of the pulse, and we can readily exclude the other varieties of absorption fever (toxins, bile, thyroid juice), by the history of the case. We can distinguish it from inflammatory fever by its very early appearance, by the fact that the pulse remains relatively low, and the patient has few subjective sensations. He may be a little flushed and thirsty, but does not show so much depression or nervous excitement as is seen in inflammation. The character of the pulse is important as well as its rate, for in

aseptic cases it remains quite soft, and has not the quick beat and wiry tension so common in inflammation. The pulse will probably be the best guide in doubtful cases. The fall of aseptic fever is not so characteristic as its rise, for it may come down in two or three days, or it may continue for as many weeks a little above normal.

We must bear in mind, however, that there are many mixed cases. In a case of laparotomy for pyosalpinx, for instance, there may be severe shock, absorption of toxins from the sterile pus in the tubes, absorption of non-infected blood-clot in the abdomen, and finally accidental infection of the abdominal wound by a suture—the result being an immediate abrupt rise of temperature from shock, continued by the toxins, and maintained afterward by the inflammation of the external wound.

CLINICAL MEMORANDUM.

THE USE OF THYROID EXTRACT IN FIBROMATA—CLINICAL NOTE.[1]

BY MALCOM McLEAN, M.D.,
OF NEW YORK.

AS a member of the committee appointed to report on the use of fibroid extracts in fibromata uteri I can only give a brief note of my observations in the use of this remedy in eight cases.

Cases of myoma or fibromyoma were generally selected, which gave emphatic symptoms, such as pain, hemorrhage, or general nervous disturbance, all of these symptoms being present in greater or less degree. In two cases there was some pain but little hemorrhage and an unusual amount of mental irritation. In three cases pressure symptoms and other manifestations of pain were conspicuous. In four cases hemorrhage was present to a severe degree, and in five of the cases menorrhagia was very marked. Five of the women were married, of whom two had borne children. Three were unmarried and between the ages of twenty-five and forty. In those cases in which pain and pressure symptoms were prominent the tumors, with one exception, were from the size of a fetal head to a diameter of eight inches; and in the cases accompanied by excessive hemorrhages the size was rather less.

In the two cases where marked nervous disturbances were conspicuous the growths were small and the ovaries evidently implicated in the diseased conditions about the uterus.

Thyroid extract was administered in one case only three times a day, in amounts of 2½ grains. But in this case it was found that the cardiac disturbance was such as to demand a suspension of the remedy for a while. In all of the other cases one morning dose was administered of 2½ grains and continued regularly during a period covering from six weeks to five months. In two cases diminution in the size of the tumors was demonstrable and the symptoms of hemorrhage became so much ameliorated as to be quite remarkable.

Pain was diminished in two cases and the intervals of respite from pain in another were quite extended.

In the "nervous" cases the effect seemed to be decidedly beneficial, the patients becoming more calm and rational, hysterical symptoms abating markedly.

In several instances the tumor continued to grow and called for surgical intervention to give necessary relief.

Incidentally it was observed that the remedy had a salutary effect upon cases of post-operative nervous disturbance such as is found so uncomfortable after ablation of the uterine adnexa. In one case involving distinct melancholia, following removal of the appendages in an operation for dermoid cyst, the continual use of the remedy in the dose above mentioned for two months accomplished a complete cure or, at least, the patient became perfectly normal under most unpromising circumstances.

It is my opinion that much more extended observation, covering a large number of cases during a period of at least two years, is necessary to give a fair estimate of the real value of thyroid extracts in these diseases. The physical and pathological conditions of these fibromata vary so much, their history and progress, without any treatment whatever, differ so markedly that we should be careful not to jump too quickly at conclusions as to cause and effect. We all know how disappointing has proved the operation of oophorectomy for the arrest of fibroids, and yet, a few years ago it was advanced as a most valuable conservative measure.

To-day the administration of thyroid extract *seems* to be followed by distinctly beneficent changes in a sufficient number of cases to make it advisable, if not obligatory, for us to give our patients the benefit of its fair trial. But we must not make the mistake of erecting a hypothesis and then strive to force our observations to coincide thereto.

Certain it is that in the majority of cases requiring interference (and there are some which may be practically ignored) we should hold ourselves ready to give that positive relief which can only come from a well-directed, well-executed modern operation.

[1] Read at the twenty-fourth annual meeting of the American Gynecological Society, held at Philadelphia, May 23, 24, and 25, 1899.

MEDICAL PROGRESS.

Three Cases of Aortic Tubercle.—BLUMER (*Albany Med. Ann.*, May, 1899) reports a third case of tubercle on the intima of the aorta, two similar cases having been previously reported by him in the *American Journal of the Medical Sciences* for January, 1899. In all three cases the source of the tubercle was evidently in the blood, as there was no direct extension of the process from an adjacent focus. In the third case in particular, the tubercle was still a small one, and nearly its whole center was composed of fibrin, so that the microscopical appearances seemed to support the theory that such a tubercle is thrombotic in origin.

A Practical Point in Intestinal Suture.—FRAZER (*Lancet*, May 13, 1899) suggests a simple method to insure accurate union along the mesenteric line, in suture of the small intestine. His plan is to rotate the two ends of bowel for a slight distance in opposite directions, so that there may be room for two or three stitches between the cut ends of the mesentery. This insures that there shall be no place in the suture line where there shall not be at least one serous surface involved in the suture. The procedure can be carried out with any end-to-end anastomosis.

THERAPEUTIC NOTES.

The Treatment of Carbuncles.—CREEL (*Cincinnati Lancet-Clinic*, April 29, 1899) strongly recommends the use of ecthol, both for internal medication, and as an external application. He employs the drug internally in doses of a teaspoonful every two hours, continuing the remedy until the healing has been completed, gradually prolonging the interval between the doses. He claims that ecthol is a corrector of blood dyscrasia, and in the best sense an antipurulent. The local treatment consists in free incision and thorough evacuation of the pus-cavity by scraping, thus removing all the dead and inflamed tissue. The wound is then carefully cleaned with peroxid of hydrogen and dressed with absorbent cotton saturated with ecthol. This dressing should be changed every four to eight hours. Creel has treated fifteen cases of carbuncle in the manner here outlined, and claims that the duration in each case has been gratefully shortened and the convalescence of the patient improved.

Cure of a Bad Paraphimosis by a Simple Method.—LEWIS (*North American Med. Rev.*, April, 1899) was called upon to relieve a patient with a bad paraphimosis of many hours' duration. A bandage was wound as tightly around the penis as the feelings of the patient would permit. This was saturated with lead and opium solution, and a rubber bandage applied outside of it. The following day the swelling had diminished somewhat, but reduction of the prepuce was still impossible, and the treatment was continued for another day. By that time the edema was so far pressed out that reduction in the usual manner was easily accomplished.

Treatment of Certain Summer Diarrheas of Infancy.—STENGEL (*North Car. Med. Jour.*, April 20, 1899) says that a certain class of summer diarrheas of infants are amenable to prompt and vigorous treatment. The cases are usually sudden in onset, and marked by some regurgitation of food, high temperature, copious brownish, then greenish and finally often watery stools and rapidly developing signs of collapse. The external temperature is low, while that in the rectum is high. The child moans, lies with upturned eyes, and occasionally gives a sharp cry like that heard in meningitis. Such cases are classified by him as entero-colitis. The gravity depends not on the extent of the intestinal lesion, but on the amount of the intoxication. The most important part of treatment is the flushing of the colon, and the use of tepid baths. These measures will cause the temperature to fall, and the symptoms to abate. A long catheter is passed into the bowel, and one or two quarts of water at a temperature of 85 or 90 degrees allowed to flow into the bowel. Two or three douches may be required daily, though in other cases one may suffice. Small doses of opium, not to check the diarrhea, but to allay nevous symptoms, are serviceable in the early stages of the disease. Following are two useful prescriptions:

℞	Bismuth subgallat. . .	gr. xxix-xxxvi
	Pulv. opii	gr. ss
	Pepsini	gr. vi-xii.

M. Div. in pulv. No. XII. Sig. One every four hours alternating with the following:

℞	Hydrag. chloridi mitis . .	gr. ss
	Cerii oxalat.	gr. ii
	Sacch. alb.	q.s.

M. Div. in pulv. No. XII. Sig. One every four hours.

Treatment of Diarrheal Diseases in Children.—UPSHER ("Keating's Cyclopedia," Vol. V.) advises in acute milk infection, the entire withdrawal of milk from the diet and thorough lavage of the bowel with warm water, to which borax is added if there is much mucus present. When the patient is in a state of toxemia, large quantities of a saturated solution of boric acid are to be used once or twice a day for washing out the bowel. When an astringent is indicated, the best agent to employ is a one or two-per-cent. solution of tannic acid, and from ¼ to ½ a grain of calomel may be given every two hours for three or four doses. When stimulants are required, either brandy or whisky may be given according to the indications. Nervous symptoms are to be met by morphin hypodermatically in doses of $\frac{1}{100}$ of a grain for a child of one year, to be repeated cautiously if necessary, and an ice-cap applied to the head. No food is to be allowed other than small quantities of Valentine's beef-juice in ice-water. In some cases, if food be entirely withdrawn for some hours, and small, frequently administered quantities of some feebly alkaline, sparkling water be given, the results are excellent. The return to a milk diet must be slow and cautious. In subacute milk infection, the child should have cracked ice to relieve its thirst and be given plenty of fresh air. Castor oil is to be given if there is evidence of intestinal irritation. Broths or albumin water may be substituted for milk, or all food be withdrawn. Calomel in doses of ¼ to ½ a grain, combined with precipitated chalk should be administered when the stools are sour, and continued until the consistence of the stools is better. Then astringents—kino, catechu, or logwood—are to be given in combination with chalk-mixture. Free lavage of the bowel with a weak salt solution should be employed every day. If much soreness or tenderness of the abdomen is present, hot spice fomentations are to be applied, or enemata of thin starch water and laudanum are to be administered. If stimulants become necessary, iced mint julep is the best form for use. If the disease remains obstinate, the child should be removed to the air of the mountains, if possible.

MUSIC AND NEUROTIC CONDITIONS IN YOUNG GIRLS.

IN the first instalment of her reminiscences, at present appearing in the *Atlantic Monthly*, Mrs. Julia Ward Howe expresses herself very clearly concerning the possible bad effects of music upon the sensitive dispositions of delicate girls during the developmental period. Although an ardent lover of music herself she recalls vividly the reaction she experienced after devoting herself to concert music. This reaction, to use her own expression, "was often very painful and induced, at times, a visitation of morbid melancholy, which threatened to affect my health." She is very outspoken in her warning regarding the danger there is in music for those who are deeply affected by it and considers that "regard should be had to the sensitiveness of youthful nerves and the overpowering response they often make to the appeals of music."

In a recent number of the *British Medical Journal* attention is called editorially to some lately published observations of Dr. Waetzhold as to the effect the devotion of considerable time to the piano has upon young girls. Of 1000 girls who devoted themselves to piano instruction 600 presented more or less grave signs of chlorosis, while many of them had all the pronounced symptoms of that affection. Of 1000 girls on the other hand who, living amid similar environment, had not been taught music, only 200 developed any chlorotic symptoms. Of course the exactions of a musical education are not the only factors that enter into the etiology of the chlorosis in the large number of cases of the first group. It is clear, for instance, that the girls who have the time and inclination to devote themselves to music are apt to be the more delicate and sensitive. Even taking this into account, however, Dr. Waetzhold's observations and conclusions are very striking and furnish a certain groundwork of actual experience for the feeling of opposition to too early musical training, which has been growing in the medical profession for some time.

The impression that devotion to music on the part of young girls is often harmful by no means finds its first expression in these communications. Especially have English medical men insisted on its evil results. There is undoubtedly too much stress laid upon musical training in the education of young girls. Though in after life most of them faithfully give up any serious attention to it, practically all of them must have the training. For the healthier girls this constitutes no source of danger. For the more delicate ones it often means a series of poignant appeals to their already superexcited and irritable nervous temperaments. For them the reaction from the exaltation of musical enjoyment or execution is especially harmful and it comes at a time when serious developmental calls upon the organism have put the nervous system in a state of unstable equilibrium, in which it reacts exaggeratedly to all external stimuli. There is no doubt that the foundation of many a persistent neurasthenia in after life can be traced to the nerve storms incident to musical training at a time when Nature demanded rest, not excitement.

There is no special reason why the burden of musical training should be foisted on every young girl at this period. And for those that have real musical talent delay will serve the very useful purpose of enabling the individual to take up the subject more seriously when greater maturity and, hap-

pily, established health have given the requisite endurance. Fortunately for womankind some of the greatest teachers of vocal culture are discovering and proclaiming that the best results are secured by delaying the training of the female voice till the functions of womanhood have been fully established.

ECHOES AND NEWS

Dr. Wiener Appointed.—Dr. Joseph Wiener, Jr., has been appointed adjunct-attending physician to Mt. Sinai Hospital.

Appointments at Bellevue Hospital.—Dr. George Roe Lockwood has been appointed visiting physician, vice Jacobi resigned. Dr. Henry A. Griffin has been appointed assistant visiting physician in the Fourth Division.

Koplik's Spots.—Dr. G. Lovell Gulland in the review of current literature on the infectious fevers for the June number of the London *Practitioner*, says: "In the early diagnosis of measles the presence or absence of Koplik's sign which I described in last year's review will be found very valuable as I have had ample opportunity of ascertaining during a recent epidemic in Edinburgh."

Bubonic Plague in the East.—Seven cases of bubonic plague have been observed in the Greek Hospital at Alexandria, Egypt. All of the patients are progressing favorably. The peculiar circumstance is that all of the patients were inhabitants of Alexandria, had not been absent from the town, nor had they had any relations with travelers coming from places where the plague existed. It is therefore inferred that there may be other cases in the town. What is known as "sanitary smuggling" goes on regularly along the shores of the Red Sea and Mediterranean. Quarantine against Alexandria has been established at most Mediterranean ports.

A New Bacteriologic Laboratory for Delaware.—The State Board of Health of Delaware has established a laboratory in Newark, Delaware, at the State College, for the purpose of aiding the physicians of the State in the diagnosis of typhoid fever, diphtheria, tuberculosis, and hydrophobia, as well as other diseases which can be elucidated by examination of urine, blood, stomach contents, etc. The aim will also be to carry on original investigations with a view of furthering the progress of sanitary science in general, and bacteriology in particular. Professor Chester, the State Bacteriologist, has been appointed director, and Dr. A. Robin, bacteriologist and pathologist to this laboratory.

A Far-reaching Anatomical Dislocation.—During the course of the discussion at the recent meeting of the American Medical Association at Columbus, on the motion to have the report of the nominating committee hereafter kept absolutely secret until its announcement to the Association at the general session at which it is to be acted upon, one of the speakers who was insisting that such a motion was, for many reasons, inadvisable, said that "the Association might rest assured that the members of the Nominating Committee had backbone enough to keep their mouths shut without any bolstering or splinting resolutions," whereupon one of the oldest members of the Association, a matter-of-fact modern Syracusan, remarked *sotto voce* that this was the first he knew of any functional or anatomical connection between the vertebræ and the maxillæ.

Faith-Healer Convicted.—Mrs. Maria Müller, the so-called sympathetic healer, who treated twelve-year-old Dora Kranz for gangrene in the left foot, was tried on June 5th, before Judges Fitzgerald, Keady, and Fleming, in the Court of Special Sessions in Brooklyn, and was convicted on the technical charge of practising medicine without a license and sentenced to five-months' imprisonment. Mrs. Müller treated Dora Kranz by means of a "black salve," the application of which was accompanied by incantations. Finally, after much valuable time had been lost, the child was taken from her hands and removed to the Eastern District Hospital, where her limb was amputated above the knee-joint on May 6th. The child is now well. This Mrs. Müller has no associates, and she alone is responsible for the evil results of her work, but there are thousands upon thousands of "Christian Scientists," members of an organization thoroughly equipped for the performance of iniquitous practices, who are daily engaged in precisely the same unlawful business as this of which Mrs. Müller has been found guilty. Why are these people not convicted?

Obituary.—Mr. Robert Lawson Tait, F.R.C.S., who died suddenly on June 13th, as announced in our last issue, was born in Edinburgh May 1, 1845, studied at Edinburgh University, and was made a licentiate of the Royal College of Physicians and Surgeons of Edinburgh, in 1866. In the year 1871 he was appointed visiting surgeon to the Birmingham Hospital for Women, and it was during his term of service at this institution that he did the surgical work and gained the experience that made him one of the foremost gynecologists of the world. He was also professor of gynecology in and president of Mason College. Mr. Tait was a bold surgeon, and, profiting by the experience of his predecessors, Spencer Wells and Keith, extended largely the field of abdominal surgery. He was the first to recognize and bring prominently before the profession the disease of the Fallopian tubes which we know so commonly as salpingitis, and gave to the profession a rational and satisfactory key to the pathology of ectopic gestation. Upon these two important discoveries and his boldness in abdominal surgery must rest the permanency of his reputation. He was a man of strong personality, and a fighter in every nerve and fiber of his being. His misfortune was that he was quite as apt to be wrong as right on all questions of popular interest, and he antagonized the profession of Great Britain by his advocacy of the fallacies of the antivivisectionists. His unflagging opposition to Listerism was also a source of irritation to the medical

profession. It is difficult to account for the vagaries of a mind which thought so clearly upon strictly scientific subjects.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fiftieth Annual Meeting, Held at Columbus, Ohio, June 6-9, 1899.

(Continued from page 784.)

GENERAL SESSION.

FOURTH DAY—JUNE 9TH.

DR. I. N. LOVE of St. Louis moved that a part of Section 12 of the Report of the Executive Committee, read and adopted at a previous meeting, which provides for the printing of a list of the members of the Association in conjunction with the revised Constitution and By-Laws, be eliminated, saying that after thorough discussion of the question, the Board of Trustees had concluded that it would be detrimental to the interests of the Association to have such a list published in pamphlet form. The motion was seconded, after which a free discussion followed. The President stated that there was a standing resolution which provided for the publication of a list of the members triennially. The President put the motion of Dr. Love to eliminate a part of the section mentioned, and it was carried. Some doubt being expressed by one or two of the members as to whether this motion was really carried or not, another motion was made and carried to reconsider the vote taken on Dr. Love's motion, when Dr. Love moved that the whole question be laid upon the table. Carried. It is understood now that the list of members will be published triennially, as heretofore, in the *Journal*, but not in pamphlet form, as was recommended by the Executive Committee.

The Executive Committee in its report suggested to the Association the desirability of taking action to secure an appropriation from the United States government to meet the necessary expenses of its delegation to the Congress for the Prevention of Syphilis and the Venereal Diseases, to be held in Brussels, Belgium, in September next, and on motion, the suggestion of the Committee was concurred in.

The Executive Committee asked permission to appoint another member on the Committee on Gold Medal in the place of the member from San Francisco, whose term of office expires. On motion, this request was granted.

The Executive Committee offered the following resolution and recommended its adoption with reference to the work of the Sections: Resolved, That no paper shall be placed on record for the consideration of any Section unless an abstract or a precis of not less than fifty, or not more than 300 words accompanies the title, and is placed in the hands of the Chairman or Secretary of the Section at least thirty days before the time of meeting of the Section. On motion, the recommendation was concurred in.

Another resolution was passed to the effect that hereafter no name shall be printed on the program unless the title of the paper is announced. The Executive Committee found twenty or thirty names throughout the program without the titles of papers being announced.

The Committee on the Senn Medal reported through a member that it had not received any essay of sufficient merit during the year to award the medal.

DR. C. E. RUTH of Iowa moved that a vote of thanks be extended to Dr. Atkinson for his long, faithful, and efficient services, and that all uncomplimentary reflections cast upon him and his work be expunged from the records of the meeting. Carried.

DR. GEORGE M. GOULD of Philadelphia reported on behalf of the Committee on Prize Competition for Meritorious Scientific Work that it had received no essay for which it recommends the award of the prize. On motion, this report was received, the Committee continued, and instructed to make efforts to secure essays for another year.

The Secretary read a report from the Judicial Council in regard to the appeal of Dr. Charles G. Cannady of Roanoke, Virginia, against the decision of the Judicial Council of the State Medical Society of Virginia, that it had instructed their Secretary to notify all parties concerned to appear before the Judicial Council of the American Medical Association at its next meeting, when this matter would be adjudicated.

Relative to the matter of appeal of Dr. W. F. Barclay, the Judicial Council referred this matter back again to the Medical Society of the State of Pennsylvania for adjudication.

The Judicial Council also reported on the resolution which was adopted at the Denver meeting in 1898 and referred to it, stating that it was unconstitutional, inasmuch as it violated Article 2 of the Constitution relating to membership.

The Secretary announced the names of delegates to the British Medical Association, and also to the International Medical Congress.

The following amendment to the Code of Ethics, offered by DR. Q. C. SMITH of Austin, Texas, was read: To amend Paragraph 9, Article 4, of the Code of Ethics of the American Medical Association. Resolved, That attending physicians are entitled to charge a consultation fee for each consultation in addition to visit fee, equal in amount to that ordinarily charged in similar cases by consulting physicians residing in the same city, locality, or community where the service may be rendered. (To lie over one year.)

SECTION ON PRACTICE OF MEDICINE.

THIRD DAY—JUNE 8TH.

DR. GEORGE BOODY of Independence, Iowa, read a paper, entitled

NOTES ON TWO EPIDEMICS OF TYPHOID FEVER IN THE IOWA HOSPITAL FOR THE INSANE.

The conclusions drawn from this paper were as follows:

1. Cases of inverted typhoid fever are comparatively quite rare and the subject is deserving of thorough investigation as often and wherever an epidemic occurs, with

the object in view of determining the relative frequency of the disease; and in doing this all the methods for confirming the diagnosis should be rigidly applied in each suspected case. In the two epidemics reported it occurred but once in forty-three cases.

2. Of the patients who recovered 25 per cent. showed marked improvement in nutrition and muscular strength, while the remaining 75 per cent. only reached their former condition in these respects. Compared with previous observations it would seem that insane patients with typhoid fever do not show such a degree of improved nutrition after recovery as do those without the mental complications. The patients who improved mentally showed a corresponding favorable change in nutrition, and those whose mental status returned to normal made the most startling and striking changes in this direction. This may not be true except for those two epidemics, but in them is beautifully illustrated the profound influence that the mind exercises over the processes of nutrition and assimilation.

3. Of this number, 16⅔ per cent., all dementias, seemed brighter mentally but relapsed as soon as convalescence was completed, except one case, which continued on some little time longer; 2⅞ per cent., all melancholias, made partial recovery, and one is fairly able to resume the ordinary duties of life; 5⅝ per cent., one a case of katatonia and one of acute mania, regained their former mental status. The behavior of the cases of dementia would lead one to think the typhoid had some slight influence upon the mental condition, but it is of no value since the relapse occurred so soon. Such cases are always beyond the possibility of recovery. The prognosis in melancholia is favorable for some improvement and it is only fair in this one case to assume that the fever played no important rôle in the partial recovery since the change was no more than was predicted previous to the fever. The prognosis for recovery in acute mania is generally favorable; and in this case it was regarded as a specially hopeful case some time before the attack of typhoid. The recovery was rapid and complete and took place at about that period in the course of the mental disturbances at which a change might be expected had he not had the fever, hence one would not be justified in giving to the latter any prominence as a curative factor in connection with the insanity.

DR. J. L. TAYLOR of Wheelersburg, Ohio, read a paper, entitled

A QUARTER OF A CENTURY'S EXPERIENCE WITH TYPHOID FEVER, WITH SPECIAL REFERENCE TO SOME UNSOLVED PROBLEMS.

In the region of the Ohio Valley in which Dr. Taylor has practised for twenty-five years, typhoid fever has become recently endemic, instead of malaria, as formerly, thus raising the question whether the plasmodium has yielded to a bacillus of superior power. The typhoid came in the form of violent epidemics which gradually grew less malignant and have now assumed an endemic form, characterized each year by varying types. It rises independent of the water-supply and its course of development is opposite to that of surface drainage. No recognizable sources of infection can be traced.

DR. ALFRED C. HAVEN of Lake Forest, Ill., read a paper, entitled

A NEW BATH FACILITATING HYDROTHERAPY IN PRIVATE PRACTICE.

The bath he devised consisted of a canvas strap, encircling the headboard of the bed, the ends of the canvas belt fastened by a simple catch, so that the belt may be drawn taut. Another canvas belt of similar design for the footboard, two rings, twenty-six inches apart in each canvas strap, a rubber sheet hemmed at both sides, in which slip ropes, on the ends of which are four snaps. The patient is rolled on the sheet, the four snaps are caught in the four rings, and the tub is ready for the water. It is emptied by lowering one corner, and finishing with a small piece of rubber hose used as a siphon, When not in use it folds in a small cotton bag.

In his judgment there is no excuse for the busy practitioner neglecting a remedy that will do for his patient what no other agent will do. This common, everyday, despised, neglected, yet potent remedy, *water*, should be more often used, and can be used by every physician who has the good of his patient at heart.

DR. L. F. ROUSH of New Haven, W. Va., read a paper, entitled

THERAPEUTIC PRINCIPLES ESTABLISHED IN TYPHOID FEVER.

He took the ground that certain agents do have an influence, specific in nature, not only in mitigating the severity, but also in abridging the duration of the disease, with a consequent lessened mortality. The principle of action is to keep up a moderate free catharsis, especially with calomel; but other cathartics may be used which will change the action of the bowels which almost always takes place sooner or later in the disease in the way of a free diarrhea, to that action which is characteristic of the medicine given. By this method the toxin poisoning which always comes on is in a measure prevented, and as a consequence the symptoms are greatly mitigated. This treatment by catharsis he especially insisted on during the first six or eight days. During the further progress of the disease, if the characteristic diarrhea comes on again, the action of medicines is sought for. The salicylate of ammonium is given in solution in 5-grain doses every two hours day and night from the beginning to the end of the fever, *except* when the temperature falls below 102° F. in the evening, and then it is only given during the day. Sponging the patient with cold or warm water frequently he insisted upon; the temperature of the water should be determined by the patient's wishes. He favored the free administration of water, as well as giving tea or coffee should the patient desire it; he also favored the giving of fruit-juices from the beginning. Milk he preferred above all other foods if it agreed with the patient. He made a point against the use of the bed-pan, believing it is detrimental to the patient, and that if the patient is properly cared for and treated he will have plenty of strength to get up

without danger from intestinal perforation or from heart failure. He asserted that no patient with much tympanites is properly treated, and he considered this symptom as the one having the most evil omen of all others. It is the evidence of the continued multiplication of the typhoid bacillus and the poisoning which results; and every effort should be made by free catharsis and strychnin internally, and turpentine stupes externally to get rid of it. The author claimed that he can and does diminish all the symptoms, and greatly abridges the duration of the disease and points, as the result of his work in a series of 143 cases, to a mortality of 3½ per cent. He sees no use in decrying the medicinal treatment of this disease by any man, whether he stand high or low in the profession.

DR. E. C. BRUSH of Zanesville, Ohio, read a paper, entitled

THE USE OF ACETANILID IN TYPHOID FEVER, WITH A REPORT OF SIX CASES.

The cases reported were those of soldiers sent home, last August and September, from Camp George H. Thomas, Chickamauga, Ga. They were treated in the Zanesville Hospital. The only antipyretic used was acetanilid, which was efficient and effective. The directions given the nurses were to give 3 grains of acetanilid every three hours, whenever the temperature was over 101° F., until it fell to that point or lower. If, after giving a dose, the temperature showed a decided tendency not to fall a second dose was given in two hours. Nearly all the patients broke out into a good perspiration after the first dose. The shortest run of the fever was 24 days, the longest 35, an average of 30 days. All but one of the patients recovered; one died during the fourth week from hemorrhage from the bowels.

DR. GEORGE M. GOULD of Philadelphia read a paper, entitled

A FALLACY OF THE REST-CURE TREATMENT.

Thousands of patients are being systematically treated for functional diseases of the body that are due to diseases of the eyes, and thousands are being treated for organic diseases of the body which were originally caused by ocular diseases. In no class of cases is there such great reason to look after the eyes as in hysteria and neurasthenia, which, by a morbid philology, we allow to be called "nervous." Dr. Gould did not contend that in the majority of cases requiring the rest cure the origin or chief factor of the disease is eye-strain, or that the rest-cure is unnecessary even in cases of reflex ocular neuroses, but he emphasized these points: (1) It is positively criminal negligence to ignore eye-strain in any case requiring the rest-cure treatment. (2) It is not enough to know that one oculist has examined the eyes, especially if it has been done without a mydriatic. (3) To mydriaticize a pair of eyes for a month or two would often do more good, would certainly be more logical, would be an infinitely better means of differential diagnosis in obscure nerve trouble and functional nutritional diseases, than to put the patient's body to bed for the same time.

DR. G. BETTON MASSEY of Philadelphia read a paper on

THE CATAPHORIC TREATMENT IN CANCER; A FURTHER REPORT.

He gave a summary of cases. Since the paper previously read before the section twenty-six cases of carcinoma and sarcoma had been subjected to this method of treatment in some manner, many of them extremely bad cases—some forlorn hopes. Of these cases 10 were operable cases and these resulted as follows: Cured, 8; probably cured, 1; failed to cure, 1. Of the inoperable cases there were: Cured, 2; probably cured, 1; failed to cure, 13. He concluded as follows:

1. The massive diffusion of nascent mercuric salts, within a growth of the body, by an electric current, constitutes a novel therapeutic procedure of great value in the destruction of foci of malignant or non-malignant germ-growths when said growths are so situated as to permit of penetration and drainage.

2. This cataphoric destruction of the germs of a primary cancerous growth in situ, including outlying colonies and so-called roots of prolongation, permits the preservation of the unaffected portions of the organ in which it is situated and offers greater security against the recurrence of the growth than efforts to remove the living malignant organisms by cutting operations.

3. While the cataphoric method may be employed as a palliative in non-operable malignant growths and may at times cure them, its chief value is in the total destruction of the malignant germs in the early stages of primary growths and in the same stages of purely local recurrences.

DR. A. A. YOUNG of Newark, N. Y., read a paper on

RHEUMATISM; ITS ETIOLOGY, PATHOLOGY, AND TREATMENT.

He stated that the conclusion had nearly, if not quite, been reached that there is a rheumatoid bacillus. A clear conception of the etiology of rheumatism can only be reached from a correct knowledge of the biology of this specific bacillus. The disease is constitutional, not local. We are forced to the conclusion that rheumatism is an acute, febrile, specific affection induced by the presence and growth of the theoretical rheumatoid bacillus. This theory is strengthened by the many points in which it resembles other known infections. Heredity has also its bearing upon it.

The pathological changes which follow in the wake of developing rheumatoid bacilli are numerous, and confined primarily to the blood; secondarily, to the joints, tendons, and tendinous sheaths. The blood is the medium which carries this morbific agent, a micro-organism, which has its development in some constituent of the blood, to various parts of the body. At its earliest manifestation blood changes are found. There is an increase of the fibrin-producing agent and a loss of alkalinity, shown by the increased tendency of the blood to coagulate. There is also a decrease in the number of red blood-corpuscles. Though the blood is alkaline there is a considerable increase in the amounts of urea and uric acid. The tend-

ency to the formation of fibrinous clots is the primary result of the uric-acid diathesis. The urine becomes highly colored, scanty, of high specific gravity, is markedly acid on cooling, and deposits the amorphous urates and uric acid, while there is little if any increase in the amount of the urea formed. This change is dependent upon the development of the rheumatoid bacillus. The joint involvement is likely to be produced from the primary blood infection. All the tissues surrounding the joint are attacked and the synovial fluid is poured forth very abundantly, and is acid, which indicates a blood-change. The membranes in and about the invaded joints assume greater vascularity and thickening. The articular surfaces become somewhat roughened from the increase of cartilaginous cells. Inflammation is Nature's way of eliminating foreign material. When this is impossible she covers up and imprisons in its nidus the fully developed rheumatoid bacillus, which, if not destroyed, is prevented from further reproductive process.

Three elements must be recognized in the treatment of rheumatism. The first is the deposition of the rheumatoid bacillus into some suitable culture medium within the body, presumably the blood; second, the bacillus must assume an active stage of development, must pass through its biological changes from the germinal vesicle to the perfect bacillus; third, the conditions or so-called sequelæ existing after the active inflammation has subsided. The first condition can only be met by prophylaxis; better hygienic, sanitary, and dietetic conditions. The second condition requires more careful attention. There is a relation existing between the biology of the bacillus and uric-acid formation. It remains to be demonstrated whether uric acid is the product of bacilli development or whether germ development depends upon the amount of uric acid present at the time of infection and subsequent to it. The writer inclines to the latter view and bases his treatment upon it. The salts of soda, especially the salicylates, change the form of the uric acid, which seems to effect an improvement in the rheumatic condition. While the irritation is lessened the uric acid is not eliminated and hence the liability to recurrence. Immunization may be the treatment of the future. Medicinal agents must come in direct contact with the germ and be its immediate destroyer, or they must eliminate from the system those elements upon which germ life and growth depend. A modification of the uric acid must modify the disease in like ratio. Pilocarpin, which produces perspiration, marked salivation, and increases all the excretory functions of the body, and after the use of which uric acid and urates may be found in the excreta, is a very effective remedy. The author positively denies that it has any injurious effect upon the heart. To promote uniformity and efficiency the hypodermic method is by far the best; the size and frequency of the dose must be left to the physician. In the treatment of those conditions known as sequelæ we must endeavor, as far as possible, to approach immunization, by eliminating uric acid, upon which germ life and growth depend.

DR. CHARLES G. STOCKTON of Buffalo read a paper on

ACCIDENTAL OR SPURIOUS ALBUMINURIA.

This term is employed to include those cases of albuminuria in which albumin finds its way into the urine from the pelvis of the kidneys, from the ureters, the bladder, and the genitalia. He stated that accidental albuminuria is not to be disregarded, and the source of the albumin should always be most carefully examined into. It should also be reiterated that when albumin is found originating in the bladder, the ureter, or the pelvis of the kidney, the urine should be frequently studied to make sure that infection is not invading the more important structures of the kidney.

DR. W. C. PURDEY'S paper on

THE QUANTITATIVE ESTIMATION OF ALBUMIN IN THE URINE

was read by DR. ARTHUR H. ELLIOTT. He considered the gravimetric method, Tanret's titration method, with the double salt of iodid of mercury and potassium, with mercuric chlorid as the indicator, the time reaction of Brandberg, the differential density method of Lang, Hoebler, and Bernhardt, Esbach's volumetric method, and his own centrifugal method, giving both volumetric and gravimetric percentages, with error not exceeding 0.02 of 1 per cent. The clinician demands something more available and accurate than those methods now used. The speaker's process consists of the following steps: Precipitation of the albumin in carefully graduated percentage tubes of 10 c.c. of the urine by means of 2 c.c. of 50-per-cent. acetic acid and 3 c.c. of 1 to 10 aqueous solution of potassium ferrocyanid; after mingling the urine and the reagents the tube should stand for 10 minutes to insure precipitation of the albumin. At the end of 10 minutes the percentage tubes are placed in a centrifugal machine, the radius of which, with tubes in position, must be exactly 6¾ inches. The tubes are revolved for exactly 3 minutes at a uniform speed of 1500 revolutions per minute. The tubes are next removed and the amount of albumin is read off in bulk percentage, which, by the aid of an accompanying chart, is converted into percentage by weight and grains per fluid ounce.

DR. CHARLES G. STOCKTON of Buffalo read an interesting paper on

CHOLECYSTITIS: ITS RELATIONS TO ANGIOCHOLITIS AND CHOLELITHIASIS.

There is a series of ascertained facts that is not to be disposed of by the simple statement that gall-stones are present and for some unknown reason migrate from the gall-bladder, and they are: (1) In a large number of post-mortems gall-stones are found present without the history of jaundice, hepatic colic, or other liver troubles. (2) In post-mortems of those dying from biliary obstruction there sometimes have been found no calculi in the biliary ducts, but one or two very large calculi in the gall-bladder, quite too large to engage in the cystic duct and, therefore, not directly guilty of the attack. (3) Obstruction of the biliary passages is not infrequently found to be complete when no gall-stone

is found present in any of the biliary passages. (4) A calculus is sometimes found in the common duct without jaundice, colic, or other symptoms of obstruction. (5) When gall-stones are found post-mortem, or in operations *in vivo*, and there have been recent symptoms of hepatic colic and jaundice, whenever these have been searched for, evidences have been found of cholecystitis or angiocholitis, or both. These observations seem to point to the fact that gall-stones may be innocent tenants of the gall-bladder; that attacks of colic may occur when the gall-stones are too large to engage, or when there are no gall-stones at all; that an inflammatory process of the biliary passages seems in some way related to the attacks of gall-stone colic. Operative procedure has for its object the cure of the cholecystitis. Undoubtedly, in a certain proportion of cases the inflammation includes the dangerous complications of chronic angiocholitis, hepatic abscess, and peritonitis, which, with the assistance of surgery, might have been prevented; but even in the cases in which operation is demanded a carefully considered plan of treatment should be applied, not only to assist in recovery, but to prevent recurrence.

FOURTH DAY—JUNE 9TH.

The proceedings were opened by the reading of a paper, entitled

A FURTHER REPORT ON THE USE OF ANTIPHTHISIC SERUM, T. R. (FISCH), IN TUBERCULOSIS,

by DR. A. MANSFIELD HOLMES of Denver, Colo.

In well-advanced cases the serum invariably causes an elevation of temperature, which occurs three to six hours after administration. There is also experienced from the prolonged use of the serum a more or less extensive infiltration of the areas used for injections; also, there is produced a depressing effect, which is relieved by a short period of rest. Sooner or later the lymphatic glands become tender and enlarged; it usually comes on within two or three days. He referred to the tuberculin test as a means of diagnosis. The advantages are twofold: (1) it serves as a reliable means of estimating the degree of convalescence, and (2) it serves as a safe and positive means of diagnosis when bacilli are not found in the sputum or excreta. He thought the study of the blood count is of greater importance as an aid in diagnosis than the study of the sputum. When the patients are experiencing the good effects of the serum there is invariably an increase in the percentage of young lymphocytes of the blood. On the other hand, in rapidly declining tuberculous cases there is a progressive decline in the percentage.

OUR TUBERCULOUS PATIENTS: WHOM TO SEND AND WHERE TO SEND THEM.

DR. J. FRANK MCCONNELL of Las Cruces, New Mexico, read a paper with this title.

In cases of fibrosis or fibroid phthisis he considered it a great error to send patients to high altitudes; they should be sent to moderate altitudes, or to the sea level. He especially called attention to Southern New Mexico, where there is an altitude of 3800 feet, a valley surrounded by mountains, and with little rain, averaging less than eight inches. It is a land of perpetual sunshine, 248 days in the year.

SEROTHERAPY, COMBINED WITH FAVORABLE CLIMATIC AND STRICT HYGIENIC SUPERVISION OF THE PATIENTS. REPORT OF 106 CASES SO TREATED DURING THE YEAR 1898,

was the title of a paper by DR. C. P. AMBLER of Asheville, N. C.

The use of antistreptococcic serum has proved of little benefit in his hands. The use of the antitubercle serum is indicated in incipient cases. It is contraindicated in cases of miliary tuberculosis, extensive softening, high pulse, marked emaciation, or in those in whom there is a decided hereditary history. The injections should not be used when the temperature reaches a higher point than 101° F. daily.

DR. EDWARD OTIS of Boston read a paper, entitled

THE VALUE OF THE TUBERCULIN TEST IN THE DIAGNOSIS OF TUBERCULOSIS.

His conclusions were as follows: (1) The tuberculin test indicates early tuberculosis by a general reaction before it can be detected by other methods, except the X-ray, in a large majority of cases, with a dose of from 5 to 10 milligrams of Koch's original tuberculin. (2) No injurious results occur from the use of tuberculin in these doses. (3) Proved tuberculosis in a more or less advanced stage may fail to give a general reaction from doses of from 10 to 12 milligrams. (4) Syphilis gives a reaction in an undetermined proportion of cases. (5) There is a dose, undetermined, at which a non-tuberculous person may react or simulate a reaction. (6) The reaction may be deferred from six to twenty-four hours.

The rules to be observed in making the test he formulated as follows: (1) Always use the same tuberculin and of a standard strength. (2) Use aseptic precautions in giving the injection. (3) Make the injections deep into the muscles of the back, arm, or leg. (4) Keep a two-, three-, or four-hourly chart of the temperature if possible, beginning twenty-four hours before the injection. (5) Allow several days to elapse before repeating the test. (6) In early cases depend upon the general reaction; in late cases if the general reaction fails, carefully look for the local.

DR. LOUIS FAUGERES BISHOP of New York then read a paper, entitled

DIAGNOSIS AND TREATMENT OF THORACIC EFFUSION.

The paper was a brief outline of an elaborate study of thoracic effusions, which was undertaken with a view to crystallize opinion on the importance of more careful search for fluid in pulmonary conditions and the necessity of early mechanical intervention. Serous effusions may be due to increase of exudation or a deficiency of drainage. The importance of the presence of fluid depends upon its amount, upon whether it is of mechanical importance, upon toleration by the patient, and upon its quality. Pus rarely may be spontaneously removed and should always be treated surgically. The diagnosis of fluid was considered at length and the importance of the exploratory puncture was particularly emphasized. The classical signs are not to be relied upon. The importance

of cultivating a knowledge of the natural relations so that fluid may always at least be suspected when present was emphasized. The technic of exploratory puncture was dwelt upon with special reference to antiseptic details. He recommended that physicians should carry a sterilized needle in a small bottle of absolute alcohol and reserve it for the particular use of exploratory puncture. The treatment by drugs was discussed and particular stress was laid upon the importance of free paracentesis. The Dieulafoy aspirator was recommended, particularly the old-fashioned, large, and powerful model which was devised at a time when aspiration of the chest excited more interest and attention than it now does, and he remarked that many inferior instruments are now thoughtlessly accepted by the profession. The danger of allowing even a small amount of fluid to remain in the chest was illustrated by the recital of several fatal cases. Sudden death from pleurisy with effusion was believed to result sometimes from a reflex nervous inhibition of the nervous mechanism of the heart analogous to the temporary hemiplegia that has sometimes occurred when the pleural cavity has been irrigated after empyema.

DR. A. T. CUZNER of Gilmore, Fla., read a paper on

THE GERM THEORY AND SERUM-THERAPY APPLIED TO THE PRACTICE OF MEDICINE,

considering briefly the physiology of the cerebrospinal and sympathetic systems, and emphasizing the great importance of the latter. He considered cellular pathology in detail, placing great importance on the following: (1) Each cell is a morphological unit having an individual life history, and is the result of the life of previous cells, and at their death they are resolved into effete matter very deleterious to living cells if retained in the tissues. (2) During their life they are favored or injured by their environments and circumstances over which they have but little control. (3) They are repellant to deleterious influences in proportion as their force or vitality is greater or less. (4) They have a very limited power of choice with respect to absorption or rejection of material brought to them by the circulation. In consequence, much good is effected by the presentation of certain drugs in certain morbid conditions of the tissues.

The functional activity of cells may thus be either increased or diminished as may be required. He showed that animal and vegetable organisms appropriate and prey upon each other's tissues under certain circumstances, and he illustrated this by giving a brief account of nut-galls, and then cited from Roswell Park's article on "Cancer." He next took up the different bacilli, microbes, etc., and he showed that they are ubiquitous; that they are to be found in enormous quantities in the air, in water, ice, and food; that they are, for the most part, dormant and innocuous, until aroused by favorable circumstances, when they become rampant; that the great majority of known germs are non-pathogenic and conserve the interest of mankind. The speaker then considered the germ theory of disease as held at the present day, and showed logically that if the present theory is correct, germicides will be the only medicine that will be needed in the future unless we can by some means render the body immune to the germs. The merits of serum pathology as understood and practised at the present time he treated as a fallacy, and to demonstrate this he quoted largely from Dr. Rupp's article.

DR. THOS. F. HARRINGTON of Lowell, Mass., then read a paper, entitled

PHILOSOPHY OF SICKNESS.

That medical science and art has made wonderful advances tending to the alleviation of human suffering and to the prolongation of life is admitted by all; that many diseases are yet beyond the reach of human skill must also be admitted; but, that there is in every sickness a quality of body or mind, or both, which is capable of recognition and influence from without seems to have escaped observation. Ancient and modern philosophers and scientists have ever struggled with the one factor which concerns us in the consideration of this subject, namely, personality. One truth shines forth—that man possesses an identity, which is neither wholly physical nor wholly psychical, but which is both, often acting through the ethical life and often independent of it; physical because it has a bearing on results which we associate with others; psychical because it is limited to the one being which, as Lotze says, is capable of being affected and producing effects. Thus, there is in every person a dual person which is susceptible to change like its physical self, but which cannot be separated either in whole or in part, from the living physical body—a being, which, while in itself, cannot be explained or influenced in the sense that physical bodies are, yet can be explained and influenced indirectly, that is, by connecting it with the physical self, a sort of parallelism between the two. That this individuality has not been capable of exact localization and description is no argument that it does not exist; even truth itself is not always possible of demonstration. Nature is constantly giving us proof that things are different than they seem. We cannot perceive this quality of individuality in man as readily as we can the quality of physical science, yet it must not only be perceived, but appreciated, if we are to do full justice to our patients. If we do not recognize the individual in sickness but rather view sickness in reference to those causes or conditions we know of (*i.e.*, pathological or others), we are apt to ascribe certain conditions to these causes. rather than ascribe them to unknown causes, hence, error. Take two individuals, having the same conditions and types of disease; when the one perishes and the other survives, we must recognize some influence other than mere physical traits in the human system. Stamina, vital force, faith, idiosyncrasy have all been offered to explain the results, and while it may be impossible to fit a term which will meet all objectors, the one fact remains, that there is something present. Again we see this self, this personality, exhibited in the form of self-discipline, sagacity, decision, honesty, etc., all of which require more than a mere physical or psychical origin for the phenomena manifested. It implies a plurality in the individual. If we believe in the present accepted theory that disease, exclusive of traumatic and mechanical disease, is due to a sort of auto-intoxication

arising from changes in materials normally present in the body, and that this alteration is subject to the same laws in a degree which regulate the organism in health, is it asking too much to admit that those qualities of mind, body, and soul, which are present in man in health may also change in sickness and become different in every essential? And as they are often the ruling forces in health, so, too, they may become such in disease; in fact, they may be the one factor in sickness requiring treatment.

FROM SADDLE-BAGS TO POCKETBOOKS

was the title of a paper read by DR. B. T. WHITMORE of New York. In olden times the doctor, whether in his gig or on horseback, was never to be dissociated from his saddle-bags. Not only were they the outward and visible sign of his profession, and the cause of his being held in high esteem, they meant what was of practical importance both to the doctor and his patients—that the doctor was his own dispenser. In those days the physician was familar with the raw materials and the processes of the gallipot. Many of his tinctures were made at the back of his own kitchen-stove, and the profession of medicine rather prided itself on the ability to make a neat pill. All this has changed with the increase of population, and the new order of things under which it is no longer necessary for doctors to make such lengthy rounds and carry with them remedies for all possible kinds of disease or passing ailment. Now the physician may carry with him his pocket-case for tablet triturates and for the hypodermic syringe, and he has ceased to be his own dispenser or the preparer of his own remedies. In the change the physician has passed along to the druggist and to the manufacturing pharmacist the responsibility for the quality of the remedial agents for which he calls in his written prescriptions. These two in practice become the adjuncts of the practitioner. By a further process of development the druggist has become and is always becoming more and more dependent on the manufacturing chemist, whose importance and consequent responsibility have been enormously increased. Manufacturing pharmacists, on whom physicians and druggists are thus dependent, have gradually differentiated into two lines: there are the manufacturers who hold themselves rigidly to open pharmacy. He is loyal both to the medical profession and to the druggists, and hence he is respected by both—as an adjunct whose special function is to attend to branches of the medical art which they have voluntarily though yielding to the force of circumstances surrendered. The second class of manufacturers are those engaged in the manufacture of patented articles or of articles made according to secret formulæ. One class of manufacturers appeals directly to the laity. The result as is well known is self-prescription, which entails a certain loss on the physician and the druggist alike, and exposes the lay user to damage of a more serious kind. The second class is more insidious in its operations. It makes public profession that it does not appeal to the laity, labels its goods "For the doctor only," asks the physician to include them in his prescription, and thus makes him the agent of his own undoing and the crippling of his assistant the druggist. When these goods are once prescribed the patient learns from the bottle what it is and when to take it, and for the future he takes it without reference to the physician. The progress to self-prescription is only a little delayed. It is none the less inevitable.

To provide a remedy for this state of things the speaker contended that it is necessary in the interest of the medical profession and of the drug profession, but to a still greater extent of that of the public, to guard on the one hand against the tendency to self-prescription, and on the other to ensure patients being provided with medicines of the quality called for by the physician. He maintained that when certain manufactured articles are in the market competing for favor, the physician should state specifically whose make he wishes used, so as to enable him to place reliance on the quality and potency of the article.

GRIP.

DR. J. E. GILCREEST of Gainesville, Texas, read this paper. He claimed that there is no specific treatment. To allay the pains and soreness, free elimination from the skin, kidneys, and intestines should be the object of treatment. He first gives calomel with soda bicarbonate in doses large enough to act upon the bowels. Acetanilid or phenacetin, alone or combined with Dover's powder, acts well. If muscular pains are pronounced he gives salicylate of sodium in 10 grain doses every two to four hours until the patient is relieved. The complications should be met as they arise. The patients should be kept in bed, and the room well ventilated and not overheated. A light diet should be given and stimulants if required.

SECTION ON SURGERY AND ANATOMY.

SECOND DAY—JUNE 7TH.

THE second day's proceedings were opened by DR. A. I. BOUFFLEUR of Chicago, who read a paper, entitled

DESMOID FIBROMA OF THE ABDOMINAL WALL AND PLASTIC OPERATION FOR THE SUCCESSFUL REPAIR OF THE DEFECT CAUSED BY ITS REMOVAL.

He said that these tumors extend inward and may be mistaken for an intra-abdominal growth. They have a tendency to infiltrate. Desmoids occur in the abdominal wall. The essayist spoke at length regarding the method of operation. In the case reported the wound healed in ten days and there was no return of the growth.

OBSERVATIONS ON PREVENTION OF SURGICAL SHOCK AND COLLAPSE, BASED ON CLINICAL AND EXPERIMENTAL EVIDENCE

was the title of the next paper, by DR. GEORGE W. CRILE of Cleveland, Ohio. He said that collapse is due to impairment of the vasomotor system. The organism responds to stimuli until changes are no longer produced and shock prevails. Collapse is due to marked interference with the primary respiratory and circulatory organs, or with the pneumogastric nerve and its branches. If pressure is exerted on the brain and an anesthetic given, shock is more frequent. The omentum is the antithesis

of the peritoneum. Manipulation of the latter causes a fall of blood-pressure. Mechanical stimulation of the uterus, tubes, and ovaries causes a rise of blood-pressure, that of the testicle a fall. In joint operations shock is due to cutting through nerves and not through bone.

DR. LEVINGS of Milwaukee spoke of the mental and physical condition of patients prior to operation. Rapid work, control of hemorrhage, and a small amount of anesthetic form the tripod upon which lives depend. He advocated the use of strychnin for the heart and nervous system. In impending shock nitroglycerin and whisky should be given hypodermatically.

DR. A. D. BEVAN of Chicago then read a paper, entitled

OPERATION FOR UNDESCENDED TESTICLE AND CONGENITAL INGUINAL HERNIA.

He spoke of the malformation, malposition, and location of the testicles, the mental effect produced by undescended testicles, the dangers of their presence, and the justification for surgical interference. The rule ought to be to transplant every undescended testicle if it can be palpated. A retained testicle may become carcinomatous. Undescended testicles are sterile as a rule. The operation is more successful than generally supposed. He makes a three-inch incision over the canal high up, and splits it open; he then draws out the testicle, and runs the finger along the vas, separating the peritoneum for two or three inches; then along the spermatic vessels and removes all covering from the cord. A pocket is made for the reception of the testicle, and the inguinal canal is restored by Bassini's method or without transplantation of the cord. The age of selection for the operation is fifteen years. This operation is to be preferred to castration.

CONTRIBUTION TO THE TREATMENT OF SPINAL CARIES

was the title of the next paper, read by DR. GEORGE R. ELLIOT of New York. He referred to the different mechanical inventions, and the work of Sayre and Taylor, to the various kinds of corsets, and the material used. Suggestions by his patients had aided him in perfecting his apparatus.

DR. ERNEST LA PLACE of Philadelphia opened the afternoon session by an interesting demonstration on alcoholic preparations of the use of his new forceps for intestinal anastomosis.

DR. DUDLEY P. ALLEN of Cleveland then read a paper on

EXTROPHY OF THE BLADDER

and, after describing in great detail the principal operations for the relief of this condition, said that there are two great objections to these operations: first, they do not prevent the constant dribbling of urine; secondly, the skin flap which is turned in to form the anterior bladder wall contains either hair or hair follicles on which occur incrustations of phosphates or other urinary sediments, which are a source of great pain to the patient. He did not wish to discuss the etiology of this most distressing lesion, but simply to report one case which he brought before the meeting and on whom he had performed Maydl's operation with the greatest success. It may be remarked *en passant*, that this is the first successful case of Maydl's operation ever performed by an American surgeon. The case was a typical one of extrophy in a boy, aged fourteen years, and the operation was as follows: All of the exposed mucous membrane of the bladder is removed except that portion which is immediately around the opening of the two ureters. Then the abdomen is opened, the ureters are mobilized, and the sigmoid flexure of the colon is drawn out of the abdominal opening. A longitudinal incision is made in the intestine and the extremities of the ureters, with their mucous covering, are inserted into the sigmoid flexure and then made fast by a series of sutures. When this has been done the intestine is dropped back into the abdominal cavity, and the abdominal wound is closed. The rectus muscles are then split on either side and the divided portions are united in the median line, thus repairing and greatly strengthening the defect in the abdominal wall. The sphincter ani is then thoroughly stretched and a drainage-tube is carried well up into the rectum. In this case the boy is able to hold his urine for from five to six hours during the daytime and does not have to arise at night to urinate. There is perfect tolerance of the rectal mucous membrane to the urine, and instead of being ostracized from his friends and society he is now welcome to both and is perfectly comfortable.

DR. C. A. WHEATON of St. Paul then read a paper, entitled

EXTROPHY OF THE BLADDER,

and said that the exact etiological factor in each case is a very difficult one to accurately determine. The correction of this terrible infliction has been a problem to surgeons since the earliest times. An exhaustive review of the literature was then made, with special reference to Brown's article in Morrow's "System of Genito-Urinary Surgery." The embryology of the genito urinary tract was then spoken of with especial reference to the fact that malformations in intra-uterine life may be an etiological factor, not only in this but in all congenital malformations along this tract. Very often the etiological factor is the rupture of the bladder during intra-uterine life, and that this may occur has been proven by the fact that cases are on record in which children were born with the scar on the abdomen of a rupture which had not only occurred but had healed during intra-uterine life. The bladder is active during the latter part of this life, and blocking, which would prevent its regular evacuation, would cause a rupture. He then reported three cases that had recently come under his observation, one of perineal hypospadias, one of penile epispadias, and one of aggravated epispadias, with extrophy of the bladder. For the relief of this last case Wood's operation was performed with fairly good results.

The discussion on these two papers was opened by DR. RUDOLPH MATAS of New Orleans, who said that the work of the last few years had been a distinct advance, and had opened up a wide field of surgical progress. It would now seem as if there was a good prospect for a radical cure of these peculiarly distressing and seemingly hopeless cases. After discussing at length the history

and statistics of the various operations proposed for the relief of this condition he stated the following conclusions:

1. Maydl's operation is the best and when its technic is improved it will be an ideal method of radical procedure, despite the fact that the element of risk of ascending kidney infection can never be entirely overcome.

2. All autoplastic methods are simply palliative and unsatisfactory, except that they have a cosmetic effect.

3. The relative mortality of the Maydl operation cannot yet be definitely determined, but it has been performed thirty-three times with only two deaths.

4. It is a most laborious operation, of difficult technic, and should be only undertaken by men of long experience in abdominal surgery.

5. It should only be applied to those subjects that can stand a large amount of shock, and whose kidneys are healthy.

DR. DE FORREST WILLARD of Philadelphia said that as the result of a long experience he had come to the conclusion that all operations were very unsatisfactory, and that the cases are usually hopeless. Many cases will demand three or four successive operations for their relief. The Maydl operation is, however, a step in the right direction, though bad in technic and increasing the danger of ascending infection of the kidneys. The autoplastic operations are simply valuable for their cosmetic effect, and at best are only palliative. Experience has proven the results of the Trendelenburg operation to be very bad. No matter what operation be performed care should be taken to use a flap that does not contain hair follicles, as the deposit on them of urinary salts is a source of constant pain to the patient.

DR. EASTMAN of Indianapolis said that the Maydl operation was not indicated in every case, and was distinctly contraindicated in those cases in which the kidneys were already infected. One case of this character had come to him for operation recently in which pyonephrosis existed in the left kidney. He removed the left kidney and ureter, and then stitched the right ureter into the root of the penis. The patient wears a portable urinal, and from having had to change his clothing every few hours in the past twelve years is now perfectly comfortable and his clothing remains unsoiled.

DR. ALLEN closed the discussion by saying that the most important part of the Maydl operation lay in preserving intact the mucous membrane around the orifice of the ureters, as it tends to prevent an ascending infection of the kidneys.

DR. J. E. MOORE of Minneapolis then read a paper on

TUBERCULOSIS OF FASCIA,

and said that the condition of primary tuberculosis of fascia is not as rare as is generally supposed. Two va-varieties are recognized: First, when the tuberculous infiltration is confined to the surface of the fascia; this is seen especially in the fascia lata and in the fascia of the popliteal space. Second, when the infiltration is not on the surface, but goes deeper, attacking the underlying muscles. The diagnosis is to be made by exclusion and the general health is usually not affected until mixed infection has occurred. A diagnosis may be impossible without an exploratory incision. The treatment consists in removing every trace of the disease by the knife or scissors, allowing the wound to heal by granulation, drainage being secured by gauze packing. Every sinus should be freely opened, the diseased area cut away, and good drainage secured.

DR. A. F. JONAS of Omaha read a paper on

SURGERY IN KNEE-JOINT TUBERCULOSIS,

and said that there is no one uniform method of treatment applicable to every case, so every one must be treated on its merits. The cases are either mild and recent, or severe and chronic; for the former conservative methods of treatment are demanded, and for the latter the more radical methods are indicated. It is impossible to draw an exact line and say when to stop mechanical treatment and resort to operative interference. He then gave an exhaustive analysis of fifty-five cases, and from this experience he had come to the following conclusions: Excision is a well-established method of surgical procedure and should not be put off too late. Resection of the joint is often better than a long mechanical treatment, which involves much pain and suffering. Exploratory incision is most valuable and should be performed early in every case, as by it foci of inflammation are exposed and can be at once relieved before the disease has progressed.

The discussion on the two papers was opened by DR. DE FORREST WILLARD of Philadelphia, who said that the thorough excision of all diseased areas, and the opening of all sinuses is the very best method of treating fascial tuberculosis. No caustic can compare with the results obtained by free excision with knife and scissors. The treatment of tuberculosis of the knee should be carried out with a due regard for the age of the patient. Erosion is a better operation for children than excision, as the latter operation always results in some shortening. Excision is a better operation than erosion for adults, and it and amputation should be reserved for them.

Injections of iodoform emulsion are worse than useless as they do harm by increasing suppuration instead of diminishing it. The diagnosis should be made early and the appropriate treatment at once instituted.

DR. SHERMAN of San Francisco said that he had seen fascial tuberculosis around joints and advocated early operative interference. The X-ray is often a valuable aid to diagnosis, but exploratory incisions should be made early in doubtful cases.

DR. MOORE closed the discussion by saying that amputation or erosion is to be preferred to excision in young children. After the age of puberty excision is the operation of choice, and this failing amputation should be performed. The injections of iodoform have been repeatedly proven to be absolutely worthless.

DR. JONAS closed the debate by saying that the term conservatism means conserving or the preserving of the function of the diseased part, and to do this often meant the free use of the knife which, in the end, may be the most conservative method of treatment. Too much importance can not be laid on the value of an early ex-

ploratory incision, the subsequent treatment being largely governed by what this shows.

DRS. W. W. KEEN and W. S. JONES of Philadelphia then read their paper on

TWO NOVEL CASES OF SURGERY OF THE TRACHEA. (1) STRICTURE OF THE TRACHEA SUCCESSFULLY REMOVED BY OPERATION. (2) SUCCESSFUL REMOVAL OF A DIAPHRAGM IN THE TRACHEA FOLLOWING CUT THROAT AND PRODUCING APHONIA.

In the first case, that of a woman, the stenosis was just below the cricoid cartilage, and extended over somewhat more than one ring. Dilatation being found impossible, operation was decided upon, and this was performed by exposing the trachea by an incision in the median line. The trachea was then incised, and the upper border of the stricture was found to be at the third tracheal cartilage, and extended over the third and fourth to the upper border of the fifth. The fibrous tissue forming the stricture was then dissected out, and the wound in the trachea closed by catgut sutures.

Primary union took place, and the patient made an uninterrupted recovery. Laryngoscopic examination two months after the operation showed slight redness of the vocal cords. The tracheal stricture shows no tendency to recur, and her voice and breathing are perfectly normal.

The second case occurred in a man as the result of an attempt at suicide. A tube was introduced into his trachea at this time, and allowed to remain in situ for some time. Then it was found that a membrane had formed across the trachea above the tube. The man had not breathed through his larynx or spoken a word since the accident. An operation was decided upon, and it was performed by making an incision extending from the tracheotomy opening to the cricoid cartilage. Then in attempting to puncture the membrane through a mistake it was found that the oesophagus had been incised instead. This opening was at once closed with Lembert sutures. Then the membrane was incised and dissected out. The two ends of the trachea were now sutured together by four silk sutures upon each side, and two posteriorily. The wound healed by first intention, and he made an uninterrupted recovery. His voice was slightly hoarse, but not to such a degree but that one would think it was his normal speech.

DR. CRILE of Cleveland opened the discussion by saying that he had had a similar case in which there was complete stenosis of the upper part of the larynx at the border of the vocal cords. The operation was performed by dissecting out the cicatricial tissue, and preventing recicatrization by the introduction of a tube through the larynx. The patient is making an uninterrupted recovery.

DR. M. L. HARRIS read a paper, entitled

LONGITUDINAL SILVER-WIRE SUTURE IN THE CLOSURE OF WOUNDS,

and said that the aim of every operator should be to secure primary union, and this was best accomplished by securing accurate coaptation of the edges of the wound. The absolute sterilization of the suture material employed is most important. Silver wire is the easiest of all known suture materials to sterilize. It having been shown by repeated experiments that it is impossible to render the skin germ free, a suture material should be employed that will not allow fluids to pass along it by capillary attraction. Silver wire, silk-worm gut, silk and catgut are best in the order given as regards their power of not allowing this action. Wire may be used as a continuous wire suture in every case in which the accurate approximation of a wound is desired. The principal advantages of this suture material are: It secures perfect coaptation, the technic of its application is simple, it is easily sterilized, is non-yielding, and can be easily removed whenever desired.

DR. J. C. MONROE of Boston then read a paper on

LAMINECTOMY, WITH REPORT OF CASES.

He said that though this was a major operation it should be more generally employed. He had performed it in eighteen cases, three of them acute traumatic cases, with good results. He then described these cases in great detail, and the operation of laminectomy. This operation is often of great benefit in seemingly hopeless cases. Speed and accuracy in operating are most important factors of success, and the operation should not be attempted until the patient has reacted from the shock following immediately on the traumatism.

DR. FERGUSON of Chicago opened the discussion by saying that this operation often afforded but little relief and was far too serious to be undertaken in many cases, but where there were distinct pressure symptoms it should always be undertaken.

DR. BOUFFLEUR of Chicago said that experience had taught him that operative interference was indicated during the stage of shock, as the relief of the lesion by the laminectomy often cured the shock.

DR. FRANCIS D. PATTERSON of Philadelphia said that he had had the opportunity of assisting Dr. Edward Martin in a laminectomy on a case of cerebrospinal meningitis. The patient was a child aged eight on whom all known medical treatment had been tried with no avail. The child's temperature was 105° F., the pulse ranging from 160 to 190, and Cheyne-Stokes breathing was present, as well as the typical symptoms of the advanced stage of the disease. The outlook was a hopeless one without operation, so a lumbar puncture with a small aspirating needle was performed, and about three ounces of cloudy flocculent cerebrospinal fluid were withdrawn. Some slight relief followed, but on the next day the patient's condition was again so desperate that the operation was repeated. Again relief followed, but some hours later the symptoms were as serious as before. So laminectomy was decided upon. The skull was trephined over the cerebellum on the chance of a cerebellar abscess being present, but repeated probing failed to show any localized foci of suppuration.

A laminectomy was then performed, considerable cerebrospinal fluid withdrawn, and the wound packed with gauze so as to secure drainage by capillary attraction. Twenty-four hours later the child was much im-

proved, and some hours later there was an entire disappearance of all the symptoms. Unfortunately, some fifty hours after the operation the child developed acute edema of the lungs and died. Bacteriological examination of the cerebrospinal fluid showed a pure culture of the meningococcus intracellularis.

DR. J. C. OLIVER of Cincinnati then read his paper on

TREATMENT OF POPLITEAL ANEURISM BY EXCISION,

and said that he had had one case in which there was a false aneurism of the popliteal artery which had been cured by excision in the usual way.

DR. B. MERRILL RICKETTS of Cincinnati then read a paper on

FEMORAL ARTERY AND VEINS; THEIR DESTRUCTION WITHOUT LOSS OF LEG; REPORT OF A CASE,

and said that occlusion of both could take place without gangrene resulting, as was proven by his case. The exact circulation can only be known in every case by a complete dissection, and so ligation should be performed, amputation being reserved as a means to be employed when ligation has failed.

DRS. FREEMAN, LORD, and MANLEY cited cases similar to those referred to in the last two papers.

THIRD DAY—JUNE 8TH.

DR. A. F. HOUSE of Cleveland, Ohio, opened the session by reading a paper on

THE SURGICAL TREATMENT OF ACUTE PERITONITIS,

and said that the peritoneum is one of the most susceptible parts of the body to infection, especially that part overlying the small intestine. Peritonitis may be either localized or general, and the usual infecting micro-organism is the bacillus coli communis, derived from the intestinal tract. The symptoms which demand immediate operative interference are abdominal pain, referred especially to the umbilicus, tenderness on pressure, early rigidity of the muscles, especially over the point of infection, the vomiting of a green, "ropy" substance, diminution or absence of peristalsis, abdominal distention, and a rise in the pulse and temperature. The treatment of peritonitis demands exactly the same methods of surgical procedure as are indicated in septic inflammation of other tissues, and without operation the result must be a fatal one. The evacuation of pus, free irrigation, and the securing of good drainage give the patient the only chance of life, and the operation should not be postponed too long. Strong antiseptic solutions should not be used in irrigating, and the best results have been obtained by the use of physiological salt solution. If the intestines be greatly distended with gas or fluid they should be brought to the edge of the wound, incised, and their contents evacuated, and then the incision closed with Lembert sutures.

DR. OCHSNER of Chicago opened the discussion by saying that he treated peritonitis, not by operation, but by stopping the administration of all food by the mouth and feeding by the rectum. The stomach should be thoroughly washed out, particularly so if stercoraceous vomiting has set in. He had employed this treatment in a large number of cases with most gratifying results.

DR. J. B. MURPHY of Chicago said that the most important factors to be determined are an accurate diagnosis and what is the type of the infection and what will be its clinical course. In those cases in which the peritoneum has lost its gloss the cause is generally a streptococcus infection, and all these patients die. When the gloss is not gone they usually recover. But there is a middle type which no one can tell what will be the outcome. It may be briefly stated, as a rule, that infection from the lower bowel is much more dangerous than that from the upper intestine. In every case operation should be performed as soon as the diagnosis is made.

DR. MCRAE of Atlanta, Ga., said that he had collected from literature, 601 cases of general peritonitis, with a mortality of 79½ per cent. All of these patients were treated by operation and the statistics of those treated medicinally do not show a lower mortality.

DR. J. B. MURPHY of Chicago read a paper on

INTESTINAL FISTULÆ,

and said that intestinal fistulæ might be classified into those of the large intestine, comprising the duodenal, jejunal, and ileac; and those of the small intestine, comprising the caput coli, ascending, descending, transverse, and sigmoid coli. They might be classified into direct and indirect. The direct fistulæ were either immediate or remote. In the former the bowel is in immediate contact with the skin opening, while in the latter a sinus leads down to the bowel. The indirect comprise the entero-intestinal, the choleo-intestinal (comprises fistulæ of the gall-bladder, cystic or common ducts), the genito-intestinal (comprises fistulæ of the tubo-, utero-, and vagino-intestinal varieties), and the urino-intestinal (comprises fistulæ of the nepho-uretero- and vesico-intestinal varieties. Their etiology might be congenital, as umbilical, vesico-intestinal and urethro-intestinal fistulæ. They may be caused by mural disease, such as round ulcer of the duodenum, ulcer of the duodenum following burns, tuberculous and typhoid ulcers, actinomycosis, gangrene or necrosis, and malignant neoplasms. Foreign bodies such as bones, enteroliths, choleliths, the ascarides lumbricoides worms, pins, needles, nails, and buttons may also be a cause. Mural strangulations, either external or internal, are a cause. The former may be either post- or preoperative while the latter may be due to bands, properitoneal pockets, etc. Intraperitoneal infections, such as ulceration from without (as of hernial sac), perforative peritonitis, pericystic suppuration, pelvic, appendical and peri-appendical abscesses, tuberculous appendicitis and peritonitis, and suppurating cysts are frequent causes. Finally they may be due to traumatisms, as bullet or stab wounds, or abdominal contusions, such as kicks, blows, falls, etc. Intestinal fistulæ may be established by operative measures either intentionally or accidentally. To the former group belong the permanent artificial anus, established for inoperative cicatrical stenosis or malignant disease. A temporary artificial anus may be established for subsequent resection, for temporary obstruction or for the relief of distention.

Accidental causes of fistulæ are: (1) Laceration of the intestines, as in separating adhesions. (2) Impairment of the wall causing subsequent perforation. (3) Division with scalpel or scissors. (4) Compression with forceps, ligature, suture, drainage-tube or packing. (5) Injuries in parturition, as in rupture of the uterus, amputation for supposed funiculous cord, etc. (6) Currettement, through perforation of the uterus. (7) Criminal abortion, as by direct penetration of the uterus or an indirect peri-uterine perforation. (8) Vaginal intestinal perforations, as from parturient lacerations, from the use of caustics, pastes and pessaries, after vaginal hysterectomies, and from the puncture of vaginal herniæ. (9) Failure of union after enterectomy or enterorrhaphy from (*a*) infection, (*b*) defective coaptation, (*c*) intestinal ischemia, (*d*) operation on diseased wall.

The indications for operation are: (1) Close the fistulous opening in the bowel. (2) Preserve the continuity of the intestinal tract. (3) Retain all of the tract for physiological purposes. (4) Accomplish all of these with the least risk to the patient. Cure may be spontaneous and is assisted by asepsis, strapping, collodion, immobilization, and diet.

Chemical applications, such as carbolic, nitric, and chromic acids, the solid stick of silver nitrate, tincture of iodin, etc., are of no value in promoting healing. In very small fistulæ the application of the Paquelin cautery may in a few cases prove to be of benefit. The following operations have been proposed: (1) Suture of the external opening (is valueless); (2) plastic operation on the sinus and the abdominal wall; (3) removal of the central septum by some form of clamp; (4) mural separation with suture of the bowels and the sinus extraperitoneally; (5) closure of the external opening or obliteration of intermediate viscus, as gall-bladder, etc.; (6) exclusion of the portion of the intestine involved in the fistula either by lateral implantation or by total exclusion and end-to-end approximation; (7) separation of adhesions with (*a*) lateral Czerny-Lembert suture; (*b*) immediate resection with end-to-end union; (*c*) vaginal separation with enterectomy or enterorrhaphy through the vagina.

DR. D. L. FAIRCHILD of Clinton, Iowa, read a paper on

SURGICAL TREATMENT OF ABSCESS OF THE LUNG,

and said that this is a sequel in about one out of every fifty cases of pneumonia. The diagnosis is usually not difficult, but in every doubtful case there should be no hesitancy in using an exploring needle. The abscess may evacuate itself through the bronchi, but as soon as the diagnosis is made the lungs should be exposed by a resection of the ribs, the lung incised, and the abscess evacuated.

DR. E. H. LEE of Chicago then read a paper, entitled

BASSINI OPERATION WITHOUT BURIED SUTURE, FOR RADICAL CURE OF INGUINAL HERNIA,

and said that he adheres strictly to the technic of the Bassini operation except that instead of using a permanent buried suture he uses a silver wire or silkworm-gut suture that can be removed at any time desired, generally in two weeks from the day of the operation.

DR. FLOYD M. MCRAE of Atlanta read a paper on

HERNIA OF THE DIAPHRAGM, WITH REPORT OF CASES.

He said that he wished to report two cases. The first one was the result of traumatism, and part of the stomach, all of the transverse colon, and part of the small intestine had entered the thorax through an opening in the diaphragm of the size of an orange. The hernia was reduced, the rent in the diaphragm closed with sutures, and the patient made an uninterrupted recovery. The second case was one in which a knuckle of the sigmoid flexure had passed through a small congenital opening in the diaphragm. The patient had stercoraceous vomiting and was in collapse when operated upon. The hernia was reduced, the diaphragmatic opening closed with continuous sutures, but the woman, on coming out of ether, vomited and swallowed the vomit, which caused her death.

DR. RAMON GUITERAS of New York then read a paper on

SOME OBSERVATIONS ON THE BOTTINI OPERATION FOR PROSTATIC HYPERTROPHY,

and after describing the histology of prostatic hypertrophy said that three clinical varieties are recognized: (1) A uniform enlargement in all directions, the general form of the gland being preserved. (2) Irregular enlargement, to which class belong by far the greater number of cases. (3) Local enlargement, in which all the gland is normal except in one small area, which is the rarest form. After a masterly review of the symptoms the treatment was taken up. Palliative treatment tending to improve the general health, relieve cystitis and vesical irritation should be carried out in every case. Resection of the vas deferens, castration, prostatectomy, etc., have all had their day and their advocates, but the operation by the Bottini galvanocautery incisor is the best. After describing the instrument and the technic of the operation he said that Bottini has reported 200 cases, but in only 23 of them is the report sufficiently full to make the statistics of any value. All of those operations were successful, 19 of the patients are reported as having been cured in one month (!), and the remaining 4 in less than three months. Other statistics of interest are those of Meyer, 12 cases, 4 deaths; Friedenberg, 32 cases, no deaths; Lowenstein, 12 cases, no deaths; all improved; Simon, 8 cases, 3 deaths; Morton, 5 cases, no deaths; all improved; Hank, 5 cases, no deaths; fair result; Bruce Clark, 4 cases, no deaths; fair result; Krespy, 6 cases, no deaths; all benefited; and the author reports 20 cases, with but 2 deaths. This operation would seem to be the best as its mortality is lower than any other (one-half that of prostatectomy), and it can be performed without general anesthesia. Improvement generally begins nearly at once after the operation, but it does not cure in a month as Bottini reports. Time is required to cure a long-standing chronic cystitis, and to restore tone to a weakened bladder.

DR. W. M. BEACH of Pittsburg then read a paper on

SOME COMPLICATIONS RESULTING FROM RECTAL OPERATIONS.

These are (1) incontinence, (2) stricture, (3) elongation of the anal septum, (4) ulceration and hemorrhage, (5) loss of rectal sense, (6) suppuration and phlebitis.

FOURTH DAY—JUNE 9TH.

DR. LISTON H. MONTGOMERY of Chicago opened the session by reading a paper on

TRAUMATIC SHOCK

in which he discussed at length the etiology, symptomatology, and treatment of the condition.

DR. WILLIAM JEPSON of Sioux City, Iowa, read a paper on

AUTOMATIC DRAINAGE,

in which he demonstrated an apparatus which would drain by capillary attraction into a receiver exhausted by air by means of a siphon apparatus.

DR. THOS. GRANT YOUMANS of Columbus, Ohio, then read a paper on

ACUTE GONORRHEA; ITS PREVENTION AND CURE.

He said that the best method of preventing the spread of gonorrhea is by parents being particularly careful to inquire into the morals of the suitors to their daughters. As regards its treatment, the best method is by daily irrigation with a 1–4000 solution of potassium permanganate.

DR. VALENTINE of New York said that he believed that ninety-eight out of every hundred men have gonorrhea at some period of their lives. From his experience the irrigation method, with potassium-permanganate solution, is the best treatment as a general rule.

DR. FRANCIS D. PATTERSON of Philadelphia said that the only known preventive of gonorrhea is to be virtuous, as statistics show that eighty-five per cent. of all prostitutes are infected with some form of venereal disease. As regards treatment, a long experience in the genito-urinary dispensary of the University Hospital had shown that the best treatment is by the irrigation method with potassium-permanganate solution. The average duration under this treatment is about six weeks. The presence of shreds in the urine does not necessarily mean that the patient is still in the infective stage. If careful and repeated microscopic examinations fail to show the gonococcus the patient should be pronounced cured, for these shreds may be due to a granular patch in which there are absolutely no gonococci.

DR. F. C. VALENTINE of New York then read a paper, entitled

URETHROSCOPY IN CHRONIC URETHRITIS, WITH DEMONSTRATION OF A NEW URETHROSCOPE,

and, after describing the symptoms of chronic gonorrhea and the various treatments proposed for its relief, said that the best treatment is by means of direct application through the urethroscope. He then showed his new instrument which is most ingenious, and apparently a great improvement over those now in use.

DR. J. B. EAGLESON of Seattle, Wash., read a paper on

A CASE OF PANCREATIC CYST; OPERATION; RECOVERY.

He described a case in which there was a very large cyst of the pancreas which was treated by evacuation and the removal of the larger part of the cyst wall. The patient made an uninterrupted recovery.

DR. R. M. STONE of Omaha, Neb., then read a paper, entitled

THE SCHLEICH SOLUTIONS.

He said that the Schleich Solution, No. 3, is the best general anesthetic. He had used it 250 times without a single death. It is pleasant to take, hardly ever followed by vomiting, and but a very small quantity is required to produce anesthesia.

DR. J. B. MURPHY of Chicago said that he had used it in a number of cases with most gratifying results.

DR. MURPHY proposed that a rising vote of thanks be accorded to Dr. Mayo, the Chairman of the Section, and the Secretary, Dr. Harris, which was carried unanimously.

SECTION ON GYNECOLOGY.

SECOND DAY—JUNE 7TH.

DR. HENRY D. INGRAHAM of Buffalo read a paper, entitled

SPONTANEOUS RUPTURE OF THE BODY OF THE UTERUS DURING LABOR.

Rupture of the body of the uterus during labor for any cause whatever is fortunately of rare occurrence, at least in this country. In Continental Europe it is reported as occurring more frequently. For obvious reasons many cases of rupture are not reported, and it is very natural that a smaller proportion of the traumatic cases should be reported than of those which occur spontaneously. Upon investigation the essayist had found in an aggregate of about 48,000 cases of labor that 12 cases of ruptured uteri have occurred, 5 of these being traumatic, and 7 spontaneous. Most of the cases occurred in the practice of midwives. An analysis shows the greater proportion in women of foreign birth. This is doubtless partly accounted for by the fact that a large proportion of the foreign-born population of this country employ midwives. Another very probable cause is the greater frequency of contracted pelves among the foreign-born element. The death-rate of the mothers in the 7 cases of spontaneous rupture was 86 per cent., and of the children, 71½ per cent. Both mother and child died in all the cases of traumatic rupture.

UTERINE FIBROIDS

was the title of a paper by DR. T. FITZGIBBON of Milwaukee, in which he discussed the varieties and position of these neoplasms.

INDICATIONS FOR OPERATIVE TREATMENT OF POST-PUERPERAL SEPSIS

was the title of the next paper, read by DR. JOHN B. DEAVER of Philadelphia. He said that the comparative frequency with which post-puerperal sepsis occurs even at the present time with our present knowledge of asepsis in surgery and obstetrics was his reason for writing the paper. He reported a case of tubo-ovarian abscess with infection of the uterus following childbirth in which

the uterus, right tube and ovary, and left tube were removed. The patient recovered.

There are three forms of puerperal sepsis from an anatomical standpoint, all of which are infectious and due to abrasion of the mucous membrane lining the cervical canal and uterus. They are endometritial, metritial, and parametritial. The most fatal form is the metritial. It is characterized by multiple foci of infection and abscess. The endometritial is most amenable to treatment, *viz.*: curettement and thorough disinfection of the uterine canal. The parametrial form is frequently mistaken for so-called pelvic cellulitis, a name which means nothing, for all the so-called cases of pelvic cellulitis are infective processes and lead to abscess formation. On general principles the speaker believes the curette is resorted to too often. This instrument should be handled with the greatest care and gentleness; in short, it requires as delicate manipulative skill to use the curette with safety as it does the lithotrite.

Two cases of uterine perforation due to the use of the curette were reported. In one, examination revealed the presence of a loop of intestine in the vagina. At operation a knuckle of small bowel, six inches in length, gangrenous, and devoid of mesentery was found. The uterus was the seat of a perforation about the size of a 5-cent piece. Supravaginal amputation of the uterus with removal of the tubes was performed. The involved portion of the ileum was resected, and end-to-end anastomosis carried out. The abdominal cavity was thoroughly irrigated and drained. Death occurred on the evening of the fourth day from peritonitis.

Other cases of pelvic abscess were detailed and the method of treatment described. He said that these cases illustrate one important point: that the early institution of so-called radical measures is true conservatism in surgery.

The afternoon session opened with a symposium on

VAGINAL *versus* ABDOMINAL SECTION.

The first paper, entitled

THE SUPERIORITY OF VAGINAL SECTION OVER LAPAROTOMY IN SURGICAL TREATMENT OF PELVIC DISEASES IN WOMEN,

was read by DR. J. RIDDLE GOFFE of New York, who said the objections to the abdominal operation are: (1) stitches; (2) adhesive plasters, which are annoying; (3) abdominal supporter; (4) scar; (5) danger of ventral hernia. Great diversity of opinion exists in regard to the closure of the abdominal incision. By vaginal incision is implied, not simply puncture, but free incision longitudinal and transverse, and, if necessary, supplemented by incision posterior to the cervix, giving ample room for manipulation. Vaginal fixation has many objections. Shortening the round ligaments through the anterior vaginal fornix is the ideal treatment for retrodisplacements. No disadvantages during pregnancy occur and it is superior to suspensio-uteri and the Alexander operation. The objections to the Alexander operation are many, because (1) of its limited application; (2) the ligaments are often absent or weak; (3) two unsightly scars are caused; (4) there is danger of subsequent hernia, which has frequently occurred. Diseased appendages may be removed, adhesions broken up, malpositions corrected, and pelvic abscesses treated thoroughly, satisfactorily, and safely by vaginal incision. If both adnexa are destroyed total hysterectomy is indicated. The intestines may be injured, but this accident also occurs during abdominal operations, but less frequently in vaginal than in abdominal section. Ectopic gestation, ovarian dermoids, fibroid tumors of the uterus may all be dealt with by way of the vagina. The pain is much less and the convalescence smoother than after abdominal celiotomy. The simplicity, facility, and comfort of this method commend it to every operator.

THE TECHNIC OF THE VAGINAL OPERATION,

was the subject of the second paper, which was read by DR. WILLIAM H. WATHEN of Louisville.

Many cases may be treated equally well by either vaginal or abdominal section. The bisection of the uterus increases the value of vaginal section. After the uterus is bisected each half may be brought outside the vulva. I have never wounded ureter or intestine by the vaginal incision, but I have been less fortunate in operating by the abdominal method. The adhesions above often prevent the prolapse of the intestines into the vaginal incision. There is less danger of infecting the peritoneum than in celiotomy. In early tubal pregnancy the ruptured tube may be removed per vaginam unless the peritoneal cavity is filled with blood. I have operated on thirty cases of ectopic pregnancy by this method without an untoward symptom.

The next paper was read by DR. F. HENROTIN of Chicago on

WHAT BECOMES OF PATIENTS AFTER VAGINAL INCISION?

He said that it is imperative to state that vaginal hysterectomy is not and has never been offered by any rational man as a universal substitute for abdominal hysterectomy. Ablation and resection of pelvic organs short of hysterectomy are better accomplished through an abdominal opening, though reserving the propriety of using the vaginal route even in these cases in a small minority of well-indicated instances. Vaginal incision, properly indicated and properly performed, represents the very ideal of perfect and conservative surgery; for no surgery is ideal unless cosmetic and conservative as to function. Of all pelvic diseases in women which call for operative intervention and opening of the abdominal cavity probably in 25 or 30 per cent. operation can be carried out to better advantage through a vaginal incision and the remainder through a suprapubic one. What becomes of the patient after either operation depends not upon the incision, but upon the characteristics and qualifications of the man behind the knife.

The discussion of these papers was opened by DR. H. A. KELLY, who said: It is a curious fact how our views have altered in years; and to those who have been watching us superficially it might seem that we have been traveling in a circle. Dr. Goffe states the proposition correctly when he says that all other things being equal the

vaginal route is to be preferred. The abdominal method is better, as a rule, for diseases which involve the structures in the upper part of the tract, because, through the abdomen one can get at them quickly and can do all kinds of extremely delicate operations. The vaginal route is preferable for affections located in the lower part of the uterus. Our vaginal sectionists must work through the pubic arch, and more or less at a disadvantage, particularly if these structures are fixed by inflammatory adhesions. The vaginal route is the one *par excellence* for treatment of pelvic abscesses (located in the tubes and ovaries). I have written to 100 of my pelvic-abscess patients treated in this way and have received a reply from 59 operated on between 1893 and 1897. Among these 59 patients there were 38 who were in good condition, 13 absolutely well and free from all symptoms, 10 had some degree of abdominal discomfort, 5 some menstrual pain, 5 more had some menstrual and abdominal pain, 2 some rectal pain and tenesmus, 3 complained of constipation, 4 experienced improvement in their symptoms, and 5 no improvement. There were 3 deaths from uremia, 1 from general infection because the operation had not been performed in time.

DR. J. B. MURPHY of Chicago said that with a gonorrheal infection the pathology is very similar to that produced in the urethra—stricture of the tube, chronic suppuration, and if you drain by the vagina you have a stricture at the neck of the tube, which prevents drainage after the communication with the vagina has closed, and the result is retention of secretion and accumulation of infection. A suppuration of the ovary can be cured by simple drainage if the wall is not a cyst wall.

We are coming nearer to an agreement, particularly with regard to the cases that come into the hospitals on litters. If you are able to make a vaginal incision, open up abscesses, or do an operation, it is a life-saving operation and in a large number of cases followed by permanent cure. You do not have a cure in all cases, but you get such cases into a condition where, in a few weeks, when the profound symptoms of septicemia have passed away you are able to go in from above and clear up all the old abscess cavity and bring about the cure of your patient. The more experience we have the more we appreciate the vaginal route in treating certain of these conditions. Views which five years ago did not seem to us good surgery we are quite willing to endorse to-day.

DR. CHARLES P. NOBLE: The patients best suited for the vaginal operation are those brought to the hospitals extremely ill, and who are septic. Any abdominal surgeon knows that a few years ago, when we had to do an abdominal operation on patients of this class, many of them died. The class of patients I believe in draining is the puerperal class. Puerperal cellulitis and puerperal abscesses occur in the broad ligament. If there is pus in the broad ligament vaginal incision is all that is necessary to make a perfect cure. Pus-tubes in puerperal cases, if well drained, in a good percentage become well and are able to conceive. I recall eight or ten confinements among puerperal cases that had been thus treated.

While an ardent advocate of the vaginal route in this class of cases, in general I am in favor of abdominal operations. The advantages are so great that I am surprised at the ingenuity of those who use the vaginal operation.

DR. CARSTENS: I believe the abdominal route is the proper one in ectopic pregnancy. Vaginal hysterectomy is proper where you have pus-tubes associated with a retroverted, lacerated uterus, degenerated mucous membrane, constant vaginal discharge, uterus, ovaries, and tubes adherent in one solid mass. It seems to me that is one of those exceptional cases in which vaginal hysterectomy at one time will produce less shock and bring about more permanent results than any other method. If the patient is a young woman every effort should be made to save some part of her generative organs.

DR. H. O. MARCY: When Dr. Goffe tells us that by a laparotomy we injure the abdominal wall I beg leave to differ; I have taken careful notice of my last thousand cases of laparotomy, and with a single exception there has not been ventral hernia. If the operation is done skilfully you look in vain for the scar.

DR. C. A. L. REED: The idea of such a discussion as this is a happy one because it brings out the fact that the two operations formerly opposed are but supplementary. A few years ago the verdict come from England that all such conditions should be treated by the abdominal route, and from France came back the word to attack them by the vaginal route. When to adopt one operation, and when the other is to be determined clinically and upon the spot; frequently after the initial steps have been taken.

DR. HENRY T. BYFORD: The men who operate from above exclusively don't know what cases to operate on from below. More than half of the ordinary small tumors and diseased tubes can be reached by the vagina.

DR. GOFFE in closing: All the critics this afternoon have admitted that in desperate cases the safe route is the vaginal route Why? Because operations through the vagina are attended by much less serious consequences than through the abdomen. All I wish to do is to take that one principle and extend it and show how it can be applied to nearly all the conditions in the pelvis. I don't mean to be understood as advocating this route for all cases. If I cannot complete the operation through the vagina I do not hesitate to do a laparotomy. When I speak of vaginal incision I do not mean a puncture but an incision throughout the whole length of the anterior wall, dissecting off the vagina, opening up the peritoneal cavity putting in a retractor and seeing what the conditions are.

DR. WATHEN: The subject has not been discussed in the broad way that I thought it would be. The remarks of nearly every one except Dr. Goffe applied to pus cases, which is only a small part of the subject of vaginal work. The ovaries and tubes unless the adhesions are very bad can be brought into the vagina and seen as perfectly as through the abdominal wall. The condition can be treated and the ovaries returned. Where could there be more conservative surgery? Every pus case is amenable to treatment per vaginam where you go below and drain out the pus or can make an incision and take out

both ovaries and tubes. It need not matter whether it is the result of gangrene, or asepsis or what not. If you find you cannot do the work from below do a celiotomy.

THIRD DAY—JUNE 8TH.

DR. RUFUS B. HALL of Cincinnati discussed

OVARIAN AND UTETINE TUMOR DURING PREGNANCY,

and said: In properly selected cases operation for these conditions is indicated during pregnancy. The danger of abortion following operation has been very much exaggerated. No definite rule can be formulated to determine which cases will or will not abort. Pregnancy favors the rapid growth of most uterine tumors. The pregnant is not the ideal condition for operation. If feasible, the patient should be tided over until the termination of pregnancy. The position of the tumor in the uterine wall will determine whether or not operation is required. This will almost always require the sacrifice of the uterus and fetus.

In discussion of this paper DR. ROSENWASSER said: I agree with Dr. Hall in regard to operations for ovarian tumor, but with regard to fibroids I think it is a difficult question, and that it should be left to each individual case. My position is that in the case of an ovarian tumor, not enormously large and not involving the pelvic cavity you can treat it conservatively until after confinement and remove the ovarian tumor after delivery. With myomas involving the lower segment, and the woman becoming pregnant, it is only safe to operate as early as possible.

DR. RICKETTS: A number of years ago I knew of a woman who while suffering from ovarian tumor was delivered of three children within five years. As to fibroids, I recently had a case of a small fibroid of the upper segment in a woman whom I carried to full term, although I came very nearly losing her. While it is true that pregnancy complicated by ovarian tumors can be carried to full term it is a dangerous procedure to make use of.

DR. CARSTENS: When a woman is pregnant and knows she has a tumor she is very despondent and I am inclined to favor operation for the mental influence. Other things being equal her chances are just as good as when she is not pregnant.

DR. CHARLES P. NOBLE: The question of what to do with an abdominal tumor as a complication of pregnancy has passed the experimental stage. I agree with Dr. Carstens that experience shows operation done during pregnancy to have most excellent results. The reason for this is clear in that they are not septic cases. My own experience has been that if I promptly remove ovarian tumors, the patients all recover and none abort. Up to the eighth month I would take out the tumor. It is important to remove a dermoid tumor during pregnancy, and if for any reason it has been overlooked it is important to remove it promptly at the conclusion of labor, because the bruising of labor sets up gangrene. The conditions must be extreme to make it necessary to remove a fibroid during pregnancy. The patient should be allowed to go into labor unless her comfort is materially interfered with.

PROPHYLAXIS OF UTERINE CANCER

was the title of the paper which was read by DR. W. W. GRANT of Denver.

Cancer of the uterus is rare in virgins; its common site is the cervix, and its common victim the child-bearing woman. The first conclusion to be deduced from this fact is the necessity for giving Nature a freer hand in the dilating stage of normal labor and the use of all possible care and gentleness to limit traumatism in obstetric operative procedures. The desirability of medical supervision during the climacteric, and even before, must be admitted by all in order to meet certain diseased conditions promptly. My belief is that the only safe course is to repair every appreciable laceration of the cervix without waiting, and looking for evidence of either benign or malignant disease.

DR. LAPTHORN SMITH of Montreal contributed a paper on

THE PREVENTION AND TREATMENT OF CANCER OF THE UTERUS,

an abstract of which was read by the Secretary:

Cancer of the uterus is not a hereditary disease. This may shock those who have been brought up to believe in the tradition of its heredity, just as it did those who believed in the heredity of consumption when they were told that it was a contagious disease as everyone now admits it to be. Cancer of the uterus has been proved by numerous experiments to be a contagious disease probably due to a microbe which does not flourish on healthy tissues but which luxuriates on tissues of low vitality, such as cicatrices, or in women whose whole vitality is below bar.

If we believe, as Emmett has conclusively proved, that cancer of the cervix almost always begins in the cicatricial tissue in the angle of the wound, then by removing the cicatricial tissue and repairing the laceration a stop may be put to this dreadful disease.

DR. F. H. WIGGIN: The time is approaching when it will be demonstrated that carcinoma is an infectious disease. One reason why this disease is increasing is that general practitioners believe that cancer will not develop until after the menopause. It is also an important matter that the patient should be taught to return to the physician for local examination three months after each confinement, and when any injury of the uterus is found the damage should be repaired.

DR. A. GOLDSPOHN: I agree fully with the general drift of Dr. Grant's paper, but I would call attention to the fact that as a prophylactic for malignant disease the so called Emmett operation is of very little use because it does not remove the structures from which malignant disease has been proven to originate. Trachelorraphy is not competent to deal with this condition and entire amputation of the cervix is indicated.

DR. REIS of Chicago: If most women who have cancer, have tears of the cervix it does not prove that the tear has anything to do with the carcinoma. As long as we do not know the cause of carcinoma there is no use in making such an assertion as the cause being a tear in the cervix. As to operation for carcinoma, it is a mistake to

say that vaginal hysterectomy has given satisfactory results. If in two years less than half are free from recurrence, that is not a satisfactory result.

DR. MITCHELL of Cincinnati: I have been a warm advocate of the Emmett operation and I believe that cancer of the cervix rarely, if ever occurs in women who have not borne children or been the victim of abortion.

DR. HOWARD A. KELLY: We know nothing about the etiology of cancer. If I were to guess from microscopic studies and pictures of the microscope I would guess that it had nothing to do with an infecting organism. It appears to be wholly an epithelial growth. We know very well that some of the opinions we still hear of cancer being due to infection of some micro-organism are from pictures of these epithelial cells which have been mistaken for organisms. What we want to get at now is a proper modus vivendi, what is best to do at present pending the settlement of this important question. Every woman who has borne a child should be examined at least once a year by a competent physician. Suppose my rule, which sounds very wholesale, should be carried out at this present moment. Then every case which in six months or a year is coming into the surgeon's hands too late for operation, would be seen in time to eradicate the disease. I think, therefore, it is the duty of every physician who attends a woman in confinement to have her come back to his office for examination as to the extent of the injuries she has sustained and to keep her under his observation until well beyond the climacteric.

Another point which has been reiterated, and must be reiterated until men learn to obey it is that every case of atypical hemorrhage in a woman should be thoroughly investigated and if there is anything abnormal discovered in the cervix a piece should be taken out and examined microscopically or the body of the uterus curetted if there is nothing found in the cervix. The best direction for our operation is to make the widest possible local extirpation of the disease and not bother about the glands which are infected only as a rule in the latter stages of the disease in the inoperable stages of the disease. Macroscopically I give the disease a very wide berth on all sides. I do an anterior colopotomy with bougies in the ureters.

NECESSARY ABORTION

was the title of a paper by DR. W. C. BOWERS of Decatur, Ill. The reasons for premature emptying of the uterus are many, but fortunately very few of them act with any degree of frequency and the indications are rarely absolute. Nephritis, advanced tuberculosis, aneurism, valvular lesion of the heart, chorea, and peripheral neuritis of pregnancy are among the indications.

ACCIDENTAL WOUNDS OF THE FEMALE BLADDER

was read by FREDERICK HOLME WIGGIN of New York City.

Accidental opening of the bladder has, for many years, been considered one of the most serious accidents that could occur in the course of the complicated work which gynecic surgeons are often called upon to do. Injuries to the inferior surface of the bladder generally occur in the course of the separation of the uterus from this wall, when the peritoneal cavity is entered by means of an incision made in the anterior vaginal wall. The accidental opening of the bladder in this situation is less common than might be supposed.

With the present technic wounds of the bladder made in the course of operating, whether extra- or intraperitoneal, should be closed immediately and the operation continued as if the accident had not occurred; notwithstanding that drainage is not used there will be little danger of peritonitis, extravasation of urine, or hemorrhage. It is of great importance when breaking up adhesions and removing tumors, or separating the bladder from the anterior vaginal wall and uterus, to be certain whether or not the bladder has been injured, and it has been the writer's custom to test this by injection of saline solution or by the uterine sound. Catgut is the best material for suturing the bladder.

FOURTH DAY—JUNE 9TH.

WHAT SHALL WE DO WITH THE UTERINE FIBROID?

was the title of a paper by DR. D. TOD GILLIAM of Columbus, O.

On the whole I have come to look on the uterine fibroid as comparatively innocent in so far as its life-destroying propensities are concerned. In its more aggravated forms it is capable of making life unbearable, but a very small proportion of the incipient fibroids ever attain to a size to give serious trouble. I contend for greater circumspection and more conservatism on the part of the surgeon; let the small and less mischievous growths alone. In those threatening serious trouble, state the dangers and the benefits of the operation, and let the patient decide.

DR. DORSETT, in discussion, said: The question of the indication for operation in fibroid tumors may be summed up under three heads: (1) Hemorrhage. (2) Those cases indicating rapidity of growth which usually indicates malignant growth, cystic degeneration, carcinoma. (3) Those which inconvenience the patient by interference with digestion, and in which the patients are suffering more or less from ptomain poison due to the mechanical interference with the rectum and the bowels, and those in which adhesions are forming.

SECTION ON DISEASES OF CHILDREN.

THIRD DAY—JUNE 8TH.

The first paper read was by DR. COTTON of Chicago, and was entitled

SOME SEPTIC CONDITIONS IN THE ORDINARY DISEASES OF CHILDREN.

He said that we have distributed diseases under various types, yet complications and sequelæ are so frequent that the type is but a guiding landmark, and may be very widely departed from. It is interesting to note that after having wandered far from the notion that disease is a special entity always the same, but manifesting itself differently in different individuals, there has been of late a return to this idea in a certain way. In none of the ctious diseases do we fear the special disease itself so

much as its complications. Diphtheria, for instance, we have now an absolute cure for when it is pure Klebs-Löffler diphtheria, but in many cases almost from the very beginning there is an accompanying infection by some form of streptococcus. But the same thing holds true for most of the infectious diseases. In pneumonia, the cases that get beyond control in measles, the serious complications in scarlet fever, the angina and membranous affections of the throat; in influenza, the otitis media and cranial sinus involvements; in typhoid fever, the perforations are all due to a mixed infection, and usually the streptococcus is at fault. The original disease seems to make of the organism a favorable culture medium for the streptococcus. Much as we may fear tuberculosis, we fear still more the mixed infection. Streptococcemia is an important factor, and its frequency of late gives cause for the question, Is this a special streptococcus period? Meantime, bacteriology is making diagnosis more exact and, as in the past, it has brought us to the knowledge of specific causes of disease, so now it is bringing us to the realization of the modifications of disease and their true origin. This will undoubtedly change our nomenclature in the future, and as we now no longer talk of dropsy, jaundice, and biliousness, but specify the conditions these symptoms are due to, so we shall no longer talk of pneumonia, rheumatism, diphtheria and the like, but make clear just the form of these diseases we intend.

Since mixed infections are most intractable it is necessary to put forth all our therapeutic efforts against them. We are able to treat them on three lines: first by prophylaxis, making all the openings into mucous-lined cavities and, as far as possible, those cavities themselves aseptic, and keeping them so. Special precautions are necessary in this matter because the primary infection has made the organism less resistive to succeeding ones; second, specific antitoxic treatment must be employed, not alone for its specific curative effect, but because the good it does in related diseases also; third, the general supporting stimulant treatment that increases cellular resistance to microbic invasion and neutralizes the effect of changes in cell metabolism that have been already induced.

DR. HARRIET GARRISON of Dixon, Ill., read a paper, entitled

THE GRIP EXANTHEMATA AND THEIR RELATIONS TO THE OTHER EXANTHEMATA.

She spoke of the importance of distinguishing the exanthemata more carefully than has been done. During the last winter she has seen a large number of cases complicated by a striking universal exanthem, which she at first considered to be German measles, but which she finally believed to be la grippe with a rash. The exanthem occurred especially in cases which were not accompanied by high fever. High temperature seemed to destroy the toxic substances that in the other cases irritated the skin to the production of the rash.

DR. R. B. GILBERT of Louisville, Ky., presented a paper (read by DR. SOLOMON) on

THE TREATMENT OF SCARLET FEVER AND THE PREVENTION OF ITS COMPLICATIONS.

As a matter of prophylaxis for other children the strictest quarantine should be maintained, and especially a point that is sometimes overlooked, all cats and dogs should be rigidly excluded from the room, as they are now known to be favorable carriers of infectious material. Inunctions are very important for the same purpose, but it must be remembered also that they are therapeutic in action, inasmuch as they allay itching, and so quiet restlessness and reduce fever. For ordinary temperatures no treatment is required; for temperature of 103° F., quinin with phenacetin; for hyperpyrexia with delirium, cold bathing. When the child is restless chloral should be given rather than opium, as it has less tendency to interfere with kidney function, and that is very important in scarlatina. From the beginning iron and supporting treatment should be given to prevent the anemic debilitated conditions that so often follow the disease. Despite the old medical adage never give iron during fevers, this treatment does good always. Hot lemonades encourage the skin function, and so prevent the throwing of too much eliminative work on the kidneys.

DR. I. N. LOVE of St. Louis read a paper, entitled

THE USE OF THYROID EXTRACT IN JUVENILE OBESITY.

Last year he had reported four cases of juvenile obesity treated with favorable results by thyroid extract. He has now had three additional cases, and is encouraged to go on with this treatment. A sample case is as follows: Boy of twelve years; weight 130 pounds; disinclined to take exercise; rather slow and dull at school.

After four months of treatment he has lost twenty-five pounds in weight, has grown able and willing to take exercise, and has become mentally much brighter, and is rapidly making headway at school. It is this last feature, the overcoming of the intellectual hebetude that is especially gratifying to the patient himself and his friends. The dose of thyroid extract given to children is half a 5-grain tablet three times a day, noting the effect, and gradually increasing the dose to 5 grains three or even four times a day. To overcome the depression that sometimes accompanies thyroid medication, he administers $\frac{1}{100}$ to $\frac{1}{60}$ of a grain of strychnin with it.

SECTION ON NEUROLOGY AND MEDICAL JURISPRUDENCE.

THIRD DAY—JUNE 8TH.

DR. HERMAN H. HOPPE of Cincinnati read a paper on

POLIOMYELITIS ANTERIOR ACUTA ADULTORUM.

He said that this disease, while described many years ago by M. Myers, is of extreme rarity, and he placed on record two well-marked cases. The first was that of a man, aged twenty-eight years, whose mother had died of tuberculosis, and whose sister had caries of the spinal column. He fell to the floor and had to be assisted to a chair. On the evening of that day he had to be carried on account of the involvement of the right leg. Forty-eight hours after the onset of the paralysis there was present a complete motor paralysis of all four extremities, together with the muscles of the neck, so that the patient was unable to raise his head from the pillow or move it from side to side. The treatment was by ergotine for the

first three days, and after that for two weeks small doses of iodin, and bichlorid of mercury for three weeks. After the third week massage and general faradization was given. Massage and the electric treatment were kept up for two years. Four years after the attack the patient was sufficiently restored to walk without an effort on the level, but has some difficulty in climbing steps. The muscles, especially those of the legs, have not returned to their normal size, but the patient thinks he has fully recovered.

The second case was in a man, aged forty-eight years, who was perfectly well up to a month before his admission to the hospital when he was attacked with diarrhea. One week before admission he noticed a weakness in the left leg. The right leg became involved on the following day, and the third day the patient was unable to walk, his arms became paralyzed, and he was perfectly helpless. There was no hyperesthesia or abnormal sensation of any kind. The mental condition was good. The electrical examination in both cases showed an almost complete reaction of degeneration in all muscles of the body. The treatment was by ⅓-grain of bichlorid of mercury, and $\frac{1}{60}$ of a grain of sulphate of strychnin, every four hours, together with a hot bath every afternoon. In three weeks he was able to walk alone with ease, and was able to use all the muscles of the body, but the movements were characterized by great weakness.

DRS. F. W. LANGDON and ALBERT H. FREIBERG of Cincinnati presented a paper, entitled

PACHYMENINGITIS EXTERNA CERVITIS, PROBABLY TUBERCULAR; RECOVERY.

The lesion was in the cervical region, and the symptoms were entirely relieved by stretching.

DR. AUGUSTUS A. ESHNER of Philadelphia read a paper, entitled

HEMORRHAGE INTO THE PONS VAROLII.

The patient was a colored man, seventy years old, who was admitted to the Philadelphia Hospital complaining of pain in the back and hips, and of headache. Some muscular twitching was noticed, but this grew less for a time. Later, however, the twitching increased and active delirium developed. The patient passed gradually from stupor into coma, while the nervous irritability increased, the head being retracted, and the jerking in various parts of the body being marked. Death resulted thirteen days after admission. On post-mortem the brain was found to be small, weighing only 1210 grams. The vessels at the base were somewhat stiff, while those in the fissures exhibited nodular atheroma. The pia on the anterior and lateral surfaces of the pons and medulla was deeply pigmented. The meninges of the convexity were somewhat opaque. In the left half of the pons, about midway between the median raphe and the superficial origin of the fifth nerve, was a small, dark-red, apparently recent extravasation of blood about 2 mm. in its several diameters. Transverse section of the pons disclosed a second extravasation of blood, also about 2 mm. in diameter, almost in the middle line, 4 mm. in front of a line joining the two fifth nerves, 7 mm. from the anterior surface of the pons, and 25 mm. from the upper surface of the quadrigeminal bodies. The ependyma of the lateral ventricles was rough and granular, especially in the fornices, in the anterior horns, and in the region of the foramen of Monro. The gray matter of the cerebral cortex was variable in thickness, and generally paler than normal. The patient had been looked upon during life as suffering from uremia, and treatment was directed accordingly. In view, however, of the developments of the autopsy, it is not impossible that at least some of the symptoms were related to the hemorrhage into the pons.

DR. W. A. JONES of Minneapolis read a paper, entitled

PROBABLE BRAIN TUMORS WITH RECOVERY.

The patient, a lad aged sixteen years, was taken ill with what appeared to be an ordinary attack of indigestion accompanied by severe headache, but his symptoms steadily grew worse, and pointed to the presence of a cerebral lesion. There was nausea, vomiting, and pain over the frontal region, particularly the right eye. He had pain on percussion over the right orbital region. He was put through the usual course of cathartics and intestinal antiseptics, without benefit, but was relieved of his pain by a small hypodermic of morphin. The following day he cried out in paroxysms of pain, demanding firm pressure over the right eye, complained of vertigo, and exhibited violent temper. On the tenth day of his illness he showed a paresis of the internal rectus of the right eye, while the pupil was slightly enlarged, and did not respond promptly to light. Ten days later there appeared a paralysis of the external rectus of the left eye, and a mild hemiparesis of the left side of the body, including face, leg, and arm, with increased knee-jerks, and ankle-clonus on the same side. He gradually begen to improve, and in three months after he was first seen he was practically well. The treatment was principally iodids by inunction. For three consecutive weeks he was rubbed every twenty-four hours with an ointment containing 4 grains of the red iodid of mercury, and 21 drams of iodid of potash, dissolved in hot water and lanolin.

DR. W. J. HERDMAN of Ann Arbor read a paper, entitled

THE PHYSICIAN AS A WITNESS IN COURT.

He detailed some of the prevalent abuses of medical expert testimony, and stated that the following suggestions might be made, as taken from three plans originating in New York, Pennsylvania, and Illinois: (1) Experts should be appointed by the trial judge. (2) Their compensation should be made a part of the expenses of the court. (3) They should have abundant opportunity to investigate all the facts of the case on trial as far as they have a bearing upon the opinion they are expected to deliver. (4) That opinion should be given to the court in writing signed and sworn to. (5) Any dissenting expert opinion must be also in writing, and contain a statement of the grounds on which the dissent is based. (6) The experts may be sworn as witnesses and cross-examined, but the range of the cross-examination is not to extend beyond the limits of the subjects embodied in the opinion which they have been asked to express.

DRS. WHARTON SINKLER and F. SAVARY PEARCE of Philadelphia contributed a paper, entitled

FAMILY DISEASES.

They gave conclusions based on 16,500 cases of nervous diseases. Out of this total there were only 50 cases in which a disease could clearly be traced as hereditary.

REVIEWS.

RETINOSCOPY IN THE DETERMINATION OF REFRACTION AT ONE METER DISTANCE, WITH THE PLANE MIRROR. By JAMES THORINGTON, M.D., Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Assistant-Surgeon to Wills Eye Hospital, etc. Third edition. Philadelphia: P. Blakiston's Son & Co., 1899.

THE first edition of this excellent little manual appeared as an abstract of the author's previous writings and lectures on the use of the shadow-test. It met with immediate favor, and to-day ranks with "Skiascopy" by Dr. E. Jackson as the standard work on this subject. The present edition has been still further improved by a few changes in diction, and by the addition of five new illustrations, and forms as complete and practical, although concise, a guide as could be desired.

THE READY-REFERENCE HANDBOOK OF DISEASES OF THE SKIN. By GEORGE THOMAS JACKSON, M.D., Professor of Dermatology in the Woman's Medical College of the New York Infirmary, and in the Medical Department of the University of Vermont; Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons, New York. Third edition. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

IN these days of rapidly advancing medical knowledge, of frequent and wide publication of new clinical and experimental data, and the resulting incessant change in accepted opinion, the practitioner looks to fresh editions of standard text-books for the collection, condensation, and interpretation of what he desires as best and most modern. We believed that it is with this idea in view that Dr. Jackson has twice subjected to revision the text-book of dermatology which he offered to the profession in 1892. That the work at once secured the reputation as a standard reference for English-speaking students and practitioners is reason enough for maintaining in its re-editions its proper form and character.

Intended as a practical reference rather than as a more or less abstract treatise, the author is to be commended for maintaining the alphabetical arrangement in his text, rather than attempting descriptions along the lines of any one of the many dermatological classifications. Nosology is not altogether slighted, however, for a few pages are devoted to it in the first part of the volume.

The addition of foreign nomenclature is a highly commendable feature from both a practical and an educational standpoint—and this, in spite of the fact that a few of the thoughtless have been led to call the work "a text-book of synonyms."

While the changes in the text have not been great they have been many, and a comparison with the second edition shows numerous, careful revisions. A few new but very brief sections have been added, *e.g.*, those on sarcoides pigmentosum idiopathicum (Kaposi), blastomycetic dermatitis, etc.

The new illustrations are chiefly photographic reproductions and, like the old ones are, for the most part, excellent. The colored frontispiece (which has been unchanged in all editions) hardly deserves as much praise. It is showy, perhaps, but neither artistic nor exact, and might better have been omitted.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. Edited by THOMAS L. STEDMAN, M.D. Volume XVII. New York: William Wood & Co., 1898.

THE seventeenth volume of this well-known work opens with a scholarly article on the pathology and bacteriology of diphtheria by Dr. W. H. Park of New York, and is followed by an equally comprehensive section on the symptomatology and treatment by Professor Jacobi. Dr. Jacobi declares that the term follicular amygdalitis (or tonsillitis) may be applied to any variety of tonsillar inflammation, catarrhal, purulent, fibrinous or diphtheritic. The writer lays great stress on the preventive treatment of diphtheria, recommends that alcohol should be given early in the disease, and in large doses, still believes in the efficacy of mercurials, and is a firm adherent of the use of antitoxin "often even before the bacteriological diagnosis has been made."

Victor Babes of Bucharest contributes an article on tetanus and Dr. Williams of Bristol one on the general pathology of cancer and sarcoma. The latter declares that the so-called cancer-cell (?) is the only real cancer and tumor germ. Dr. W. B. Coley writes on the symptomology and treatment of cancer and sarcoma. Though the efficacy of the injection of the mixed toxins of erysipelas and of the bacillus prodigiosus in sarcoma is now almost generally doubted in this country and abroad, Coley still firmly believes in the specific action of these toxins on sarcoma, especially of the spindle-cell variety. We believe, with most recent writers, that their use is only justifiable in otherwise hopeless cases. In short, the evidence that has been collected of the therapeutic value of Coley's method of treatment of sarcoma is neither convincing nor conclusive.

Dr. J. T. Bowen contributes a short article on malignant new growths of the skin and Dr. E. McGuire of Richmond a short essay on the malignant diseases of the female organs of generation. The volume would have made a much better impression on us had the last article been omitted. The section on the malignant diseases of the female organs of generation is incomplete, no mention at all is made of malignant diseases of the tubes and ovaries and the treatment of malignant disease of the uterus contains little more than one can find in the smallest text-books.

Of the seventeenth volume of the Twentieth Century Practice, as a whole, we must say that it is one of the best of the series that has been thus far issued.
